GRUBER ON THE TREATMENT OF INFLAMMATIONS OF THE MIDDLE EAR.—Professor Gruber read before the k. k. Gesellschaft der Aerzte in Vienna, a paper which is reported in the *Allgemeine Wiener Medizinische Zeitung* for December 22, on the treatment of inflammatory affections of the middle ear. He pointed out especially the fact which ought to be kept in mind by aurists, that the tissues bounding the tympanic cavity are very unfavourable to the resorption of exudation in the cavity, while the natural outlet, the Eustachian canal, has in those cases where it is most desired that it should be open, viz., when mucous or purulent accumulations are lying in the cavity, its mucous lining so much swollen, and the lumen so narrowed thereby, that the passage of such masses is not easy, and, moreover, the muscles of the tube are in such cases often disturbed in their function and incapable of acting sufficiently. The means employed by surgeons to remove such accumulations have been, and are, perforation of the membrana tympani, passage of the air-douche through the Eustachian tube, or both combined; some insisting that the evacuation of the cavity without perforation of the membrane is not possible; others, among whom stands Professor Gruber, holding that the air-douche alone is often successful, while in others it is not so, or only imperfectly. To determine the cause of failure in some, Gruber has examined fifty temporal bones. He found in normal auditory organs great differences in the distance from the isthmus to the mouth of the Eustachian tube, the distance varying from one and a half to four and a half millimètres (0.06 to 0.18 inch). In some the opening of the canal was circular, in others very irregular, and in other cases so narrowed that it had a breadth of three-quarters of a millimètre, with a height of from two to three millimètres. From the walls of the bony tube, also, were sometimes seen ridges projecting, which, especially when the mucous membrane is swollen, must lessen the lumen of the tube considerably. The tympanic opening of the tube was sometimes as high as five millimètres above the floor of the cavity, while in others it opened close on the floor. The posterior wall of the carotid canal, in some cases, projected into the tympanic cavity on its anterior wall, while in others its course on that wall was not recognisable. The convexity formed on the floor of the cavity by the jugular fossa was found smooth or irregular, according to the development of the superior wall of the fossa. Lastly, bony lamellæ were sometimes seen to spring from the walls of the cavity projecting into it, and so forming deep recesses in which masses of exudation might become fixed.

These peculiarities must have, as Professor Gruber says, an influence on the action of the air-douche; and he raises the question of the advisa-

bility of employing this remedy always for the removal of exudations from the tympanic cavity. He believes that in some cases where purulent or ichorous exudation is present, the air-douche may drive it into the mastoid cells, and so cause inflammatory processes there; and, with this belief, he proposes to remove the exudation by means of a suction-instrument, passed through the membrane in the same manner as has already been done in England.

HAGEN ON PERCUSSION OF THE SKULL AND ITS SIGNIFICATION FOR THE DIAGNOSIS OF EXUDATION IN THE TYMPANIC CAVITY.—In the *Monatsschrift für Ohrenheilkunde* for October, 1874, Dr. R. Hagen gives the results of his observations of percussion on the skull in healthy and diseased ears. If the percussion be on the middle line of the vertex, the noise occasioned thereby is synchronous and equally loud in both ears if they be healthy, have an equal hearing power, and both meatus be open. Under the same circumstances, when the percussion is on the mastoid process or to one side of the middle line, the noise is heard on the corresponding side only. Closing one meatus by any means will cause the noise to be louder in that ear. Where the membrana tympani is clogged from the inside, and not from the external meatus by a serous accumulation, as has been determined by the speculum before making the percussion experiment, every patient, without exception, has experienced in the affected ear a clattering noise. In using the three limbed auscultation-tube in such cases, Dr. Hagen was not able to detect a difference in the sounds conveyed to his ears, as one would have expected. By Weber-Liel's tympanic catheter he removed and replaced repeatedly the serous exudation in a diseased ear, and always with the same results as above-mentioned, *i.e.*, the abolition of the clattering noise on the removal of the serous exudation, and its return on the re-introduction of the exudation. He thinks, therefore, that where from thickening of the membrane the presence of serous exudation may be doubted, this method may be relied upon as pathognomonic of its presence, and in no case where he has acted upon his diagnosis so obtained has he been deceived. He has made numerous observations in cases where purulent or mucous exudations were present, but the patient does not experience the same sound in these cases.

In the serous exudation which Dr. Hagen has removed in such cases he has found, microscopically, white blood-corpuscles and epithelial cells, a few fat-cells and pus-cells, now and then peculiar crystalline bodies, and always one or two ciliated epithelial cells still in active motion. W. LAIDLAW PURVES.

REVIEWS.

Free Phosphorus in Medicine, with Special Reference to its Use in Neuralgia: A Contribution to Materia Medica and Therapeutics. By J. ASHBURTON THOMPSON, Surgeon at King's Cross to the Great Northern Railway Company, Surgeon Accoucheur to the Royal Maternity Charity, etc. London: H. K. Lewis. 1874.

This work of Mr. Thompson's is one of those useful monographs published at a time when the attention of the profession is being specially directed to

the use of phosphorus. He has evidently devoted much thought and attention to the subject, and has taken pains to ascertain what others have written upon it: in fact, the history of the employment of phosphorus commencing from its discovery by Brandt in 1669, is one of the most complete we know.

In treating of the pharmaceutical preparation, he shows that the internal administration of free phosphorus may be effected by three methods; by its reduction to a state of subdivision, by its solution, or by the decomposition of a chemical combination of it with a metal within the body. He enters very fully into the various methods of prescribing phosphorus, giving four-and-twenty different formulæ for its administration, and discussing at length the relative merits of each, thus affording to the practitioner many valuable hints and suggestions that may save him much trouble and anxiety in deciding what formula to adopt so as to ensure gaining the full benefit of the drug and avoiding all uncertainty and danger—two of the most important reasons why phosphorus has not been more largely employed.

As regards the absorption of phosphorus, Mr. Thompson seems to think this may be effected in various ways: 1. By its vapour; 2. By the formation of phosphuretted hydrogen; 3. By its solution in hypophosphorous acid formed at its own expence; but chiefly 4. By its solution in the fatty parts of food.

He objects to Lecorché's theory of its mode of action, *viz.*, that phosphorus is absorbed from the stomach as phosphoric acid, and so acts; and holds, with Tardieu and Roussin, that it must enter the blood in the free state to produce its characteristic effects. In support of this view he gives a large amount of evidence that appears to be quite conclusive, and shows that the more perfect the state of reduction in which phosphorus is ingested, the more actively will it exert its powers; and secondly, that the better adapted the solvent is to protect the phosphorus from chemical action in the intestines, the more readily free phosphorus will enter the circulation, always provided that the solvent itself is easy of absorption. These two requirements are best fulfilled by the solution in oil.

In his critical remarks on the various pharmaceutical preparations, Mr. Thompson shows evidence of much original research, and the profession at large cannot be otherwise than indebted to him for 'removing a stigma from a remedy which is at least as valuable as any other in the *materia medica*,' by proving 'that the evil reputation phosphorus has hitherto borne, as a drug treacherously poisonous and of uncertain action, is entirely owing to an imperfect knowledge of its special qualities and properties under varying conditions.' By a careful, elaborate, and exhaustive examination of historical and clinical records, he has shown why phosphorus has been justly regarded as uncertain in action; and that this was all that was necessary to establish the remedy in professional favour, since, notwithstanding it was already acknowledged to be possessed of remarkable therapeutic powers, no one had hitherto demonstrated that phosphorus was a practically useful remedy in the way that he has done in these pages.

He concludes from a number of experiments and observations:

1. That solutions of phosphorus in virgin vegetable oils are not safe, and should therefore be entirely rejected:

2. That the solid form is not a perfectly safe mode of administering phosphorus; it may, however, be employed, but should never be presented to the empty stomach :

3. That the administration of zinc phosphide should be attended by the use of an acid at the same time.

The dose of phosphorus seems to vary considerably with the formula employed. The toxic effects of the drug, such as burning pain in the epigastrium, hepatic pain, tenderness of the gums, nervous symptoms, etc., are all fully described, and should be carefully noticed before attempting to prescribe phosphorus. A large experience of the action of the drug in many and various conditions has enabled the author to point out exactly the earliest symptoms necessitating its discontinuance. 'Apart from any specific power which it may possess, phosphorus may subserve two distinct ends at least, according to the manner in which it is administered. It may stimulate, and it may nourish.' This seems to be an entirely original observation, and one for which he distinctly claims priority.

In cases of typhus, where there is muttering delirium or incipient coma, the stimulating effects of phosphorus, when given in sufficiently large doses, are very marked. Mr. Thompson asserts that it should be given in such cases not by rule, but until the patient either recovers or dies; persons in want of phosphorus being able to take far more with impunity, than those not in want of it.

Of the therapeutic uses of phosphorus the author gives us not merely opinions, but has illustrated his remarks by a series of carefully recorded cases that will well repay perusal. He alleges that he has established, by a series of forty-one consecutive cases, what has been known of isolated cases since the time of Lobel—1805—viz., that phosphorus is curative of some forms of neuralgia (briefly, the ataxic and catarrhal acute). It is in these distressing and troublesome cases, where frequently other remedies have failed, that phosphorus seems to exert such a marked influence, and no one will now be justified in condemning a case as incurable until he has studied this monograph and tried the remedy in the manner suggested.

His remarks on the employment of phosphorus in cases of impotence are worthy of consideration. He asserts that it is not an aphrodisiac except in poisonous doses. Its true function is the removal of the hypersensibility, which is a general cause of the disorder, by elevating the nerve-tone.

The bibliography contains nearly 200 references, which will prove invaluable to all future investigators.

We shall hope to see in the next edition an index for facility of reference. The work as a whole is one of great merit, and does much credit to the author. It will, we feel sure, be welcomed by many as an exhaustive monograph on an agent whose powers have hitherto been but imperfectly recognised, more especially in its influence over that most distressing malady, neuralgia. We can conscientiously recommend the work as one of much value.

Key to Skin-Diseases. Four Charts with Notes. By TILBURY FOX, M.D. Renshaw, 1875.

This little brochure 'for clinical use and for those preparing for examinations' was drawn up for the students of University College; and it is now published, because, as Dr. Fox observes, the student is bewildered for want of a short systematic arrangement

of the principles and essential parts of dermatology. 'I here supply the deficiency. To become acquainted with the contents of the following nine pages is to master the difficulties of the subject.' The difficulty of students has possibly arisen rather from the multitude of 'short systematic arrangements' than from their deficiency; and we fear that they may still meet with difficulties even after acquaintance with Dr. Fox's charts. But we may fairly say that this is the best of such aids to knowledge which has yet appeared. The first of the four general rules (to see the whole of the affected surface) and the last (that there are no peculiar pathological changes in the skin) are excellent and thoroughly 'Hebräisch.' The classified chart is clear, and except in a few details, agrees with the accepted doctrines of modern dermatology. We may perhaps suggest that it is convenient to keep the term *roseola* for rashes (*hyperæmiæ*) without evident exudation, and erythema for those with papular, nodular, or diffuse effusion; and that it is undesirable to use 'tubercle' except in the modern pathological sense of the word. The table of elementary lesions is excellent. That of etiology surely admits far too readily some 'internal causes.' That of therapeutical headings is the most individual, and perhaps, on that account, the most valuable of all.

Catalogue of Artificial Arms, etc. STUMP: London.

Mr. Stump's catalogue of artificial legs, arms, hands and noses is a very useful illustrated list of prothetic pieces, which surgeons and practitioners generally will find very convenient for reference. Every amputation is illustrated by the artificial limbs made for each case, with diagrams for measurement and instructions for the same. The pieces range from those of the most exquisitely finished limbs that ingenuity can devise to meet the exigencies of wealthy misfortune to those suitable for the needs of a working man. Thus there is here under one cover, in an accessible very intelligible form, all the information which the medical man needs on the spur of the moment for answering questions, whether in his work at the hospital, or union, or in treating amputations in his private practice.

MISCELLANY.

ANOTHER DISEASE OF CIVILISATION.—The frequenters of theatres have doubtless observed, with more wonder than admiration, that peculiar evolution of the ballet-dancer which consists in coming down the stage on the points of her toes. This, we believe, is considered the crowning feat of the art of the danseuse, and, like all great achievements, is not attained with impunity. It appears that at a meeting of the Society of Physicians in Vienna, reported in the *Wiener Medizinische Presse*, Dr. Schulz described a new form of disease which hitherto he had observed only in ballet-girls, and which manifested itself in a cramp of the muscles of the calf of the leg. The disease appeared to be similar in its character to writers' palsy, and occurred chiefly amongst those who were in the habit of performing a *pas seul* on the points of the toes. The position indispensable for this feat, which is accompanied by a rigidity of the whole limb, can only be maintained when the foot is supported by a shoe made for this particular purpose. It is satisfactory to learn that the cramp is susceptible of relief, which is afforded by the application of that form of electricity known as faradisation.

SHELL IMPLEMENTS.—M. Barnier, a French engineer, at the head of the copper and silver lead mines at Luchan, near Toulouse, has made some very interesting archaeological discoveries in that locality. He caused a grotto, which seemed to him to present the characteristics of the prehistoric age, to be explored, and found in it fragments of the skeletons of wild beasts and human remains, together with some coarse pottery. But the most interesting discovery consisted of some daggers formed of sharpened bones, and especially some pieces of shells laboriously formed into curved forms pierced with a hole, so that they could be suspended round the necks of their owners, and which were evidently the knives in use in those remote ages. This employment of shell implements is a novel fact, and one which has not yet been observed in diluvian caverns. M. Barnier gives reason to suppose that the extensive plains of Roussillon formerly formed part of the sea.

MALLEABLE GLASS.—The *Kölnische Zeitung*, of March 25, contains the following notes on the recently invented 'hardened glass.' According to the reports of Pliny, Petronius, and Dion Cassius, a man is said to have invented the making of flexible and malleable glass in the time of the Emperor Tiberius. The happy inventor—some call him a glass-maker, others an architect—brought to the emperor a vase made from the new glass, with the hope of a rich reward. The emperor, fearing that the new material might cause a decrease in the value of gold and silver, threw the vase to the ground in a passion. The vase, however, did not break, but was only bent like metal, and the inventor at once repaired the damage done with a little hammer, whereupon the emperor had the poor fellow killed on the spot, so that he should not tell his dangerous secret to any one. For years people have lost themselves in conjectures of what material this malleable glass might have been; some thought it was aluminium, others that it was melted chloride of silver; none, however, were certain. From various quarters the invention is now announced of a new glass which resists blows and the action of fire. Last autumn a company was formed at Bourg, in France, with a capital of 1,200,000 francs, for the working of an invention in this line, made by a M. de la Bastie. The German Glass-makers' Union communicated with this company with a view to purchase the invention, but this remained without further consequences, as the demands of the company were exorbitant. In the meantime it had been found that the elasticity was given to the glass by dipping it, while it is heated to a half liquid state, into a hermetically closed bath of oil or fat, substances therefore which melt far below the boiling-point of water. In Silesia, where repeated experiments have tested the qualities of the De la Bastie glass, another new glass has been invented by Herren Lubisch and Riederer, in Count Solm's glass-works, Andreashütte, at Klitschdorf, near Bunzlau. This glass, which the inventors call 'metal-glass,' is so hard, that when a pane lies on the ground and a leaden ball of forty grammes weight falls upon it from an elevation of twelve feet, it receives not the slightest impression; nor is it in the least affected when dipped whilst red-hot into cold water. Window-panes, lamp-cylinders, and other articles of domestic use made from this metal-glass, can therefore almost be regarded as unbreakable.

DRESS AS A CAUSE OF PELVIC DEFORMITY.—When the body is erect, says Dr. Aveling, in a discussion of this subject in the *Obstetrical Journal* for January, the influence of dress is of sufficient importance to demand careful attention. Attitude depends upon clothing more than is generally supposed. The stooping position, which has been referred to as injurious, is often produced by the peculiar feminine vestimental arrangements at present in fashion. The greater part of the burden of a woman's clothing hangs from the posterior part of her body. All the folds of her skirts are carefully disposed behind, and the swaying influence of their weight here is much increased by the leverage power granted them by the numerous ingenious devices adopted for insuring their

projection backwards from the body. As the balance can only be maintained by inclining the body in the opposite direction to that in which it is drawn, it must necessarily be bent forward to counterpoise this retroverting influence. High heels also throw the body out of its proper balance, producing stooping, relaxation of the abdominal walls, and debased pelvic inclination. But dress, in its strictest sense, has still another potent way of causing mischief—namely, by its weight when suspended from the waist; a weight not inconsiderable in itself, but rendered of much consequence by its persistent action. The bands, from which the garments that women wear hang, are chiefly supported by the abdominal walls and the viscera beneath them. Ultimately, therefore, they must compress the pelvic organs, and cause their downward displacement. As a rule, all vestments should be carried by the shoulders. Long robes, falling from them, and girded at the waist, are the least harmful, if not the most beautiful garments a woman can wear. If, however, it be absolutely necessary that her dress should be divided into two portions at the waist, let her, by all means, adopt some method of suspending the lower half from the shoulders. Braces of a very simple and inexpensive kind, having safety hooks, which may be passed through the bands of the skirts, are now easily obtainable, and their general adoption is much to be desired. The position of the waistband must also be considered, for whether it should be high or low is a point of much importance. The fashion of short-waisted dresses is by far the more healthy. Long waists involve abdominal compression by stays, and that closer contact of bands with the walls of the abdomen which enables the downward dragging weight of skirts to exercise its influence most injuriously. The natural position of a woman's waist is neither high nor low, but in that part of her body which happens to be the smallest in circumference. If fashion would only allow this to be the proper place for the waistband, we should not, as now, have the constriction of stays and the gravitation of garments conspiring in the production of prolapse and its concomitant disorders.

CHAPPUIS' DAYLIGHT REFLECTORS are adaptable to any window, skylight, area-grating, etc., and will be found most effective to diffuse daylight, and dispense with gas, thereby saving expense, and adding to the comfort and healthiness of the premises. The prices vary from 3s. per square foot and upwards, according to quality. Prospectuses to be had at the factory, 69 Fleet Street, London.—[ADVT.]

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, MAY 12, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

VULPIAN'S EXPERIMENTAL PATHOLOGICAL STUDIES ON THE PHYSIOLOGICAL ACTION OF TOXIC AND MEDICINAL SUBSTANCES.

(Continued from page 273.)

Thanks to the study of physiological action, great progress has been made in the advancement of forensic medicine. As a matter of fact, if there are clearly defined and crystallisable toxic substances, which can be extracted from the viscera of an individual who has died from poison, and which can be placed under the eyes of the judge and jury by an expert, still there are others which cannot be entirely separated. Some of these substances may be recognised by the help of certain chemical reactions; but the physiological test offers a valuable resource to an analytic expert. If it be a case of poisoning, he may thus be able to determine, with a sufficient amount of precision, to what kind of poison the death must be attributed. It is thus that the presence of digitaline, nicotine, nay even of daturine, hyoscyamine, extract of belladonna, extract of Calabar bean, may be suspected, either in the dejections or in the digestive organs. But physiological experiment likewise brings its complement of information even respecting substances which can be recognised by their chemical characteristics. It is thus that experiments on animals will show the existence of a convulsion-producing poison, such as strychnine, in the substances submitted to the examination of the expert. This kind of examination, combined with microscopical, chemical, and physical investigations, is of such utility that it may safely be affirmed that at the present time there is no poison known which can escape juridical research. Nor do therapeutics derive less profit from the physiological action of drugs, for it is by that study that the use of these substances can be regulated, and the indications to which they correspond clearly defined. For instance, it is not enough to know that digitalis has a powerful action on the heart, and can slacken its movements, if it is necessary to know by what mechanism it produces these effects so as to carefully define in which cases of heart-affection digitalis should be taken, and in which its use is prohibited.

The physiological study of the purgatives, by showing that these substances do not all act by an absolutely identical mechanism, may serve as a guide to the prescription ordered; the same thing will also hold good of emetics. The knowledge of the *modus operandi* of chloral has led to its employment in the treatment of certain convulsive affections, such as tetanus, eclampsia, and chorea. M. Vulpian limits himself to these few instances, and adds that if even the study of the mechanism of the effects determined by medicinal substances has not led to any new therapeutic data, it is impossible not to acknowledge the importance for the physician who

is worthy of the name, knowing the reason of the effects obtained by such and such a drug. Researches into the physiological *modus operandi* of medicinal substances have even cleared up certain pathological points; thus it is only since the way in which the extract of nuxvomica and strychnine act on animals was known that a just notion of the pathological physiology of tetanus has been acquired. The great resemblance existing between this affection and strychnism has given cause to believe that tetanus, like the convulsions produced by strychnism, is due to a condition of exaggerated excitability of the grey matter of the spinal marrow and of the bulb. The irritations which set out from the wound (traumatic tetanus) and are conducted to the medulla by the sensory nerves, induce and keep up this morbid condition of the grey matter of the medulla, and give rise to the tonic spasm of the muscles of the jaws, neck, back, etc. The paroxysms of these convulsions are brought on either by the same irritations, or by excitations influencing other sensory nerves. It is a matter of fact that this knowledge, furnished by the comparison between tetanus and strychnism, has guided all the efforts of therapeutics, such as the division of the nerves affected by the wound, amputation of the wounded portion, and the administration of the substances (chloral and bromide of potassium) which weaken the reflex power of the medulla spinalis.

Neither until the effects of nicotine were known had any clear notion been conceived respecting the seat of the modification of the nervous centres which produces the tremblings of paralysis agitans. In experiments on frogs, M. Vulpian found that one of the first effects produced by nicotine consisted in a very remarkable trembling of all parts of the body.

This trembling did not occur in a limb of which the principal nerve had previously been cut; the poison therefore does not act either on the extremities of the nerve nor on the muscles in relation with this nerve. Transverse section of the medulla also prevented the tremblings from becoming evident in those parts of which the nerves originated in the lower or backward segment of this nervous centre. Neither, then, is it by the intermediary of the medulla spinalis that nicotine produces the effects in question. Proceeding to make the experimental research in the opposite direction, M. Vulpian removed successively the cerebral lobes, the optic thalami, the tubercula quadrigemina, and the cerebellum, before introducing nicotine under the skin, and still found that nicotine brought on the same tremblings. But when he removed that portion of the isthmus of the encephalon which corresponds to the pons Varolii of the mammalia, there was an absence of the tremblings. In these cases it was a matter of general tremblings, showing themselves in all parts of the body, and M. Vulpian thinks, without any strained comparison, the datum arising from these experiments may be applied to the pathological physiology of the trembling of paralysis agitans, of senile, alcoholic and even mercurial trembling. It may be inferred that these various sorts of trembling are caused by a morbid modification of certain points of the pons Varolii. Considered from the point of view of general physiology, the knowledge of the physiological action of certain toxic or medicinal agents have given greater facilities than have existed up to the present time for studying the physiological properties of the different parts of the organism. It is thus that curara has given us fresh

indications on the mode of physiological relation which exists between the motor nervous fibres and the primary fasciculi of striated fibrous muscles. It is by thoroughly examining the mechanism of the action of atropine, that the more definite information respecting the moderator or frenator nerves of the head and glands has been acquired, and the study of the accelerator nerves of the heart has also profited by the same researches. It is by the help of this method of experimentation that the first clear indication of the probable existence of nerves having a direct action on the secretions, and therefore having a title to the name of secretor nerves, was obtained. M. Claude Bernard's experiments on the effects of faradisation of the chorda tympani have shown that a hypersecretion of the submaxillary glands is brought on at the same time, and a considerable hyperactivity of the sanguineous circulation in this gland. It is a question whether salivary hyperæmia is due to a true oxidation of the elements of the gland, or whether it is the pure and simple result of the afflux of blood and the augmentation of pressure necessarily produced in the vessels of that organ. Thanks to the labours of M. Ludwig and M. Claude Bernard, it is possible to oppose serious arguments to the hypothesis which wished to explain the exaggerated secretion of the submaxillary saliva by hyperactivity of the intraglandular sanguineous circulation. But the positive proof of a direct independent action of the chorda tympani on the secretory action of the gland was not then acquired; it seems to have been furnished by the study of the action of atropine on the salivary glands. M. Keuchel had ascertained that, in animals submitted to the toxic action of atropine, faradisation of the chorda tympani produced no increase in the flow of the submaxillary saliva.

M. Heidenhain took a step in advance and recognised that if M. Claude Bernard's experiment be repeated in all its details on an atropinised dog, electrification of the chorda tympani no longer produces increase of salivation, but that it still brings on vascular phenomena, that is to say, congestion of the gland and excessive activity of the circulation of blood throughout the gland.

The vascular and secretory effects of the faradisation of the chorda tympani therefore are not linked together in an indissoluble manner. They both depend on the excitation of different nervous fibres, in fact, so different that atropine can abolish the physiological action of some while respecting that of others. It might, indeed, be objected that atropine induces secretory impotence of the gland, by acting on its peculiar qualities, but M. Heidenhain has shown, as will be set forth in another lecture, that the characteristic cells of the gland preserve their functional aptitudes in the atropinised animal. Therefore it is evident that the atropine acts by influence on the nerves. The chorda tympani contains two kinds of nervous fibres: vaso-dilatator fibres, which escape the toxic action of atropine, and secretory fibres, which are paralysed by this poison. The existence of secretory nerve-fibres thus seems placed beyond doubt. This is a fact of the greatest importance, for it applies to the physiology of all the glands, and especially to the accessory glands of the digestive system. It may also be applied, as will hereafter be shown, to physiology and sudoral secretion. The physiological study of poisons and drugs is and can only be an experimental study. The conditions in which experiments are carried on are far

from being unimportant as regards the result of the experiment. As a general rule, the animals to be experimented on should be chosen from those whose organisation does not differ too much from that of man. M. Vulpian's principal laboratory experiments are made on dogs, rabbits, guinea-pigs, and rats, that is to say, on mammiferous animals. But it is not always practicable to conform to this rule. When the movements of the heart are to be studied in this organ laid open to view, it is better to make use of frogs. In the higher animals the great functions of life are intimately connected together, so that any great disturbance or the stoppage of any of them, brings on perturbation or cessation of all others. If the lungs are removed from a dog, the animal inevitably dies directly. It is not so with frogs, the thorax may be opened and all the viscera removed without their dying immediately. The heart of a frog may be laid bare after the removal of its sternum, and the heart-beats may be observed several days after the operation.

Frogs have the advantage over the higher animals of possessing a cutaneous respiration which may sustain a sufficient hæmatosis to keep off asphyxia, when pulmonary respiration is discontinued. Therefore it is possible to institute experiments on curarised frogs, in which pulmonary respiration no longer takes place, even lengthened experiments going on for two, three, or four days and more, which cannot be carried on on mammiferæ on account of the necessity of keeping up an artificial respiration by pulmonary insufflation. Thus it is scarcely possible to study, except on the frog, the ultimate effects of strychnine, that is to say, the state of the different functions during the period of resolution which succeeds strychnic tetanus. On the other hand, it is possible to perform considerable mutilation on frogs, for instance, to remove the whole of the encephalon, or destroy the whole spinal marrow; and these animals thus mutilated may live long enough to allow observations on the action produced by given poisons under similar conditions. Such advantages would, it is true, be useless if the effects of toxic substances were always very different in batrachians and mammalia; there is, however, no difference. Many poisons exercise the same kind of influence on both classes of animals; and certain poisons even have an intensity of action on frogs which makes these animals most valuable for the study of these substances. Thus these batrachians are particularly sensitive to the action of strychnine, of which they are, so to speak, the physiological reagent. This circumstance is of great utility in legal medicine, for a very minute quantity of strychnine extracted from a corpse suffices to produce on a frog the convulsive phenomena characteristic of this toxic agent. It is the same with the other convulsion-producing poisons, as well as poisons affecting the heart, and muscular poisons.

PERRONCITO ON THE REGENERATION OF STRIATED MUSCULAR TISSUE.

At a meeting of the Society of Medicine and Surgery in Turin, on January 13, Professor Perroncito made a communication on the new formation of striated muscular tissue from the pre-existing tissue after injury of its continuity (*Gazzetta delle Cliniche*, January 26).

He begins by remarking that, notwithstanding the results obtained by Gussenbauer with regard to the

formation of new muscular tissue from that already existing, the mode of reproduction has been much disputed, and the opinions on the subject are still very diverse. With the object of elucidating such a very important question, Dr. Perroncito undertook, towards the end of last year, a series of experiments on the muscles of frogs and dogs, and has continued them this year. The following are the results which he has obtained.

In the frog, some days after section of the muscles, he has been able to observe the production, from the contractile substance of the divided ends of the muscular fibres, of a new granular protoplasmatic material, poured out in such a way as to form a prolongation of the old substance of the fibres. These protoplasmatic prolongations are very fragile, and continue to increase in length as time advances, so that after from twelve to twenty days they may attain a remarkable length.

He has also observed a similar behaviour in the muscles of the higher animals. In dogs, forty-seven hours after dividing the muscles, there is seen at the extremities of the divided ends of many of the fibres a new granular very delicate muscular structure, differing from the already existing muscle in being formed of granules and void of striæ. In this there is generally to be seen a proliferation of nuclei, from two to five corpuscles being irregularly arranged in the new substance. The nuclei have an ellipsoidal or roundish form, with a glistening outline and a large nucleolus. The new matter soon assumes a conical form, and is continuous with the old contractile substance of the muscular fibres. It gradually increases in length, forming prolongations sometimes with a sharp, sometimes with a rounded end; the margins are sometimes straight or slightly convex, sometimes irregular and dentate. Sometimes the new substance becomes gradually thinner, presents a wavy appearance, or is placed at an angle with the point terminating in various directions, generally towards the deep part of the wound.

The newly formed prolongations are always enclosed in new connective tissue and in numerous capillaries, which extend as far as the free ends of the protoplasmatic prolongations. Very frequently, at the free end of the cone of new formation, there is observed a kind of exudation, a hyaline material, which is readily tinged by carmine, and sometimes has roundish cells adherent to it. This form of hyaline exudation is seen more frequently and more abundantly in fibres forty-seven hours after section, and sometimes it is directly continuous with the old fibre without the interposition of new muscular protoplasm.

In numerous examinations made four, six, eight, or more days after the section of the muscles, Dr. Perroncito has very rarely seen new cells with the characters of migrated cells lying along the newly formed prolongations. On the other hand, ellipsoidal nuclei of various sizes and in various numbers are constantly present in the new muscular substance. The absence, in most cases, of migratory cells, and the constant presence of nuclei and muscular corpuscles, deprive the former of much, perhaps all, of their importance in the formation of new muscular tissue, while the latter acquire a very great importance. Migratory cells may, by their amoeboid movements, be readily supposed to penetrate the outside of the new contractile substance; but, in this case, their presence is purely accidental.

A muscular fibre at the point of division, or in its

proximity, may produce a various number of prolongations of muscular substance; and this is specially observed in sections made at the end of twenty or more days after the muscle has been divided.

As has already been said, the young prolongations are very delicate, and are readily torn during the manipulations necessary for their examination. For many days they are granular, and it is not until a later period that they present striæ.

These observations Dr. Perroncito regards as comprising those of Gussenbauer (*Archiv für Klinische Chirurgie*, 1871), and also as placing beyond doubt the new formation of muscular tissue in the continuity of divided fibres.

A. HENRY, M.D.

BROWN-SÉQUARD AND LABADIE-LAGRAVE ON AUDITORY VERTIGO.

We have already given an account of Menière's disease in our numbers for April 22 and 29, 1874. The subject, however, is one of such great practical importance that we present an abstract of a recent paper thereon. The reporter has published a case of Menière's disease in the *Lancet*, Nov. 21, and refers to it chiefly to acknowledge an important omission. We ought not to forget the work Brown-Séquard has done on this subject. At page 195, Séquard's *Lectures on the Physiology and Pathology of the Nervous System*, 1860, will be found an account of experiments on the auditory nerve, and clinical observations showing their bearing on practical medicine. Now that Menière's disease is attracting much attention, we shall be excused for reproducing the following. Its reproduction is not unnecessary, as many medical men are very incredulous as to there being any causative relation between ear-disease and vertigo. Before we give the quotations, we ought to say that so far back as 1853 Dr. Brown-Séquard (*Experimental and Clinical Researches applied to Physiology and Pathology*, New York), had shown by experiments that the auditory nerves have a most remarkable power over the nervous centres.

The persistent spasmodic contractions due to a mechanical injury to certain parts of the nervous centres are always curious, but never so much so as when they result from some irritation of a part like the auditory nerve, which we were accustomed to consider simply as a nerve of sense. M. Flourens (*Recherches sur les Propriétés et les Fonctions du Système Nerveux*, 2de éd., 1842, p. 454 et seq.) has found that the section of the semicircular canals in certain animals is followed by a strange disorder of movements, and sometimes by a rotation (circus movement). The reporter has ascertained that the phenomena observed in these experiments do not depend on the section of these canals, as this operation may not cause these phenomena, but that they are the results of an irritation of the auditory nerve from the drawing upon it by the membranous semicircular canals when they are divided. In frogs and in mammals the direct irritation of the auditory nerve is followed by the most interesting phenomena. It is well known that in frogs the peripheric extremity of this nerve is enclosed in a bag containing carbonate of lime. As soon as this bag is laid bare and slightly touched, and still more if it be punctured with a needle or a bistoury, the anterior limb, on the opposite side, is thrown into a state of slight convul-

sion, and kept almost constantly in a spasmodic pronation; and almost at every attempt to move forwards the animal turns round on the side injured. As long as it lives (many days, or even many months) these phenomena may be observed, although not quite so marked as immediately after the injury, or after the first twenty-four hours. In mammals, the least puncture of the auditory nerve causes rolling, just as after the irritation of the processus cerebelli ad pontem; violent convulsions then occur in the eyes, the face, and many muscles of the neck and chest. The doctrine that the nerves of the higher senses are not endowed with general sensibility (*i. e.*, are not able to cause pain) seems not to be true with regard to the acoustic nerve; at least, the signs of pain given after an irritation of this pretended nerve are often as great as those observed after an irritation of the trunk of the trigeminal nerve. In man also the auditory nerve seems to be able to act as it does after an injury in animals. 1. Any one who has received an injection of cold water in the ear may know that it produces a kind of vertigo, and that it is difficult to walk straight for some time after this irritation. 2. A sudden noise makes the whole body jump, particularly in old people, or in persons attacked with anæmia, chlorosis, epilepsy, chorea, hysteria, hydrophobia, and in certain cases of poisoning; in a word, in all circumstances in which the control of the will over reflex actions is lost or diminished. 3. Vertigo and various convulsive movements, in cases of irritation of the acoustic nerve,* have been observed in adults and children. Rotatory movements have taken place in cases of suppurative inflammation of the ear, and twice immediately after an injection of a solution of nitrate of silver (see the case of Professor Burggraeve, recorded by himself.† A most eminent military man, we are told, has twice been seized with rotatory convulsions after injections in the ear. Quite recently Mr. Hinton has read a paper to one of the London medical societies, in which he relates several cases of convulsions in children without any other visible alteration after death except in the ear. We could point out several other facts to prove that irritation of the auditory nerve may cause vertigo, rotatory movements, and various other kinds of convulsions; but we think we have said enough to call the attention of practitioners to this subject, and this was our principal object. We will only add a few words more to say that the causes of rotatory movements are numerous, and that besides the one which is the principal in most cases (and that is the spasm produced in some muscles, as has been already said) there is a cause similar to that of simple vertigo, depending upon anæmia, or generated by an irritation upon some centripetal nerve (as for instance, in cases of gastralgia), and producing a contraction of some blood-vessels of the brain, by a reflex action, and this cause is the insufficiency of blood and the consequent alteration in the nutrition of certain parts of the brain.

The literature and current knowledge of this subject are succinctly presented by Dr. Labadie-Lagrave, in some recent articles in the *Gazette Hebdomadaire*. In a brief historical *résumé* it is shown that, although isolated cases had been reported long ago by Vieussens, and by Itard, Toynbee, and others, it was

not until the laborious researches of Menière that auditory vertigo was recognised as a distinct disease. Since then it has received full attention from numerous investigators, amongst whom may be mentioned Trousseau, who proposed the title *vertigo ab aure læsa*; Duplay, who named it Menière's disease, a name subsequently adopted by Charcot, Hillairet, Politzer, Voltolini, Knapp, Hinton, and many others. The author insists that, although the disease derives its name from Menière, it is not to be forgotten that it is to the experiments of Flourens that we owe a rational explanation of the dependence of the symptoms on the labyrinthine lesion.

The outset is sudden. An individual in the midst of perfect health, and without appreciable cause, is seized with confusion, headache, tinnitus, and vertigo. His gait is uncertain and stumbling; when he rises objects seem to turn round him; he staggers as if the ground sank beneath his feet. He cannot keep his balance without support, and he executes involuntary movements which impel him in a certain direction. At the same time his hearing is affected; sometimes he can only hear certain sounds. The noises in the ears are very pronounced. He seems to hear the sound of an orchestra, ringing of bells, the rushing of a cascade, or the whistle of a locomotive. Charcot dwells on the intimate relation which exists between the sudden development of noises in the ears, or the sudden exacerbation of these noises, and the onset of the vertigo. Though tinnitus is a common accompaniment of various kinds of vertigo, its intensity and predominance from the very first are characteristic of Menière's disease.

The face is pale, the forehead bedewed with sweat, the skin cold. Then occur nausea and vomiting, which usually indicate the termination of the attack. The patient can obtain relief only by observing absolute rest in the horizontal position. There is no affection of speech, no spasm of face or extremities. Menière once saw spasm of the face, followed by incomplete hemiplegia (on the same side as the affected ear), which disappeared in a few days. There is never tingling, numbness, nor any sensation analogous to an aura. These symptoms pass off after a variable time, and reappear sooner or later, each attack increasing the tinnitus and deafness, until the hearing is wholly lost.

The pathological conditions which give rise to auditory vertigo are sufficiently numerous, and some of them at least can be distinguished by the symptoms. In detail they are: 1. Vertigo from traumatic irritation; 2. Vertigo from galvanic excitation; where the electrodes are applied to the mastoid processes the head turns towards the positive pole; 3. Labyrinthine vertigo from internal otitis; of this the author distinguishes three kinds; 4. Vertigo from disease of the middle ear; 5. In rare instances vertigo occurs from obstruction of the auditory meatus; 6. Reflex vertigo; in some persons the access of a drop of water to the membrana tympani brings on a violent attack of giddiness.

Taking otitis labyrinthica as the lesion which gives rise to the most characteristic symptoms, the author proceeds to treat of these latter in two groups, according to the two divisions of the auditory nerve. The vertigo, the sense of rotation or the actual rotation, with their accompaniments, staggering, weakness, pallor, sweating, nausea, vomiting, and headache, are due to lesions of the semicircular canals. On the other hand, the tinnitus, and the gradual and

* Walter and Lincke, quoted by Harless in article 'Hören,' in *Wagner's Handwörterbuch der Physiol.*, vol. iv. 1853, pp. 420, 423.

† *Gazette Méd. de Paris*, 1842, p. 25.

finally complete loss of hearing, are owing to alterations of the cochlea.

To explain the deafness for certain sounds, the author adopts the hypothesis that a limited portion of the cochlea is injured in such cases; and that, as the injured fibres no longer vibrate in response to their corresponding sounds, no impression of these sounds reaches the nervous centre. JHS

ANATOMY AND PHYSIOLOGY.

GRUENHAGEN ON VARIATIONS IN THE SIZE OF THE PUPILS AT DIFFERENT TEMPERATURES.—

At the session of the Königsberg Verein für Wissenschaftliche Heilkunde, held on March 23, 1874 (*Berliner Klinische Wochenschrift*, January 11, 1875), Herr Gruenhagen made some remarks on the influence of temperatures between 0° and 37° Cent. (32° and 98.6° Fahr.) on the size of the pupil; and explained the reasons which led him to attribute the varying diameters of the pupil not to contractions or relaxations of the sphincter pupillaris, but to swelling or shrinking of the non-muscular portions of the iris. [See Schur, On the influence of light, heat, and other agencies on the iris; Henle and Pfeuffer's *Zeitschrift für rat. Med.*, Band xxxi. p. 373.] In accordance with this, the marked dilatation of the pupils in some mammals, particularly cats, at 37° Cent. (98.6° Fahr.) is to be regarded as a consequence of a loss of water; whilst myosis at 9° to 25° Cent. (48.2° to 77° Fahr.) is regarded as the consequence of absorption of water, occurring in the parts of the iris mentioned above. The at first sight apparently paradoxical opinion, that animal tissues lose water at 0° Cent. (32° Fahr.) may be confirmed by the familiar observation that many saline solutions begin to exhibit a separation of the salt from the water at this temperature; and by the fact that the albuminous solution of the fibres of the lens of the cat's eye becomes turbid by the formation of vacuoles at 0° Cent.; and again, that at or near this temperature some animal tissues undergo alterations of their physiological functions exactly analogous to those produced by desiccation, or loss of water in the same tissues. For instance, one sees in the muscles both of the living frog, and in those of the frog killed by woorara, that the muscular irritability of the voluntary muscles, as evinced by mechanical irritation, is much increased after cooling to 0° Cent. (32° Fahr.). Whilst the muscles of the frog at ordinary temperature must be pinched rather forcibly to excite contractions, a very slight touch suffices to excite manifest movements in those cooled to 0° Cent. This condition soon vanishes at ordinary temperatures of the air, but returns on fresh cooling. A similar condition occurs when the muscles of a frog are gradually dried. A frog's hinder extremity skinned, and exposed to a summer temperature of 20° to 25° Cent. (55° to 77° Fahr.), becomes after five or six hours so sensitive to mechanical stimuli, that slight stroking with the finger suffices to throw the muscle touched—and, in consequence of its movements, all the neighbouring muscles—into a state of tetanus. Such contractions, however, do not occur spontaneously. Similar phenomena occur in the frog's nerves by cooling to 0° . In conjunction with Herr Samkow, it was found that immersion of fresh sciatic nerves in neutral fluids at 0° to 2.5° Cent. (32° to 36.5° Fahr.), such as 0.6 per cent. salt solutions, oil of poppies,

and even distilled water at the freezing-point, constantly induced long-continued (two to four minutes) clonic contractions of the muscles supplied by these nerves. It seemed indifferent whether the nerves were suddenly cooled from 15° Cent. (59° Fahr.), or from 38° or 40° (100.4° to 104° Fahr.) to freezing-point. These contractions vanished immediately when the excited nerve was exposed to the medium temperature of the room, or to a temperature of 100.4° , and returned on renewed cooling; but not in the case where the nerve had been exposed to a temperature of 40° Cent. (104° Fahr.), which in itself seemed to predispose to powerful clonic contractions. Nerves thus cooled to freezing-point were uncommonly sensitive to mechanical irritation. Nerves partially desiccated exhibited similar phenomena. Gruenhagen remarks that, if he could succeed in bringing the nerve-centres, such as the spinal cord, into a similar state of tension [*Spannung*] by cooling them down, like the nerves and muscles, the nature of rheumatic tetanus would be elucidated; and he points out that a demonstration of the great mobility of the molecules of water helps to explain the variations in the 'tone' of the tissues. The affinity of the tissues for water gives a new source for the development of electric power, since galvanic currents are caused by the swelling of animal tissues (animal membranes, lit. *Blase*), which are not the same as Quincke's 'diaphragm-currents.' The direction of these imbibition currents [*Quellungs-Ströme*] is constantly such that the surface of the animal tissue, at which the absorption or imbibition of fluid begins, becomes positively electric. Accordingly, if the extended and well-dried gastrocnemius of a frog, with the tendo Achillis and a part of its belly, be moistened in distilled water, and a transverse section be made just above the level of the water by means of a section-knife, and the transverse and longitudinal sections be brought into momentary contact, a rather strong imbibition-current is induced, scarcely inferior in intensity to the ordinary muscular current. These artificial muscular currents, like the natural ones, pass from the longitudinal section to the transverse one towards the needle of the multiplier, and in other ways are regulated by the laws of currents in a muscle at rest.

[Drs. Brown-Séquard, Budge and Waller, and Dr. Letheby long ago enunciated somewhat similar views; but the experiments of the first three were made on eyes removed from the animal after death, whilst Dr. Letheby's, if we mistake not, were founded on experiments made with belladonna.—*Rep.*]

WICKHAM LEGG ON A SINGULAR EFFECT OF LIGATURE OF THE BILE-DUCT IN ANIMALS.—In the *St. Bartholomew's Hospital Reports* for 1873, vol. ix. p. 175, and in a reprint from the *Archiv für experiment. Pathologie und Pharmakologie*, Dr. J. W. Legg draws attention to a curious effect of ligature of the bile-duct, first observed by him during a series of experiments on animals intended to elucidate the pathological histology of the liver. It has been noted for some time, that after previous puncture of the fourth ventricle, poisoning by phosphorus prevents sugar from being found in the urine. Dr. Legg obtained a similar result on puncturing the fourth ventricle of an animal whose bile-duct had been ligatured six days before. This induced him to make fresh experiments. He began with six rabbits, but they succumbed to the operation too soon to allow further experiment. Cats were next selected;

the procedure adopted being to first tie the bile-duct, and then, after five or six days, to feed the animal with milk, or milk with cane-sugar. It was then placed on Czermak's rabbit-holder, chloroformed, and an incision made over the occipital protuberance. Bernard's chisel was introduced immediately behind the protuberance; after boring through the bone, the chisel was pushed forwards and downwards, till it cut the line joining the two auditory meatus; it was then cautiously withdrawn. Then the cat was removed to a warm place, and an hour afterwards the urine was squeezed out of the bladder, and Trommer's test applied. In four successive trials no sugar could be detected; although in four other healthy cats, in whom the bile-duct was not tied, glycosuria was induced by a similar puncture of the fourth ventricle.

W. BATHURST WOODMAN, M.D.

WATSON ON A PHARYNGEAL DIVERTICULUM.—In the current number of the *Journal of Anatomy and Physiology*, Professor Watson records an extremely rare, in fact, an apparently unique occurrence of a diverticulum connected with the pharynx. This was found in an adult male human subject. Beneath the deep cervical fascia covering the anterior triangular space, on the right side of the neck, a muscular tube was seen to extend from beneath the tendon of the digastric muscle, which crossed it superficially, as far as the interclavicular notch of the manubrium sterni. This structure, at its proximal end, communicated with the pharynx just above the level of the stylo-pharyngeus muscle, by a narrow slit-like orifice in the free margin of the posterior pillar of the fauces, immediately behind the tonsil; while distally it terminated in a dilated *cul-de-sac* containing a quantity of grumous material. The tube intervened, in fact, between the stylo-pharyngeus muscle and the glosso-pharyngeal nerve—structures which, in the normal disposition of the parts, are closely applied to one another. Its vascular supply was derived from the occipital and inferior thyroid arteries, while its nerves were contributed by the glosso-pharyngeal. Histologically it was composed of only two coats—an internal tough mucous lining, resembling that of the œsophagus, and a layer of longitudinal fibres, mostly of red striated muscular tissue; circularly arranged fibres, such as are found in other portions of the digestive tract, being altogether absent. As regards the teratology of this abnormality, the position of the pharyngeal opening points to some modification in the closure of the first postmandibular cleft of the embryo.

J. C. GALTON.

MEDICINE.

DUMENIL ON UNILATERAL PARALYSIS OF THE VELUM PALATI OF CENTRAL ORIGIN.—Dr. Dumenil (*Archives Générales de Médecine*, April, 1875) draws attention to this symptom which, he observes, has hitherto possessed rather a physiological than a clinical interest, but which, he adds, should be traced to the different conditions giving rise thereto.

This symptom, according to Dr. Dumenil, is to be regarded as by no means uncommon, since he can himself collect at least a dozen examples. It has been spoken of as deviation of the uvula—an incorrect expression, inasmuch as it conveys the idea that the presence of this inclination is sufficient to show the presence of paralysis. It has been observed by Debrout that the uvula is inclined more or

less from the middle line in many individuals, and hence the diagnostic value of this deviation is destroyed. There is, however, Dr. Dumenil points out, a more sure indication to be found in the unsymmetrical condition of the two halves of the isthmus of the pharynx during muscular action. The two halves when at rest will appear to be alike, but when, by touching the fauces, muscular contraction is excited, the asymmetry is evident. On the healthy side, the normal movements take place, on the other the parts remain without change. Dr. Dumenil adds that this is not a mere anomaly; he has verified the observation many times. It is not to be confounded with the results of paralysis of the facial.

A series of twelve cases is given in two categories: 1. Unilateral paralysis of the velum palati without appreciable paralysis of the facial muscles; 2. The concurrence of paralysis of the velum with facial paralysis.

The question arises in the mind of Dr. Dumenil whether the nervous filaments which supply the muscles of the velum palati have a distinct origin, or whether the pathological condition is restricted to a few filaments so closely adjoining that they may almost be regarded as having a common origin. The author further draws a comparison between the form of paralysis and that of the iris, which is observable in general paralysis, and which is undoubtedly of grave diagnostic import.

The value of this form of paralysis in diagnosis is fully borne out by the histories of the cases that accompany this essay by Dr. Dumenil; our space forbids their more extended notice. The lesion appears to be one of frequent occurrence, and one, the author remarks, that has not been recorded sufficiently often because it has not been carefully looked for. Dr. Dumenil takes the precaution to observe that he does not regard every unilateral paralysis of the velum as being of central origin. He eliminates lesions of the facial nerve in the aqueduct of Fallopius as one of the causes, which is readily distinguished by the effect of electricity. At the same time he points out that this last form of paralysis may be coincident with a central lesion. In one case, Dr. Dumenil states that he found the nerves of the velum destroyed by syphilitic ulceration of the parts.

The author does not proceed further to develop the diagnosis of different forms of facial paralysis; he contents himself with having brought into prominence what he considers to be a very important symptom of lesion of the nervous centres.

W. B. KESTEVEN, M.D.

GRAS ON MICROSCOPIC EXAMINATION OF BLUE LINES ON THE GUMS SUPPOSED TO BE DUE TO LEAD-POISONING.—*La Revue Médicale* for April 12, 1875, quotes a paper by Dr. Gras on this subject from the *Archives de Médecine Navale*. He insists strongly that the lead-line is no mere deposit of that metal in or on the epithelial cells or connective tissue of the gum. It is due to a transformation of a soluble salt of lead into a sulphide of that metal during the slow circulation of the blood in the very minute capillaries of the gum. He says the demonstration is exceedingly simple, and almost painless. When we are in doubt whether a given blue-line on the gum be due to lead or not, we should excise a fragment of the gum containing the line with a fine sharp scalpel or the point of a lancet, wash it with a camel's hair pencil, and add a drop of glycerine; if necessary, flatten it out with needles, and examine it

under the microscope with a low power. If the line be due to lead, in the midst of the normal tissues of the gum, we shall find capillaries injected, filled and obstructed by blackish granules. These capillaries are in loops, or semicircular, or like double hooks, the outlines varying somewhat according to the section. In very old lead-lines the capillary walls are less evident, and their outlines somewhat indistinct. If a piece of buccal mucous membrane be excised, we should use carmine with glycerine, and a little dilute acetic acid, which shows the mucous papillae, and the capillary network. He suggests that in fatal lead-colic, the intestinal capillaries and the nerves of the solar plexus should be examined in the same way for lead. [The Reporter does not know to whom the credit of the suggestion belongs, but it has long since been proposed to examine the lead line by a simple microscope, or in other words a one or two inch biconvex lens; when, if in the capillaries, as the true lead line is, it will be seen clearly to be dotted, and to follow the course of the vessels. It will thus be seldom necessary to remove any of the gum in the living subject, though after death this suggestion of M. Gras may doubtless be of considerable use.] W. BATHURST WOODMAN, M.D.

DARBY ON A CASE OF TRAUMATIC EPILEPSY GREATLY BENEFITED FROM OPERATION. — Mr. Cline, it is well known, cured two cases of epilepsy resulting from injury to the head, by the use of the trephine; and the late Professor Dudley, of Lexington, reported (*Transylvania Journal of Medicine*, vol. i. 1828; see also *American Journal of Medical Sciences*, vol. ii. p. 489, 1828) three cases of epilepsy arising from the same cause successfully treated by the same operation. More recently Dr. John T. Darby communicated to the New York Neurological Society (*Psychological and Medico-Legal Journal*, February, 1875) another case greatly benefited by the same treatment. In this instance the manifestation of epileptiform convulsions occurred ten years after the injury (a kick on the head by a mule), and the operation for relief was performed in the thirteenth year succeeding the accident. Several similar cases were related by members during the discussion of Dr. Darby's paper.

SURGERY.

LANDI ON A CASE OF LIGATURE OF THE INTERNAL ILIAC ARTERY FOR WOUND OF A BRANCH OF THE GLUTEAL.—Dr. Landi (*Lo Sperimentale*, January and February, 1875) first comments on Bouisson's work,* and states that that author reported only four cases of ligature of the gluteal, one of the sciatic, and four of the internal iliac artery; while

Porta, who published his great work in the same year as Bouisson, collected twelve cases of ligature of the latter artery. To these Dr. Landi adds eight others, all (with the exception of two performed in America) operated on by Italian surgeons—Toracchi, Cianfione, Coluzzi, Gallozzi, Porta, and himself.

He first classifies the ligatures of the gluteal artery. It was tied four times for hæmorrhage, twice in cases cursorily noticed by Velpeau and by the American surgeon-general, and twice in cases by Baroni and Bouisson, of which a full account is given. Then follow two well-known cases in which the same artery was tied for traumatic aneurism—Murray's case and Carmichael's. Of these six cases, four were successful. Murray's case was fatal. The issue of the American case is not known. Then follow three cases of ligature of the sciatic for traumatic aneurism—John Bell's, Syme's, and Sappey's.* The two former were successful. In Sappey's case the disease recurred, and the patient was treated by Nélaton with perchloride of iron injection, and, it is believed, with success.

From the history of these cases, Dr. Landi concluded that the diagnosis of the exact vessel affected in traumatic or spontaneous aneurism of the buttock is often difficult, and that other mistakes are very probable, between aneurism and abscess, or erectile tumour or cancer; that it is by no means a certain indication in voluminous aneurism of the buttock to tie the affected artery by opening the sac, an operation which may be extremely difficult, and is very uncertain and dangerous; and that in small aneurisms in this region, the best method is to tie the affected artery on the method of Anel by the operative proceedings which Bouisson has described.

After having discussed the cases in which the gluteal and sciatic arteries have been tied, he then turns to those in which the internal iliac has been operated on. We pass over the observations he makes on the twelve cases referred to by Porta, of which the original case (of Stevens) is the only one the history and *post mortem* appearances of which have been adequately related. Next we have the accounts, as far as they are published, of the five Italian cases which preceded his own (one of which, that operated on by Professor Porta on a mistaken diagnosis, was recently referred to in our columns), and the few particulars preserved as to the two cases operated on in America; and then he details the case on which he himself operated. The operation was performed on account of repeated arterial hæmorrhage from a wound of the nates, which was believed to come from a branch of the gluteal artery (though the wounded artery could not be exactly discovered at the *post mortem* examination), and which proved fatal, on the seventeenth day after the operation, from pyæmia. The wound had been suppurating for some time; and the patient had had rigors and other bad symptoms before the operation. Out of these last eight operations, only one terminated successfully.

Then follows a long and able discussion on the indications for the ligature of the internal iliac artery, an operation which this author believes to be preferable in certain cases, contrary to the opinion of Bouisson and Broca, who prefer in all cases the ligature of the affected vessel, either by the method of Anel or of Antyllus, as the case may be.

The cases in which it is better, in Dr. Landi's

* 'Mémoire sur les Lésions des Artères fessières,' etc. M. Bouisson, *Tribut à la Chirurgie*.

* Bell's and Syme's are usually regarded as operations on the gluteal artery, and to judge by the reports of the cases correctly so.

opinion, to tie the internal iliac, are those of very voluminous aneurism, in which it is doubtful whether it would be possible to find the artery, and in which, indeed, the arterial orifice may be within the pelvis; and those of extensive sanguineous infiltration (so-called 'diffuse aneurism'), or sanguineo-purulent collections, in which, from the alterations of the parts, the uncertainty as to the seat of the injury, and the grave condition in which the patient is, it seems useless to attempt to find the wounded vessel.

[This paper is a very valuable one; and is especially useful to an inquirer into this part of surgery, as containing the details of several cases which, being published in Italian journals and works little known in this country, are hardly accessible here. It does not contain, as the author seems to have intended, all the cases which have been published up to the present time; nor, indeed, is it possible for any statistical writer in the present day to pick up all the cases of any given kind which are to be found in the periodicals of various countries. If the author had consulted Fischer's treatise in the 11th vol. of Langenbeck's *Archiv*, and the other authorities referred to in the lecture by the present compiler, which is abstracted in the *Archives Générales de Médecine* for March, 1875, he would have found several other cases of each kind which have escaped his research. But this is a matter of very minor importance, since, after all, if the statistical part of a paper of this kind were even absolutely complete at the moment of its publication, it would probably not be so when some years afterwards it is made the basis of fresh researches. The only important questions are whether the cases collected together are numerous enough and sufficiently typical to afford the materials for a judgment; and whether the judgment is correct. On both these points the present writer is most happy in being able to agree with Dr. Landi, and is glad to find that the conclusions at which he arrived independently in the above lecture are supported by an author of so much research, and who has had the opportunity of treating one of these rare and most dangerous cases. The absence of any distinct discussion of the methods of treating these aneurisms by compression of the aorta or common iliac, by galvano-puncture, or by coagulating injections, is perhaps to be regretted. In other respects Dr. Landi's conclusions agree pretty closely with those of the present writer, which it may be permissible thus to state again, as given in the *Archives Générales*.

1. Traumatic or spontaneous aneurisms in the buttock are favourably circumstanced for the treatment by gradual or rapid pressure on the aorta or common iliac.

2. If this treatment be insufficient by itself, it may be assisted by coagulating injections or galvano-puncture, performed while the patient is narcotised and the circulation commanded.*

3. If such treatment fail, the method of Anel, or that of Antyllus, should be selected if the tumour be entirely outside of the pelvis.

4. And in other cases the ligature of the internal iliac may be practised; but it ought not to be undertaken till all other treatment has failed.—*Rep.*]

T. HOLMES.

* I meant by this word 'commanded by pressure.' The reporter in the *Archives Générales* has misunderstood it, and has translated it 'régularisé par l'administration de la digitale.'—T. H.

MORTON ON STATISTICS OF AMPUTATIONS.—In the *American Journal of the Medical Sciences*, for April, 1875, Dr. Morton gives the results of amputations performed at the Pennsylvania Hospital.

Of the 152 amputations on 151 patients performed during the five years from 1870-1874 inclusive, 41 died, or 27 per cent.

One hundred and sixteen were primary (1 double amputation). Of this number 81 were cured; 34 died, or 29 per cent.

Five were secondary. Of this number 3 were cured; 2 died, or 40 per cent.

Twenty-nine were for chronic diseases. Of this number 23 were cured; 6 died, or 26 per cent.

Of the thigh amputations 8 were primary, 7 died; most of these were practised in cases of very severe injury; 8 were pathological (chronic), 1 died. Of the leg amputations, 35 were primary, 14 died; 11 were pathological, and of these 4 died.

Fifty-six of the amputations were of the upper extremity; of this number 9 died, or 16 per cent.

Ninety-six of the amputations were of the lower extremity; of this number 32 died, or 34 per cent.

It is observed that the smallest number of deaths occurred in January and November when the hospital wards have pure but heated air by forced ventilation, while in the months of May, June, July, and August, when ventilation is by open windows the largest number of deaths is found. Unfortunately, however, the author has only given the number of deaths in each month; a statement which is of little value from there being no percentage return of the deaths as compared with the recoveries during the periods referred to. On the face of the report, it is possible that fewer amputations may have been performed during the winter months.

Not a single case of pyæmia had occurred in the hospital during the last six months. The author adds in a note that the managers of the hospital have appointed an 'officer of hygiene,' who is required daily to examine and report the condition of every part of the hospital. GEORGE W. CALLENDER.

MASSEI ON THE REMOVAL OF A GROWTH FROM THE LARYNX WITH THE AID OF LOCAL ANÆSTHESIA.—Dr. Massei reports a case, in *La Clinica* of March 31, in which he removed a papillomatous growth from the larynx of a lady, aged thirty-two, who had suffered from aphonia for five months. The growth was multiple, the greater part springing from the free border of the right vocal cord, and occupying the anterior commissure of the vocal cords; whilst two or three vegetations, about the size of hemp-seeds, were disseminated over the anterior third of the left vocal cord. The throat being so irritable that Dr. Massei was unable to operate in the ordinary way, he determined to make use of local anæsthesia, and accordingly commenced at 9.30, on February 21, by pencilling the interior of the larynx with pure chloroform. This caused slight gidiness, which was relieved by an ammoniacal draught. At 11 the larynx was pencilled with a saturated solution of morphia, which was well tolerated; chloroform was again applied at 12.30, and morphia at 2. Notwithstanding this persevering treatment, at 2.30 anæsthesia was not established; further repetitions of the anæsthetics were made at short intervals, but still at 3.30 the desired result was not completely obtained. The patient, however, was tired of the anæsthetic treatment, and Dr. Massei proceeded to operate. It was found that, though

complete anæsthesia had not been produced, the sensibility of the larynx had been greatly diminished, and Dr. Massei succeeded in removing the growths with forceps comparatively easily. The following day the voice was found to be perfect, and there remained only slight hyperæmia of the left vocal cord. [This case is interesting, as illustrating both the advantages and the difficulties of producing anæsthesia of the larynx. This auxiliary is frequently employed by Schrötter, of Vienna, and Labus, of Milan, but is seldom used by other laryngoscopists. —*Rep.*]

MORELL MACKENZIE, M.D.

ROBERTS ON A NEW MATERIAL FOR FIXED DRESSINGS.—Dr. John B. Roberts, in a report of a clinical lecture at the Pennsylvania Hospital, states (*Philadelphia Medical Times*, February 13, 1875) that after experimenting with various kinds of fixed dressings, Dr. R. J. Levis seems to have arrived at one which fulfils all requirements; being cleanly in its application, drying with sufficient rapidity, removable without difficulty, exceedingly light, and withal very cheap. The fixed material is ordinary glue, with which oxide of zinc has been incorporated, either by the manufacturer or by the surgeon at the time of using it, in order to cause it to harden rapidly. Several pieces of flannel—old blankets or worn-out underclothing answering the purpose admirably—are selected and cut to the requisite size. One of these is laid around the limb, and the two edges are tightly stitched together along the anterior surface, allowing the edge to project above the seam; then the melted glue, with oxide of zinc, is painted upon this with a brush. The dressing may be strengthened by an additional layer of flannel or blanket saturated with the glue and oxide of zinc, and made to adhere to the underlying layer. A third or even a fourth layer may be thus applied, if it be deemed necessary, and the limb supported until the dressing dries, which requires from four to eight hours. The stitches of the seam on the front of the limb having been cut with scissors, the edges of this elastic case are sprung apart, and the dressing removed. The edges are then trimmed smooth, and a number of eyelets inserted, in order that the case may be laced like a shoe, and the degree of pressure regulated. This fixed fracture-apparatus is exceedingly light, is made from materials almost everywhere obtainable, and is much cheaper than the silicate dressing. There are at all times pieces of waste flannel or cloth about a large hospital which can be appropriated, while the glue and zinc could probably be supplied at a very low price per pound, in quantity sufficient for the manufacture of many such splints. Another advantage is its elasticity, which permits removal without endangering the splint, for it can be pulled apart, and immediately springs into place around the limb to which it has been moulded. By a little care and dexterity in stitching on the layers of flannel, the surgeon can readily shape the dressing so that both the leg and the foot are completely encased.

MODESTIN ON SPIDER-BITES.—In four cases of bites by spiders observed in Dalmatia by Dr. Modestin, and reported in the *Giornale della Reale Accademia di Medicina di Torino*, 1874, and *Gazzetta Medica Italiana Prov. Venete*, January 9, 1875, appearances of poisoning similar to those which accompany the bite of venomous serpents were present. In the case of a woman, aged thirty-six, five months advanced in pregnancy, and who

was bitten on the right lip of the vulva, there were sweats, cramps in the muscles of the back and abdomen, with suppression of the urine and fæces. These symptoms lasted two days, and were treated by a mixture of camphor, gum arabic, sugar and vinegar. The symptoms disappeared under this treatment, followed by a purgative. An exanthema, similar to measles, appeared at the end of a week, and was quickly cured without leaving any traces.

MATERIA MEDICA AND THERAPEUTICS.

LITTLE ON THE TREATMENT OF SCARLATINA.—The *Dublin Medical Journal* for April contains two papers on this subject, based on experience gained in the epidemic which prevailed extensively in the Irish metropolis last year. One of these papers is by Dr. Little, the professor of medicine at the Royal College of Surgeons of Ireland, and the other by Dr. Wynne Foot, of the Meath Hospital.

Dr. Little considers that scarlatina is, of all diseases, the one in which it is most necessary to abstain from the administration of drugs, unless there is a very distinct indication for treatment, and that the ordinary treatment by chlorate of potash and tincture of the perchloride of iron is not only useless, but sometimes even injurious. The mere act of swallowing these drugs is painful, and Dr. Little thinks that they are apt to cause gastric catarrh, sickness, and diarrhœa.

When there is severe inflammation of the tonsils, and much offensive secretion in the throat, Dr. Little applies locally twice daily, or in bad cases more frequently, on a large soft camel-hair brush, a mixture of one part of glycerine of carbolic acid in two of water. The sucking of ice he does not consider beneficial, as it entails frequent painful acts of deglutition.

When there is much restlessness and sleeplessness, with delirium, Dr. Little thinks that bromide of potassium is useful, together with the application to the legs of flannels wrung out in mustard and water; or if the temperature be high, tepid sponging and cutting the hair close; even in the case of young women this latter proceeding does no harm, as the hair commonly comes off during convalescence. When there is much heat of head he applies also leeches to the temples and ice to the scalp.

When there is sleeplessness without marked heat of skin, he thinks opium useful and more reliable than chloral. If there be any symptoms of renal

congestion, or much swelling or secretion about the throat, opiates are of course inadmissible.

When instead of wakefulness there is screaming and grinding of the teeth, with injected eye and a condition approaching coma, tea and coffee are the best remedies. In such cases the secretion of urine is usually scanty or absent. Dr. Parkes made some years ago a series of experiments which went to show that tea and coffee possessed the power of increasing the elimination of urea in fevers, and Dr. Little has certainly found the kidneys act more freely after a cup of rather strong tea than after medicinal diuretics. Stimulants he considers less beneficial in scarlatina than in most fevers. J. W. LANGMORE, M.D.

MACNAUGHTON JONES ON DIGITALIS IN TYPHUS FEVER.—In the *Dublin Journal of Medical Science* for April, Dr. Macnaughton Jones, of Cork, relates his experience of the treatment of typhus fever by digitalis, following out the observations of Drs. Little and Grimshaw on this matter. Dr. Jones administered it to 110 cases of typhus. Of these eleven died, two of which were marked hopeless on admission. The total number of cases of acute disease treated by digitalis was 310, of which eighteen died. The effects upon the respiration and pulse were to lower them both. The pulse, after repeated doses, falls to 40 or 60. The temperature is usually affected within two days. Its action was particularly marked in the young. The doses used were twenty drops of the tincture or half an ounce of the infusion every three or four hours; twenty drops of chloric ether being given with each dose. In some cases the drug was stopped at night. The drug had no effect over the duration of the fever. The effect upon the nervous system was very marked. There appeared in a large majority of cases to be complete immunity from delirium. Most of the cases went through the fever quietly, and there was a marked contrast with those which he had treated with alcohol. The tongue was moist in nearly every case, and there was a noticeable absence of the hard, brown, and dry tongue so characteristic of this affection. There was no effect upon the petechiæ, except their early disappearance. The secretion of urine was free in nearly all the cases. The convalescence was quicker after its administration. In few of the cases did it produce vomiting. Dr. Jones concludes that in digitalis we have a powerful cardiac stimulant, which, while it gives force to the heart, does not do so at the expense of the system, but rather is a conservative agent, which controls expenditure and limits waste of vital action; always, of course, remembering that a large number of cases will get better without any specific treatment, save that care and guidance which provides for the wants of the system, and secures the patient from the risks of complications. He further says that digitalis appears to be indicated in the early periods of many cases of typhus in which we have a rapid pulse and a high temperature range, regulating our administration by its effects on both, using it rather with the object of guiding the patient up to a certain point than of curing the disease.

J. MILNER FOTHERGILL, M.D.

BOUCHUT ON ESERINE AS A REMEDY FOR CHOREA.—M. Bouchut (*Bulletin Général de Thérapeutique*, April 15, 1875), gives the results of 437 experiments performed with the active principle of the Calabar bean. The eserine was employed either pure or in the form of sulphate. It was some-

times administered by the mouth, in solution or in pill, sometimes hypodermically; the dose in each case varying from two to five milligrammes ($\frac{1}{35}$ to $\frac{1}{14}$ of a grain). The subjects of experiment were children from seven to twelve years of age suffering from chorea in all its stages and varieties.

The physiological effects produced by a single dose of five milligrammes of eserine injected under the skin were the following: pallor, nausea, salivation, intense *malaise*, occasionally vomiting. No colic or diarrhœa occurred. The pupils often remained unaffected; they were sometimes dilated, sometimes contracted, but always active. Abundant perspiration was frequently noticed. The retinal veins were contracted and the fundus of the eye pale. The most serious and disagreeable symptom which occurred was an enfeeblement or even paralysis of the diaphragm. These symptoms lasted from one to three hours after the injection; no unpleasant sequelæ were observed.

The phenomena produced by smaller doses, subcutaneously administered, or by the same dose introduced into the stomach, were similar in kind, but much less intense. The most suitable dose for hypodermic use is two and a-half milligrammes ($\frac{1}{28}$ of a grain); this never causes any very disagreeable effects, and may be repeated twice or three times a day.

Next, as regards the remedial efficacy of the drug, the choreic movements are invariably arrested so long as the physiological effect of the injection lasts; when this has passed off, they return, but usually in a less severe form. Daily injections cure the disease in an average period of ten days.

E. BUCHANAN BAXTER, M.D.

FLINT ON THE REMEDIAL USES OF WATER.—The valuable researches of Dr. James Currie, entitled 'Medical Reports on the Effects of Water, Cold and Warm, as a Remedy in Fever and Febrile Diseases, whether applied to the Surface of the Body or used Internally,' have been latterly too generally overlooked. Dr. Austin Flint (*American Practitioner*, January, 1875) gives a very excellent and appreciative analysis of Dr. Currie's volumes, compares the views of the author with those of the advocates of this therapeutic measure in modern times, and finally presents the results of his own experience. He states that he has had considerable experience in this mode of refrigeration at Bellevue Hospital, and he says it has proved more successful than any other treatment.

The internal use of water, as a remedial measure, irrespectively of the action of cold, is worthy, Dr. Flint thinks, of more attention than it has received. He says: 'A source of more or less benefit, derived often from the so-called mineral springs and artificial waters, seems to me to have been overlooked; namely, the usefulness of simple water ingested in considerable or large quantity. Undoubtedly much of the benefit which is received by those who drink mineral waters at the watering-places is attributable to the change of scene, relaxation, the expectation of improved health, freedom from business and other cares, together with sanitary advantages pertaining to climate, regimen, and diet. But aside from these it is fair to attribute something, and perhaps not a little, to the drinking of the waters. It is evidence of this that mineral waters brought from the springs and those artificially prepared are often beneficial to those who remain at home. That the benefit may

be due, measurably or chiefly, to the water and not to the medicinal constituents is shown by the fact that some waters supposed to possess extraordinary remedial potency have no medicinal constituents. The Missisquoi water, a few years since famous for the cure of cancerous and other affections, was analysed by Squibb, and found to be only remarkably pure water.' In cases of renal disease, Dr. Flint adds his testimony to the efficacy of water used internally as sometimes proving a potential remedy.

PARET ON THE THERAPEUTIC ACTION OF VALERIANATE OF CAFFEINE.—Dr. Paret, in his *Thèse de Paris*, 1874, No. 464, describes this substance as a product crystallised in white flakes, having a very disagreeable odour like decayed cheese. He has administered it in the form of ten centigramme pills, of which he gives from two to three. It may also be given as a syrup containing ten centigrammes of valerianate of caffeine. Dr. Paret comes to the conclusions 1. That valerianate of caffeine has, in some cases, appeared to put an end to the nervous vomitings co-existent with hysteria; 2. That this medicine had given to invalids increase of a decided appetite, and a physical as well as moral strength which they had not previously possessed; 3. That the vomitings of consumptive patients had not been checked by it. It has also been tried in the sickness of pregnancy, but without favourable results. It appears that Dr. Labadie-Lagrave has twice used the syrup of valerianate of caffeine for infantile whooping cough, and that this medicine, taken in doses of two fluid drachms per diem, produced a very marked improvement. The fits of coughing, which at first amounted to fifteen daily, fell to four, after a week's treatment.

OPHTHALMOLOGY AND OTOLOGY.

STEINHEIM ON DISEASE OF THE CHOROID CONSEQUENT ON THE USE OF CHLORAL HYDRATE.—Under this title, Dr. Steinheim has recorded (*Berliner Klinische Wochenschrift*, February 8, 1875) a remarkable instance in which inflammation of the choroid followed the administration of chloral hydrate on three several occasions in the same individual.

A married woman, aged thirty-nine, who in early life had enjoyed very good health, and who had

given birth to five children, without any apparent reason had become the subject of most distressing asthma, so that, when she first presented herself to Dr. Steinheim, she was extremely emaciated and thoroughly worn out. The paroxysms of dyspnoea were very frequent, although she enjoyed short intervals of rest. A fortnight previously, when her sleep had been constantly broken for several nights, she took for the first time a dose of chloral, the immediate result of which was that her eyesight became dimmer, so that she saw everything as through a cloud, and could with difficulty see her way about; in the course of a few days her eyesight was gradually restored, but her conviction was very strong as to the effect of the medicine she had taken. On a second occasion, when chloral had been given to her much against her will, her eyesight again suddenly left her, so that she could with great difficulty distinguish light from darkness; at the same time her eyes appeared red and streaming with tears; but on this occasion the symptoms did not disappear as they had previously done, and consequently she sought further advice. When examined by Dr. Steinheim, she was extremely emaciated and in distress, her respirations 40 and pulse 140 in the minute; rhonchus and sibilus were present on both sides of the chest, but the heart was normal. The conjunctivæ on both sides were injected, but without chemosis; in the right eye there were punctiform opacities in the posterior layer of the cornea, the aqueous humour was turbid, and the pupil was full of lymph and was adherent to the capsule of the lens. In the left eye the aqueous humour was turbid; there were one or two synechiæ in the pupil, but not nearly to the same extent as in the right eye. Ophthalmoscopic examination was impossible, and the extent of the visual field was uncertain, although it was clear that there was good perception of light in each eye. As the employment of atropine produced no effect upon the pupils, an iridectomy was performed upwards in each eye, and with good results, inasmuch as the corneal wounds healed readily and well in spite of the patient's unfavourable condition; the media became much clearer, and the perception of light much increased; it was now possible to detect with the ophthalmoscope floating opacities within the vitreous body, although no details of the fundus could be made out. Subcutaneous injections of morphia had given her such relief, that at her own desire the patient was allowed to return home. For some time her condition and her health improved in every way, but after a recurrence of a most severe paroxysm, while under the care of another physician, she again took a dose of chloral which, as before, produced a quiet night, but on the following morning the same loss of vision occurred as on the previous occasions; but in this instance, unfortunately, the loss of vision appears to have been permanent and nearly complete. The nature of the symptoms in this remarkable case can hardly be doubted; the asthma was essentially the result of some severe disturbance of the nervous system, and the occurrence of disease within the eye in the shape of iridochoroiditis, on three several occasions immediately after taking a dose of chloral, cannot be looked upon as a mere coincidence. Steinheim is of the opinion that the order and the appearance of these symptoms were due to venous thrombosis in the choroid, owing to the enfeebled condition of the heart and the arterial circulation. On its first occurrence, it was but partial, and the collateral circulation was

sufficiently active to prevent any decided structural alteration, and consequently the loss of vision was limited and of short duration. On each subsequent occasion, however, the disturbance to the circulation was greater, and the structural change was more marked. In considering the features presented by this case, Steinheim attaches great value to recent observations made by Russian authors, Blesig and others, on the frequent occurrence of choroidal affections in connection with recurrent fevers, in which it is suggested that venous thrombosis is the starting-point within the eye, induced by the enervated condition of the heart.

It is very well known, at the present time, to how great an extent the action of chloral is able to influence the heart's action and the respiration, its influence no doubt being due to its action upon the sympathetic nerve. The observations of Crichton Browne and of other writers upon the causation of many cases of urticaria and of erythema are illustrative of the derangements which result in the circulation, in consequence of defective or disturbed innervation of the blood-vessels; and Dr. Steinheim is of opinion that in this instance the disturbance of the choroidal circulation and the subsequent choroiditis were the direct result of the action of the chloral upon the nerves which preside over the intraocular circulation.

MANZ ON THE APPEARANCE OF THE OPTIC NERVE DURING ACUTE DISEASE OF THE BRAIN.—In the *Klinische Monatsblätter* for December, 1874, will be found an interesting paper which was read at the last meeting of the Ophthalmological Congress, in which Professor Manz sums up at some length the result of his observations with the ophthalmoscope during the various forms of disease of the brain and its membranes. The phenomena which he had observed were hyperæmia of the optic disc, engorgement and tortuosity of the retinal veins, and optic neuritis. As the author had nothing new or of special interest to relate with reference to the last of these conditions, his remarks are confined to the former two only.

With regard to hyperæmia of the disc, meaning by that term the condition in which it appears unnaturally pink, in consequence of overfulness of its arterial capillaries, he has come to the conclusion that it is an uncertain and a most unreliable symptom; and his reasons for doing so are probably sufficient. It can be shown that the colour or tint of the disc may be materially modified by the state of the circulation within the carotid vessels, quite independently of any general hyperæmia of the cerebral contents; and the peculiarity of the arrangement of the blood-vessels around the entrance of the optic nerve, by which a communication is established between the retinal vessels and those of the choroid, explains the occurrence of hyperæmia of the disc in cases where there is only a disturbance of the choroidal circulation, and where there is no reason whatever to suspect any intracranial mischief. It is highly probable, then, that the colour of the disc may change frequently in the same eye at different times; and as the variation may arise in several ways, it is obvious that hyperæmia of the disc can be no very certain index of a similar condition within the brain or its envelopes.

The engorgement of the retinal veins, however, in Professor Manz's opinion, is much more indicative of serious mischief. In the majority of instances the

venous congestion was seen to be associated with a hazy and apparently oedematous condition of the retina to some extent; these conditions, when combined, may be regarded as pathognomonic of some interference with the cerebral circulation; but in many instances it is uncertain whether the veins are engorged or not, as they no doubt vary in size in the same individual. It might be supposed that the appearance of the retinal vessels would be materially influenced by the condition of the circulation generally, but Manz has not found this to be the case in the eyes of those who have come under his observation; he has not, for instance, found it so in the eyes of those who have been extremely anæmic or chlorotic, nor in the eyes of epileptics. He believes that the venous congestion and the opacity of the retina may be explained on the assumption that there has been some impediment to the circulation through the lymphatics, and that the lymph-canals, which are formed by the sheaths of the optic nerve, and which, according to the researches of Schwalbe, communicate on the one hand with the lymphatic spaces within the eye-ball, and on the other hand with the subarachnoid spaces, become distended with fluid, and increased in size so as to press upon the surrounding veins, and to prevent the free escape of the venous blood from the retina and from the optic nerve. It was admitted on all hands that the explanation was plausible, and so far true in that this distension of the sheath of the nerve could occur; but it was urged at the same time that it was almost impossible to say when this distension had or had not occurred, and the *post mortem* examinations which had as yet been made with reference to this point, had not determined what was the normal size or capacity of the lymph-spaces in question. [Whether Professor Manz's explanation be the true one or not, his paper is very valuable, inasmuch as it offers a plausible explanation of an appearance and a condition of the optic disc which are very common, and which are, in many instances, considered as evidence of optic neuritis, although symptoms of active inflammation are otherwise wanting.—*Rep.*]

KLEIN ON SYMPATHETIC OPHTHALMIA AFTER CATARACT OPERATIONS.—A short paper, by Dr. Klein, of Vienna, appears in the February number of the *Monatsblätter*, as part of the proceedings of the Ophthalmological Congress (1874) in which he narrates the particulars of two cases of sympathetic ophthalmia which had occurred in his own practice subsequent to an operation for cataract; until this time he knew of but a few such instances on record, which had been described by Arlt, Critchett, and Schweigger. An important result of the discussion which ensued amongst the members of the Congress was to elicit the fact that no less than sixteen such cases had been observed. In the first of Klein's cases, the operation for extraction had been attended by considerable prolapse of the iris, which gave a good deal of pain and was consequently excised. Some weeks afterwards, the vision of the other eye became impaired and an attack of iridocyclitis soon developed itself, in order to combat which the removal of the offending eye was proposed, but the patient declined to submit to any further operation. The second case was that of a middle-aged woman who had a complete cataract in one eye, which was operated upon, and an incomplete cataract in the other. The operation appeared in every way satisfactory; but, as in the

other case, it was followed by a prolapse, and in the course of a short time by iritis in the other eye. Enucleation was recommended, but was declined; iridectomy was performed in both eyes, but without any good result; the pupils became obstructed by adhesions; the eyes became soft, and vision was reduced to mere quantitative perception of light.

In Klein's opinion, the prolapse and strangulation of the iris originated the sympathetic mischief in the sound eyes of his two patients, but the opinion of other and distinguished members of the Congress was not altogether in favour of such a view. It was urged that if it were so, we should expect to see sympathetic inflammation a frequent result of leucoma adhærens, which it is not; and especially should we expect it after the performance of iridodesis, an operation in which a portion of iris is intentionally strangled in the margin of the cornea—very near to the ciliary region. It was demonstrated also that it had occurred after operations which had been attended by no prolapse whatever, and in these instances it was thought probable that the section had been carried too far within the ciliary region. But there were still other cases in which it was evident that no fault could be found with the extent or with the position of the section, and in these it would appear that the dragging upon the ciliary region, which was caused and maintained by contraction of the opaque capsule, had been sufficient to originate an inflammation resulting in the destruction of the other eye. The President might well say that such an array of facts tended strongly to support the opinion of those, who declined to operate for cataract while the other eye was yet unimpaired.

GAYAT ON OPHTHALMOSCOPIC EVIDENCE OF DEATH.—The number of the *Annales d'Oculistique* for January, 1875, contains an extract from a small work of Dr. Gayat, in which he describes the appearance of the eyes of criminals after decapitation. In the outset, it is shown that no great reliance can be placed upon the condition of the pupil as a sign of death; for not only does this alter under many different circumstances during life, but the researches of Grünhagen have proved that the state of the pupil after death depends in some measure upon, and can be regulated by, the degree of temperature. It is well known that the pupil varies with the amount of refraction which the eye possesses, so that a dilated pupil is usually one of the phenomena which accompany myopia; and it has been ascertained by Landolt and Nuel, that after sudden death from loss of blood, the eyes of rabbits, which during life are hypermetropic, have become emmetropic, or even myopic. The changes in the fundus oculi, which Dr. Gayat observed in all his cases of decapitation, were complete emptying of the arteries and of the veins, not only upon the optic disc, but for a limited distance around it; beyond this point, however, the vessels were still filled with blood. At the Ophthalmological Congress at Heidelberg, Wecker alluded to the emptiness of the arteries of the retina as being ophthalmoscopic evidence of death; and upon this it was stated by A. Weber that, having made a series of observations upon the eyes of animals which had previously undergone sudden death after ligation of the aorta, he had invariably found that the vessels immediately around the optic disc had been completely emptied, while those at the peripheral part of the fundus still contained blood. In

one or two instances, Dr. Gayat found that the column of blood still remaining in the vessels appeared to have been interrupted in places, as he suggests, by irregular contraction of the blood-vessels; and he thinks it very probable that the same condition would be met with in the arteries of other tissues if it were possible to see them. He considers the complete emptiness of the vessels upon and around the disc to be caused by the pressure which is suddenly and evenly applied to the disc, by the tonicity of the muscles of the eye acting upon the contents of the globe for some short time after death.

JACUSIEL ON A CASE OF ENCEPHALITIS AND INTERSTITIAL MYELITIS WITH ULCERATION OF BOTH CORNEÆ.—In the *Berliner Klinische Wochenschrift* for March 8, 1875, will be found a short clinical account of a case of this kind, similar to that described by Von Gräfe in his *Archiv* (Band xii.) William G., aged six months, came under Dr. Jacusiel's care on account of vomiting with diarrhœa; these symptoms were very severe, but appear to have yielded to active treatment. The child was enabled to take food; and the pulse and general temperature became natural. But he appeared singularly apathetic, and his eyes were wanting in expression, otherwise he might have been considered as nearly well. The conjunctivæ soon appeared dry (xerosis) from absence of secretion, and from this moment the suspicion of cerebral mischief was aroused; a few hours later both corneæ were found to be infiltrated, ulcerated at their lower margins; the conjunctivæ were injected, and their sensitiveness had diminished. A very short time elapsed before both corneæ were entirely destroyed; and on the fifth day from the commencement of the child's illness trismus set in, and at the same time the pulse became more frequent, and the cheeks appeared flushed. The eyelids, the conjunctivæ, and the mucous membranes of the nose and of the lips were now completely insensible; the child did not cry, and did not appear to suffer much, but remained in the same remarkable apathetic condition until its death, just five days after the first attack. On one occasion, it was reported, there had been some slight convulsive movements of the upper extremities. No *post mortem* examination was permitted. During his illness the child was seen by Professor Schweigger, who confirmed the opinion expressed by Dr. Jacusiel. The cause of the attack could not in any way be explained. The parents were in good health, and had never had syphilis; their other children were healthy; and this child up to this attack had appeared strong and thriving, and had not been exposed in any way to exanthemata. In addition to that described by Von Gräfe mentioned above, other cases of the same nature have been recorded in Virchow's *Archiv* (Band xxxviii.); and in earlier numbers of this same journal (*Berliner Klinische Wochenschrift*, nos. 31, 32) similar cases have been recorded by Hirschberg.

REVIEWS.

A Series of American Clinical Lectures. No. I. On Disease of the Hip-joint. By LEWIS SAYRE, M.D. New York, G. P. Putnam's Sons. January 1, 1875.

This series will be read with much pleasure and profit in this country if the succeeding numbers of it should be equal in interest to the present lecture. Dr. Lewis Sayre is well known in Europe as an eminent surgeon, particularly in connexion with the subject of hip-disease; and although the present brochure hardly contains anything which will be novel to those who have read his previous writings on the subject, it condenses his doctrines, and puts them graphically and in a brief space before the reader.

The first point on which Dr. Sayre dwells, is the traumatic as contradistinguished from the constitutional origin of hip-disease. On this point he speaks as follows : 'Hip-disease generally results from an injury, blow, fall, wrench, strain, over-exertion, jump, violent exercise, and sudden checking of the perspiration, or some other violence done to the part, and may occur to any child in the world. In fact, from careful observation of some hundreds of cases, I have found it more frequently in the active, robust, healthy child than in the dull and sickly one, for the reason that these children are more reckless, wild, and romping, and therefore run more risk of injury than the feeble, sickly child. I know, gentlemen, that this is not the doctrine that you find in any of your text-books, and is, at the present time not generally believed by the mass of the profession. I was taught, and all your standard works and text-books teach you, that it is a disease essentially of a strumous origin, dependent entirely upon a tuberculous or scrofulous constitution. One of the most distinguished writers on surgery states distinctly, "No struma, no hip-disease."'

The traumatic origin, or, at least, the frequent traumatic origin, of hip-disease is, we believe, now an admitted fact; and Dr. Sayre can hardly be familiar with the modern text-books, at least those which circulate in this country if he believes that it is not asserted in them. Certainly if he had read Mr. Bryant's *Practice of Surgery*, pp. 820-827, or had honoured the writings of the present reviewer with his attention (*Surgical Diseases of Childhood*, p. 434, second edition), he would have seen that some, at any rate, of the writers of text-books are quite as alive as he is to the fact, which the present writer, for one, believes to be indubitable, that hip-disease is not always strumous. But Dr. Sayre appears to us to have gone just as far on the other side; or perhaps only to have, as lecturers are apt to do, used terms more absolute than exactly express the truth. It would certainly be understood, from his way of putting it, as if struma were a positive protection against hip-disease, and as if the latter could not arise spontaneously. Daily experience

seems to show on the contrary that strumous children, and the children of consumptive parents, are far more prone to hip-disease than the robust and healthy; and that in them it may be generated spontaneously, or, at least, if its origin be traumatic, the injury is so slight as to escape the most careful investigation. We pass over the method of examination which Dr. Sayre employs for the purposes of detecting the disease in its earliest stage. It is very minutely described, as if the precise manipulations used were of extreme importance; but, in fact, it only comes to this, that the surest test of the early stage of the disease is that the joint is stiffened, so that in extensive movements without anæsthesia the pelvis moves with the thigh. We are glad to note the following sentence, which we can confirm from personal observation. 'If the disease be detected in this early stage and properly treated, I am satisfied, from extensive experience, that the great majority of cases will entirely recover, with perfect motion and without deformity.' (page 5.)

Dr. Sayre, like other authors, divides the disease into three periods, which he denominates—(1) the stage of irritation; (2) the stage of effusion; and (3) the stage of rupture of the capsule and perforation of the acetabulum; and he follows Mr. Barwell and other surgeons, in making the position assumed by the limb depend on the assumed fulness of the capsule in the second stage, and its evacuation in the third. We should have been glad of some better anatomical evidence than has as yet been adduced to prove the truth of this mechanical doctrine. We have certainly over and over again seen cases presenting all the external signs of Dr. Sayre's second stage with no evidence at all of effusion within the joint, at least to such an extent as could produce any change in the position of the bone; and as to the mechanism of the third stage, it appears to us very dubious whether perforation of the capsule ever occurs, except as the result of the bursting of an abscess. Dr. Sayre speaks of the escape of 'pus or other fluid' from the capsule; but surely there is no proof that the capsule is ever ruptured by mere synovitis, nor does Dr. Sayre appear to us to take sufficient account of the changes going on in the head and neck of the bone. In fact, he speaks of them as if they were consequences of the muscular spasms. 'Constant muscular contraction,' he says, 'promotes interstitial absorption of the head and neck and the acetabulum'—a statement which is, to say the least, dubious. Inflammation of the femur and acetabulum appears quite as capable of generating muscular spasms.

With regard to the treatment of the disease, two points only seem to us to require notice. One is the treatment by the splint which has received Dr. Sayre's name, and the object of which is to produce extension of the thigh, and so relieve interarticular pressure and the pain and spasms accompanying the disease, without confinement to bed. The present writer, after having tried this splint repeatedly, must confess to having failed in this object, that is to say whenever the disease has been in so acute a stage that the child was unable to bear the ordinary starched or leather splint. If this was our fault we should be glad to give a renewed trial to the apparatus. After Dr. Sayre's visit to England some two years since, we believe the apparatus was tried tolerably freely on his recommendation, and we should be glad to learn whether it has been generally found to answer.

But the most important part of Dr. Sayer's lecture is that in which he speaks of excision of the hip. In commencing this topic, Dr. Sayre makes the wonderful assertion that 'this operation is very simple, indeed, *and attended with no danger whatever*,' p. 20 (the italics are ours). We cannot too strongly protest against such a description of an operation in which, to use Dr. Sayre's own words, 'the patient being laid upon the well side (a curious expression which is always used in this paper to express what we call the sound side) an incision is made from a point midway between the crest of the ilium and the top of the trochanter major, the knife carried firmly down to the ilium, and drawn with a single sweep downward and outward over the posterior edge of the trochanter major, and then curved forward and inward, making a crescent-shaped incision of some four to six inches in length,' and then the periosteum is peeled off the femur, the whole of the trochanter major and head and neck of the bone is removed, and very probably the acetabulum freely scraped, gouged, and rasped. Such an operation, undertaken on a sickly child, weakened with long confinement and worn out by pain and suppuration, is really one of extreme danger, and it can serve no useful purpose to blink the fact. In Dr. Sayre's opinion, the trochanter should always be removed, even when not diseased, an opinion we cannot share. In fact, his method of operating seems to us to involve more extensive incisions and more disturbance of the parts than is commonly necessary; nor can we see the motive for removing a healthy portion of the femur on the speculation that it may be regenerated by the periosteum. That the trochanter does not oppose any obstacle to the exit of the discharge, we have satisfied ourselves by frequent experience. But whether Dr. Sayre's subperiosteal or the ordinary method of excising the hip-joint is the better, we cannot believe that either can be free from danger and very grave danger, and we deprecate the hasty use of language so calculated to mislead. Dr. Sayre's plan is to fill the wound with Peruvian balsam, insert a plug of oakum, stitch up the greater part of the wound, leaving the plug projecting, then place the limb in a screw apparatus, provided with a footpiece. The limb being firmly secured in the apparatus so that the knee cannot bend, the footpiece is brought down till the limbs are of the same length—and now, according to Dr. Sayre, immediately the patient has recovered from the anæsthetic, 'he is capable of being stood up (*sic*) against the wall, or riding out in a carriage or boat, and can take his daily exercise in this way' (p. 23). Dr. Sayre also claims for this method the advantage of procuring the complete restoration of the movements and of the length of the limb. 'In one case,' he says, 'the motion is greater in that joint than upon the opposite side, and the limb less than a quarter of an inch shorter than the other, although it was sawed three inches below the top of the trochanter major; the head and neck having been entirely absorbed, and the acetabulum perforated' (p. 23).

With these remarks, we must commend this tract to the attention of our surgical readers, merely adding that, though we cannot accept all Dr. Sayre's theories, and though he claims an amount of success for the operative treatment greater than any that we can hope to obtain, his lecture is of very great interest, and his plan of operation well worthy a careful and sufficient trial.

T. HOLMES.

MISCELLANY.

DR. BELL PETTIGREW, F.R.S., Lecturer on Physiology at Surgeon's Hall, Edinburgh, has been awarded the Godard Prize of the French Academy of Sciences for his original anatomical and physiological memoirs. Dr. Pettigrew, in virtue of the above distinction, becomes a laureate of the Institute of France.

DRUNKENNESS AND ITS PREVENTION.—Dr. Lunier lately read a paper at the Paris Academy of Sciences, in which he sought to show that drunkenness becomes more general in proportion as the alcohol of commerce is introduced into common use. Thus, in wine-producing countries, where wine is the ordinary drink, drunkenness is rare; whilst, on the contrary, it is general in countries which do not produce wine. His remedy for this state of things is to give every possible facility for the consumption of wine in those countries where it is an imported luxury.

FECUNDITY OF THE SHARK.—The *Union Médicale* of February 20, contained an account of a female of this species, caught by M. Lesseps, which on dissection was found to contain twelve living young ones. This viviparous character of the shark is confirmed by Dr. Moinet, an ex-naval surgeon, in a letter published in the *Union Médicale* of April 29. In it he relates that, when off the Antilles, an enormous blue shark was taken, which when opened was found to contain seventy very lively young ones, which, when thrown into a tub of sea-water, swam about with great vivacity. In order to avoid any chance of being devoured at a later period by these interesting orphans, Dr. Moinet thought it advisable to cut short their career in a bath of boiling water. The small sharks varied from about nine to ten inches.

THE MEDICAL NIGHT SERVICE OF ST. PETERSBURGH.—The *Voix* gives some details of the practical working of this new institution, already referred to in these columns, and which has now been in operation for a twelvemonth. At first, this new night service, founded by the private exertions of a few medical men, had many difficulties with which to contend, but perseverance triumphed in the end, as it usually does. This novel institution is now found to be extremely useful to the inhabitants of St. Petersburg, and reckons persons of all ranks and means amongst its clients. The medical men on duty are always ready to render the services asked at their hands, without any previous knowledge that their labour will prove remunerative; neither do they shrink from going, when required, to the most dangerous and notorious localities. The number of visits made and carefully registered during the current year amounts to 1,024, of which the greatest number was in January, when they amounted to 152; the maximum of visits made in one night being six and the minimum three. The patients comprised 524 men, 363 women, and 137 children of both sexes. These nocturnal duties were performed by fifteen of the permanent staff and thirty-five occasional helpers. The fees paid by persons in good circumstances have been utilised in completing the necessary arrangements for this night medical service and in organising small surgeries, where the necessary appliances may be always found at hand. The example thus set by the medical profession at St. Petersburg has been followed by the sincerest of flattery, 'imitation,' at Moscow, Odessa, Warsaw and other large cities of the north.

PROFESSOR HUXLEY ON THE CROCODILE.—Professor Huxley, who has undertaken the duties of Professor Wyville Thomson's chair of Natural History in the University of Edinburgh during the present summer session, gave his introductory lecture, on the 3rd instant, to a large audience. He put before his class the considerations which resulted from the careful study of a single animal, the crocodile; an animal which was worthy of attentive study, as it might be said that a knowledge of its organisation

was the key to the understanding of a vast number of extinct reptiles, and the key to the organisation of birds; while it helped them to connect the higher with the lower forms of vertebrate life, and was, in part at any rate, the key to the history of past life upon the globe. There might be asked respecting this animal, as respecting every other living thing—first, what was its structure? second, what did it do? third, where was it found? and fourth, in virtue of what chain of causation had this thing come into being?—this last having only been recently recognised as one of those questions which might legitimately be put. He then proceeded to describe the organisation of the crocodile—its morphology, physiology, and distribution; and remarked that there were few animals about the palæontological history of which they knew so much, as they could carry back its history through the tertiary and secondary epochs. The answer to the last question constituted etiology, or the science of the causes of the phenomena of morphology, physiology, and distribution. Here, as in all cases where they had to deal with causation, they left the region of objective fact and entered that of speculation. With their present imperfect knowledge, the only safe thing they could do, in attempting to form even a conception of the cause of this extraordinary complex phenomenon, was what a wise historian would do—stick by archaeological facts. He pointed out that palæontological facts showed that there had been a succession of forms of that animal to the present day, the oldest being something like the lizard.

INAUGURATION OF THE ZOOLOGICAL STATION OF NAPLES.—After the first working year a formal inauguration of this new institution took place on April 11. Dr. Dohrn had invited the Italian Minister of Public Instruction, Signor Borghi, and the German Ambassador at Rome, Herr von Kendell, to be present as representatives of the two countries which had most assisted in completing the new establishment, the one granting the locality, whilst the other paid a subvention of 3,000*l.* towards the expenses of the construction. Unfortunately both gentlemen were at the last moment prevented from being present, but sent two letters stating their great sympathy and the sympathy of the two Governments which they represent, for the Zoological Station. The inauguration solemnity consisted chiefly in an inaugural address by Dr. Dohrn himself to an audience of distinguished gentlemen, and a short answer given by Signor Paureri, Professor of Anatomy of the Naples University. During the first year of the existence of the Zoological Station, the following naturalists have made use of its laboratories:—From England: Mr. Balfour, Mr. Dew Smith, Mr. Marshall, from Cambridge; Mr. E. Ray Lankester, from Oxford. From Holland: Mr. Hu-brecht (Leyden), Dr. Hoek (Haag), Professor Hoffmann (Leyden), Dr. Hoorst (Utrecht), Professor Van Ankm (Groningen). From Germany: Professor Waldeyer (Strassburg), Professor Wilh. Müller (Jena), Dr. Korsmann (Heidelberg), Professor Hesslöh (Constanz), Professor Greeff (Marburg), Professors Kollmann and Ranke (Munich), Dr. Steiner (Halle), Professor Oscar Schmidt (Strassburg), Professor Langer Lans (Freiburg), Dr. v. Thering (Göttingen), Dr. Gotte and Dr. Lorent (Strassburg), Dr. Vetter (Dresden), Professor Selenka (Erlangen). From Austria: Professor Claus (Vienna) with two students of the Vienna University. From Russia: Professor Salensky (Kazan), Dr. Rajewsky (Moscow), Dr. Bobretzky (Kiew), Dr. Ulianin (Moskau), Dr. Rosenberg (Dorpat), Cand. Isnoskoff (Kazan). From Italy: Dr. Cavanna (Florence), Dr. Fanzago (Padua), Dr. Zingone (Naples). If the number of naturalists coming to Naples in former years to study Marine Zoology be compared with the number of those who are named above, it is at once obvious how great an effect the Zoological Station has had on the increase. Formerly from three to five zoologists used to come during the year to Naples, often even less or none. From Easter 1874 till Easter 1875, there were thirty-six naturalists, and during March and April of this year alone there have been working contem-

poraneously in the Zoological Station eighteen zoologists. At present the following governments and universities have entered upon contracts with the Zoological Station for one or two tables:—Prussia, Italy, Russia, and Austria, each for two tables; Bavaria, Saxony, Baden, Mecklin-burg, Holland, and the Universities of Cambridge and Strassburg, each for one table. Negotiations have been entered into with Württemberg and Hesse-Darmstadt. Accommodation for twenty-four naturalists will be ready for next winter, and it is hoped to augment the daily arriving quantity of marine animals for investigation by help of a small steam launch, which will be always out on fishing expeditions, weather permitting. In Dr. Dohrn's inaugural address, reported in *Nature*, of May 6, he remarked that the decreasing importance which the study of zoology holds in the medical curriculum can hardly be avoided without inordinately lengthening the time required for such a course, since medical science itself has become so subdivided and specialised. Still, those who look upon the medical profession as something more than merely a means of livelihood, will not treat zoology with indifference, but will perceive the important bearing it has on the proper understanding of many medical problems. He then insisted on the importance of the principles of the development theory on the progress of medicine, affirming that in the case of transmission of a hereditary tendency to certain forms of disease, the application of these principles might be made to serve a most important purpose, if thoroughly understood and carefully carried into practice. Dr. Dohrn bespoke the utmost toleration for the Darwinian theory from all classes. He hoped that the fact that he had connected the name of the station with the development and application of the Darwinian theory would not prevent any one from lending it his support. The important bearing which the work at the Naples and similar stations had on the elucidation of this law was then pointed out in these terms. 'Every fish, every crab, every Medusa, is the result of a long process of development, which we have to trace, and the determination of which the zoological station is intended to facilitate. That is its purpose; it was for that end that I built it, and for that reason I have asked you to lend your support to my efforts.'

DAYLIGHT *versus* GAS.—There can be no excuse for burning gas during day-time wherever there is either a window, skylight, or area-grating through which daylight can be admitted; by adopting a Daylight Reflector, a considerable saving will be effected, and the healthiness of the premises wonderfully improved. The public are strongly recommended to visit the manufactory of the Reflector Patentee, Mr. Chappuis, of 69 Fleet Street, who will give every requisite information.—[Adv't.]

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 1*rs.* 4*d.*; free by post, 1*rs.* 6*d.*

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 1*rs.* 6*d.* Cloth Cases for binding the Numbers for each year may be had for 1*s.* 6*d.* each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

WEDNESDAY, MAY 19, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

VULPIAN'S EXPERIMENTAL PATHOLOGICAL STUDIES ON THE PHYSIOLOGICAL ACTION OF TOXIC AND MEDICINAL SUBSTANCES.

(Continued from page 286.)

Toxic and medicinal substances may be introduced into the animal economy by various methods. Gases and vapours are introduced by the surface of the respiratory organs; and this method is likewise put into practice for liquid substances, because the pulmonary mucous membrane is a better absorbent than the mucous membrane of the digestive system.

The experiments of Golner, who was able to inject about thirty-nine pints of water into the lungs of a horse without killing it, as well as those of M. Colin, who made some injections of the same kind, and saw twenty-two pints and a half of water, which were injected into the lungs of a horse, in the space of three hours completely absorbed, are well known.

M. Claude Bernard, in his lectures on anæsthesia and asphyxia, also cites the experiments of M. Ségalas, in which three centigrammes of extract of *nux vomica*, dissolved in sixty grammes of water and injected into the trachea, killed the dogs injected in two minutes; while the introduction of ten centigrammes of the same extract into the stomach did not produce any effect. The cases published by M. Jousset de Bellesme, and related in M. Claude Bernard's lectures, show that in urgent cases, when, for instance, we have to deal with pernicious intermittent fever (under which conditions M. Jousset's experiments were made), the injection of sulphate of quinine into the trachea may offer great advantages. It might, perhaps, be wise to try this way of introducing drugs in other instances in which absorption takes place with disheartening slowness, as in cases of cholera. For some experiments, absorption by the mucous membrane of the digestive organs is useful, although it presents numerous inconveniences. Thus poisons ingested into the stomach may bring on vomitings or diarrhoeal evacuations, which eject the ingested substances. It may also happen that the toxic substance may be modified by the action of the gastric juice. On the other hand, absorption is more or less rapid according as the stomach is full of food or empty. This refers, of course, to the absorption of the toxic or medicinal agent. The effects of certain substances may be rendered more rapid or more certain by the presence in the stomach of matters in process of digestion. This will occur with the cyanides, which, under these conditions, will produce a disengagement of hydrocyanic acid. But the emptiness of the stomach will favour the penetration into it of those substances which are naturally absorbed. In a general way, it may likewise be

said that the gastric mucous membrane of the mammalia absorbs the majority of poisons somewhat slowly, even when the stomach is empty. It is thus that curara, introduced into the digestive passages of a mammiferous animal, only produces toxic effects when it is ingested in very large quantities. This is in consequence of the slowness of absorption. The curara thus gradually absorbed is eliminated in the same proportion, so that at no time does there remain a sufficiently large quantity in the organism to exercise its characteristic action. This is thoroughly proved by the fact that, when an animal's kidneys are removed before introducing curara into its stomach, we find, like M. Claude Bernard, the effects of curarisation produced, because the poison is able to accumulate in the organism, its principal eliminative outlet being suppressed. Strychnine is in the same way very slowly absorbed by the mucous membrane of the stomach. M. Bouley had noted that horses, whose pneumogastric nerves had previously been divided, and into the stomach of which a salt of strychnine was introduced, were not poisoned. It was thence concluded that the mucous membrane of these animals does not absorb strychnine. This conclusion is erroneous; for, if the strychnine be sought for in the contents of the stomach some hours after the experiment, it is found to have disappeared. How is it, then, that horses in which the vagus nerves are intact are quickly poisoned by the same dose of strychnine which remains harmless when these nerves are divided? This result comes from the paralysis of the muscular fibres of the stomach, produced by the division of the nerves. The strychnine then remains confined in the stomach, which in the normal condition only possesses a very small power of absorbing this substance. Absorption goes on very slowly, and the poison is eliminated in the same proportion as it is absorbed; so that the strychnine is never, at any moment, found in sufficient quantity in the organism to produce its usual effects. When, on the contrary, the vagus nerves are intact, the movements of the stomach cause the strychnine to pass into the intestine, where absorption is very active, and poisoning quickly occurs.

The veins are frequently chosen for the introduction of poisons into the organism. This method offers great advantages with regard to the rapidity of absorption; but is not without inconveniences. There is danger of coagulating the blood, of injecting air or solid particles in suspension in the fluid used as a vehicle, and a still greater danger of producing syncope and sudden death by the direct action of the injected liquid on the heart. The endocardium being endowed with sensibility, if that membrane be suddenly brought into contact with an irritant liquid, a disturbance, and even a stoppage, of the pulsation of the heart takes place. M. Vulpian states that he has often verified this fact in cases of injection of chloral into the femoral vein. He here protests strongly against the custom adopted by some experimentalists of making injections by the jugular vein. The danger he has pointed out in the case of the femoral vein is much greater when the jugular vein is in question, since it is so near to the heart, that the poison reaches it before it has had time to mix with the mass of the blood and thus to lose its irritant properties. He insists in the strongest terms on the necessity of never choosing the jugular vein for the purpose of injecting toxic or medicinal substances. The error will thus be avoided that has been committed by many experimentalists, who

have pointed out, as a physiological effect, the cardiac disturbance caused by a direct action of the injected liquids on the internal wall of the heart.

The most generally employed method of introduction is the injection or subcutaneous insertion of poisons or drugs. This method is in general preferable to the preceding methods. It is specially excellent when it is desired to inject a small quantity of the dissolved substance under the skin. It has, however, been the source of numerous errors, the results of a defective operative method. Toxic substances introduced under the skin may act locally and directly, and bring on local inflammatory accidents, which in certain cases help to complicate the effects of the substances of which it is wished to study the physiological action, by giving rise to secondary general disturbance. On the other hand, if a liquid capable of acting chemically on the tissues (concentrated alcohol, acids, etc.) be employed as a vehicle, this liquid may bring on a corrugation of the region into which it is introduced; the circulation of the vessels becomes impeded, and the absorption of the active substance, of which it is desired to study the effects, thus becomes impossible. M. Vulpian likewise calls special attention to the point, that substances dissolved in liquids easily absorbable spread themselves by diffusion from one point to another to a very considerable distance from the place where they were introduced. This, at least, is what always happens with the frog, even when the substance is introduced in the solid state, it being understood that it is easily soluble in the interstitial fluids of the animal economy. It is through not having taken sufficient note of this fact that many experimentalists have made very lamentable errors, with regard to the physiological action of certain toxic substances. Thus, it has been asserted that the soluble salts of copper mercury, etc., are poisons acting on the heart. It is easy to give prominence to the error which has been committed, and to show how it might be avoided. Sulphate of copper, for instance, has been considered by M. Armand Moreau as a cardiac poison. He introduced this substance under the skin of the back of several frogs, and he saw the heart stop before the peripheric nerves had lost their physiological properties; but if the poison had been introduced into a point of the body distant from the heart, the same result would not have been produced. M. Vulpian here relates two comparative experiments made in his laboratory. In one, a crystal of sulphate of copper was introduced under the skin of the back of a frog; whilst under the skin of the lower part of the leg of another frog a similar crystal was introduced. The first frog died immediately after the experiment; and M. Vulpian thinks it probable that, according to his own experiments and M. Moreau's assertion, the heart stopped while the nerves and the muscles of the limbs had preserved their physiological properties. The other frog survived, and was shown by M. Vulpian to his pupils at the next lecture; only the foot and leg which had been in contact with the sulphate of copper were green and cadaveric. If, in the frog, of which the dorsal region was placed in contact with the sulphate of copper, the heart stopped, it was because that substance, dissolving by degrees in the lymphatic fluid, penetrated by diffusion through the wall of the heart, and acted directly on the myocardium. It is even quite certain that the sulphate of copper would have

in this frog attacked the spinal marrow by the same process, and would have destroyed its physiological properties. Thus certain metallic salts diffuse themselves with great rapidity throughout the whole extent of the body, and destroy the physiological properties of the muscles *in situ* by chemical action. These salts are classed as muscular poisons, which is also an error proceeding from the same source. It is necessary to avoid this diffusion of soluble substances as much as possible when we make experiments on frogs, and for this purpose two indispensable precautions should be taken. The toxic substance should in the first instance be introduced as far as possible from the heart and the nervous centres. The importance of precaution with regard to the nervous centres, is shown by the experiment made in 1842 by Stilling, who showed that the characteristic effects of strychnism could be obtained by introducing strychnine under the skin of a frog from which all the viscera, including the heart, had been removed. It is very evident that in this case strychnine produced its action after having impregnated all that remained of the frog at the same time as the medulla. With regard to the heart, M. Vulpian reminds us of his observations on sulphate of copper, and states that he could cite numerous other instances. The toxic substance then must be introduced under the skin of one of the hands or feet. The second precaution to be taken consists in never injecting a large quantity of fluid. If a cubic centimetre of water be injected, the danger of errors which should be avoided is incurred. It is by thus injecting solutions of metallic salts that many substances which have no action on the muscles through the medium of the circulation have come to be classed amongst the number of muscular poisons. The substance to be tried, then, should be introduced either in the solid state or in the most concentrated possible form of solution, so as to allow but a very small quantity of fluid to penetrate under the skin. The characteristic physiological action of a poison or a drug only takes place with certain agents in fixed determinate doses. If the dose of certain substances be too strong, the animal under experiment may be killed without producing the effects which truly characterise the physiological action of these substances. MM. Gréhaut and Duquesnel's experiments on aconitine are an example. These experimentalists, in fact, have shown that, if a weak dose of crystallised aconitine (the twentieth part of a milligramme) be injected under the skin of a frog, effects analogous to those of curara are produced; that is to say, an abolition of the motility of the nerves, whilst the muscular contractility is still intact. If, on the contrary, a solution of a milligramme of the same substance be injected, the same effect is not produced. Now it is easy to see that this difference of action is referable to the fact that, in the second case, the heart stops under the influence of aconitine before this poison has had the time to abolish the influence exercised by the motor nerves over the muscles.

The physiological action of poisons is a field of research which has not been completely explored; and in the labours undertaken on this subject, a certain number of errors are met with which will be pointed out in due course. The researches of M. Claude Bernard on poisons and drugs have served as a basis for the classification of these substances. They have been classed as poisons of the motor nerves, poisons of

the sensitive nerves, poisons of the muscles; but M. Vulpian thinks that this classification is very open to objection. He is not disposed to allow the existence of toxic agents which would kill the motor nervous fibre, which would annihilate its property during the life of the animal by the medium of the circulatory passages, and of which substances curara would be the type. According to him, curara, at least at the outset of its action, leaves the physiological property of the motor nervous fibre, the neurility, perfectly intact, as it leaves intact the primary muscular physiological property, contractility. At a certain stage of its action it, so to speak, breaks the physiological continuity between the nervous fibre and the primary muscular fasciculus, so that the excitations which traverse the nervous fibre can no longer communicate themselves to the muscular fasciculus; it must, however, be particularly noted that there is not at this moment any abolition of the physiological property of the nervous fibre. The modifications which take place throughout the whole extent of the nervous fibre under the influence of excitants, in a healthy animal, are again produced in a curarised animal when the motor nerves are irritated by mechanical or galvanic exciting agents; but the muscle, though still irritable, is no longer provoked to contraction by these excitations. There is an obstacle between the two elements which stops all communication. Neither does strychnine kill the sensitive fibres of the nerves. It excites and exalts the properties of the grey matter of the medulla; tetanic convulsions make their appearance; then, after a certain period of strychnic tetanus, the animal (frog) falls into a complete state of relaxation. But even then it is easy to demonstrate that sensibility is preserved.

Finally, if it be true, which is doubtful, that there are any muscular poisons, these poisons are vegetable substances (digitaline, upas antiar, veratrine, etc.) or animal substances, the venom of the frog, and of the triton or water-salamander. It is inaccurate to place in this group the metallic salts. Sulphocyanide of potassium itself, which has been considered as a type of this kind of toxic agent, only destroys the properties of the muscles when it enters directly into contact with them; it does not seem capable of producing the same effect when it diffuses itself throughout the organism by way of the circulation. M. Claude Bernard himself, it should be remarked, has made some reservation as to the *modus operandi* of this substance. But physiologists who have repeated his experiments have been more decided on the subject than he has. M. Vulpian observes that the present remarks on sulphocyanide of potassium are not novel; he published them long since, and holds the same opinions with regard to the generality of salts which have been very erroneously termed muscular poisons.

The next lecture will treat of jaborandi, now, in M. Vulpian's opinion, justly occupying much of the attention of the medical world.

(To be continued.)

MINOR ON ERYSIPELAS AND CHILD-BED FEVER.

The author of a review in the *American Journal of Medical Sciences* for April, 1875, of Dr. Minor's work on 'Erysipelas and Childbed Fever,' writes as follows.

The design of the author in this work will be seen by the following quotation:—'An inquiry into the

connections said to exist between child-bed fever and erysipelas; also a short account of both diseases as they prevailed sporadically in the United States during the census year 1870, and an appendix containing the history of a puerperal fever epidemic observed in south-western Ohio, in the winter of 1872' (p. 5).

Dr. Minor's special attention was directed to this subject by the difference of opinion manifested in the Cincinnati Academy of Medicine, during a discussion on the question: Should a physician attend a case of labour, who has recently been in attendance upon patients suffering from erysipelas?

After some remarks upon the history of puerperal fever and its epidemics, and upon the epidemics of erysipelas which were more or less coincidental with the former, the author takes up the old battle subject of contagion, a question which ought to have been set at rest long ago, but which we presume must, from the character of the human mind, always have its advocates and opponents, although it has to be admitted that those who believe in its potent influence can present an array of historical facts not at all easy to overbalance or controvert.

The question of the instrumentality of physicians and nurses in conveying a mysterious miasm, capable of inducing peritoneal inflammation in parturient women, was at one time a very active one in Philadelphia, and gave rise to the publication in the *American Journal of Medical Sciences*, and several medical works, of numerous valuable papers, which collectively afford an exceedingly important, if not almost exhaustive record. The moving spirit in this discussion originated with the late Dr. David Rutter, who was so unfortunate as to meet in his own private practice, with ninety-five cases of puerperal fever with eighteen deaths, in a period of four years and nine months (1841-1846), and at a time when there were very few cases in the hands of other physicians. The visitations of the disease at the Pennsylvania Hospital on several occasions, and at the Philadelphia Hospital, added to the general interest of the subject.

Some of the more important testimony in proof of contagion in this disease and its intimate connection with erysipelas are:—

1. Discussion at the College of Physicians, of Philadelphia, reported in the October number of the *American Journal of Medical Sciences* for 1842 (pp. 410-418).

2. Puerperal fever cases reported by Dr. Robert Storrs, of Doncaster, England, showing the propagation of the disease at his hands, from a case of gangrenous erysipelas, followed by repeated abscesses requiring the lancet (*Ibid.*, January, 1843).

3. Notice of a malignant epidemic which prevailed in the lying-in department of the Philadelphia Hospital, in March and April, 1842 (*Ibid.* p. 244, *op. cit.*) Out of nine children whose mothers had puerperal fever, five died of peritonitis in about a week after birth.

4. Contagiousness of puerperal fever, by Dr. Oliver W. Holmes (July, 1843, p. 260). This paper contains quite an array of cases bearing upon the connection between the contagion of erysipelas and puerperal fever, and their power of interchange.

5. Drs. Hall and Dexter's account of the erysipelalous fever of Vermont and New Hampshire (January, 1844, p. 13.) . . . This is an interesting and valuable paper, showing the remarkable pathological connections which exist between some of the

types of epidemic erysipelas and puerperal fever. 'The most fatal results, for the most part, were to be anticipated in the affection of the internal organs, particularly the bowels and uterus; and during the season when the epidemic might be said to be at its height, not one in seven escaped, who had disease of the last-mentioned organ' (p. 191).

Those who are only familiar with erysipelas as a cutaneous malady, can form but a very imperfect estimate of that terrible type which is so allied to peritonitis as we find it after parturition, that some pathologists have been inclined to term the latter, 'malignant internal erysipelas' (p. 19). Erysipelas in fact will attack skin, connective tissue, intermuscular laminae, the mucous membranes, serous cavities, and many important viscera, such as the uterus, liver, intestines, etc. 'In the county of Caledonia, Vermont, thirty cases of puerperal peritonitis occurred, only one of which recovered. And in Bath, New Hampshire, containing a population of 1,500 to 1,600, twenty mothers died from puerperal peritonitis, and about forty with erysipelas' (p. 21).

In 1843, the cases in Dr. Rutter's practice amounted to forty-five; whilst at the same time Dr. William Klapp, who lived and practised in the same section of Philadelphia, several times having labour-cases in the same row, did not meet with one instance of the disease in two hundred parturient women, as he himself informed the reviewer. As there were no evidences of the disease being properly an epidemic, either from its relative fatality or general distribution among obstetricians, the misfortunes of Dr. Rutter excited a great deal of interest, and contagionists and their opponents warmly discussed the questions involved. Those interested in the matter are referred to the *American Journal of Medical Sciences* for October, 1842, p. 412; Charles D. Meigs, on *Diseases of Women*, p. 590; and Churchill, on *Diseases of Women*, edited by Condie, p. 618.

Dr. Rutter, to rid himself of the mysterious influence which appeared to attend upon his practice, left the city for ten days, and before waiting upon the next parturient case had his hair shaved off, and put on a wig; took a hot-bath, and changed every article of his apparel, taking nothing with him that he had worn or carried, to his knowledge, on any former occasion: and mark the result. The lady, notwithstanding that she had an easy parturition, was seized the next day with child-bed fever, and died on the eleventh day after the birth of her child. Two years later, he made another attempt at self-purification, and the next case attended fell a victim to the same disease.

Dr. Condie says (*op. cit.*):—'But he was charged with being a carrier of contagion. How could he carry the cause? What was the cause? Was it some ozone that stuck to his hands or coat?'

Dr. C. D. Meigs remarks (*op. cit.*):—'Does the doctor generate and distil the poison, or merely transfer it? If he transfers, why don't I also diffuse it? We are equally men, equally clothed. No, gentlemen, you do not carry the poison; you are merely unhappy in meeting with such accidents through God's providence.'

Now suppose we should state, as we do upon the authority of an obstetrical contemporary of Dr. Rutter, that, at the period referred to, he was the subject of an obstinate muco-purulent coryza, would not that give a reasonable solution of the mystery? Was his pocket-handkerchief not capable of conveying septic poison through his hands to the patient?

Some would say no. But what says M. Chauffard, of Paris, as quoted in the last number of the *American Journal of Medical Sciences*, p. 287? Every suppuration, every disease which produces morbid discharges, if in the vicinity of women in child-bed, will give rise in the latter to puerperal fever; and he says he has particularly noted the effects of abscess, purulent ophthalmia of infants, and erysipelas. The very successful and distinguished ovariotomist, Mr. Spencer Wells, is in the habit of exacting a written and signed statement from each visitor to his operations, to the effect that he has not been in attendance upon any case of zymotic disease. Ask Dr. Goodell, why he has not had a visitation of the fever among his cases at the Preston Retreat. He recognises the danger that lies in infection and contagion, and acts accordingly, using every precaution to prevent the possibility of septic or other poisoning, manual or local.

Dr. C. D. Meigs states, page 591:—'Seeing that I could never convict myself of being the means of spreading the contagion, I remain incredulous as to the contagiousness of the malady.'

It may be entirely coincidental, but we well remember a case upon which a brother physician put an entirely different construction. An eminent obstetrician stated to the writer, that Dr. M. was called in an emergency to deliver a patient of his, after he had left her a short time, the labour having been unexpectedly hastened in his absence. When he found what had been done, he remarked to his wife on reaching home, that he feared for the lady and anticipated trouble for himself, because Dr. M. had been called from an opposite dwelling, where he was in attendance upon a case of puerperal fever. We do not say that Dr. M. took the disease to her; but she was shortly seized with it, and made a narrow escape for her life. A celebrated obstetrician, who placed no credence in contagion in any disease, once said to the reviewer, upon discovering that one of his patients (and he had had a number of cases) had puerperal fever, 'Well, Doctor, this is always my unfortunate luck.' We accounted for this case, from the fact that his assistant in the labour had been dressing patients under surgical treatment; no doubt a fruitful source of the disease in the lying-in wards of many a general hospital.

Dr. James Blundell, in his *Principles and Practice of Obstetric Medicine*, p. 551, remarks:

'Remember that the facts affirmative of contagion are so strong, that on this affirmation it becomes our duty to act.'

In the records of puerperal fever, we shall find many instances, where the disease has appeared in cases of sudden emergency, when the attendant has not had time, or has failed, to make the proper precautionary ablutions and changes necessary to prevent risk to his patient.

Seventy pages of the work of Dr. Minor are taken up with a critical examination of the census reports of the American States and Territories for the year 1870, touching the mortality from puerperal fever and erysipelas; the geographical position, altitude, temperature, and rain-fall being given in each case. From this investigation it will appear that there was no epidemic of either malady at any point that year; that the two generally kept pace more or less with each other; that they were much less frequent among the white race than the black; and that they were most often met with in the spring months. The whole mortality amounted to 3,162

from erysipelas, and 1,828 from puerperal fever, in a population of nearly 39,000,000; and the largest proportion of deaths from each malady was in the month of March, which is memorable for its damp, cold winds.

In 1872 and 1873, puerperal fever and erysipelas prevailed as an epidemic in Cincinnati, Ohio, the deaths being 122 of the former, and 68 of the latter, against an annual average for the previous five years, of $13\frac{3}{5}$ and $13\frac{1}{5}$ respectively. The history of this epidemic gives some curious evidences of the interchangeable character of the two diseases.

'Dr. A. loses a patient from puerperal fever on the — of July; duration of illness, eight days. Six days afterward another "death-certificate," puerperal fever; duration of illness, eight days. On August, "death-certificate," from erysipelas. Four days afterwards, "death-certificate," from puerperal fever; duration of illness, six days. Several other instances of the same character are quoted, with regard to other physicians' (p. 116).

'It is a sad commentary on this last epidemic, that a few men who attended cases of erysipelas and puerperal fever promiscuously, should have been most unfortunate in their practice. On the contrary, we notice some physicians, having a large practice, who lost not more than one or two cases of puerperal fever, and no erysipelas cases at all. I think the majority of our physicians refuse to attend confinement cases, when they have erysipelas or puerperal fever cases on their hands' (p. 117).

Dr. Minor sums up the results of his investigations as follows.

1. 'Erysipelas and puerperal fever seem to prevail together throughout all the States.

2. 'Any marked increase in any locality of one disease, seems to be accompanied by a corresponding increase of the other.

3. 'Where histories of past epidemics of either disease are obtainable from any of the States, the seeming connection of the two diseases was noticed by physicians at the time of such epidemics, and remarked on.

4. 'For these reasons we are, I think, justified in concluding that there is an intimate connection existing between puerperal fever and erysipelas.' (p. 119.)

From a study of the Cincinnati epidemic, he makes the following deductions.

'Where an isolated death from puerperal fever was noted outside of the infected districts, a corresponding death from erysipelas was noted in the same locality. This was almost invariably the case.

'Infants die of erysipelas shortly after or before their mothers die of puerperal fever.

'A few physicians, attending puerperal fever cases and erysipelas cases at the same time, as exhibited by the death-register, were most unfortunate in their practice.

'Physicians having large obstetrical practices, who are known to believe in the doctrine enunciated regarding the connection of puerperal fever and erysipelas, make an exhibit of but few death-certificates from either cause' (p. 120).

The following statement of Dr. Minor is of considerable interest and importance.

'An epidemic of scarlet fever is at this date (June, 1874) prevailing in this city, although now happily on the decline. This epidemic commenced in May,

1873, after the subsidence of the puerperal fever epidemic. No month was exempt from scarlet fever, although there were only fifteen deaths from the disease during the first four months of the year. Only one of these occurred in April. After that, the deaths from scarlet fever increased each month, until there were from it 113 deaths in November, and 108 in December. The total deaths from this cause were 410' (p. 126).

Dr. Braxton Hicks remarked before the London Obstetrical Society (*Trans.*, vol. xii. 1870): 'There is no doubt that scarlet fever and erysipelas have much affinity; indeed, some have suspected them to be but a slight modification of the same poison, apparently interchangeable.'

But what says the Health Report of Cincinnati? In 1874 (up to June 1) puerperal fever did not prevail; less than the usual number of cases being reported; and the same is said of erysipelas. From May, 1873, to June, 1874, there were about 800 deaths from scarlet fever; and the number of cases was computed at from 6,000 to 8,000.

If epidemic puerperal peritonitis is due to the same peculiar poison which produces erysipelas, the peritoneal variety of which closely resembles it, then it must result from a combination of certain conditions and circumstances in and around the patient. Traumatic disturbance, acting upon a system peculiarly susceptible of erysipelas, will readily produce it, if the state of the atmosphere, the physical health of the subject, and his hygienic relations are favourable to its approach. We had one female patient who had several attacks of erysipelas in her left arm, but never in any other region; and by far the most severe one was excited by the prick of a needle in the index finger. Another subject, a boy of seventeen, with a penetrating wound of the thigh, had seven attacks of erysipelas at short intervals, due, apparently, to attempts made by stimulating dressings to cause the wound through the skin to granulate and heal over; for under a very simple application there was no renewal of the inflammation, and the parts cicatrised.

There are seasons when, in a hospital, not only the slightest wounds become erysipelatous, but the disease will attack, as we have seen, cases under simple mechanical treatment, in the most severe and fatal form; such, for example, as a leg undergoing straightening of the knee by a screw-splint, for partial ankylosis, etc. . . . Let a parturient woman have induced in her the same susceptibility, and her utero-placental laceration, like an amputated limb, will offer all the traumatism requisite as a starting-point for a fatal puerperal peritonitis. Increase this danger by an exposure to the infection of this disease, or erysipelas, and she may have the former without any special susceptibility other than the parturient state often produces. Expose her again to atmospheric or manual contamination from septic poison in the form of purulent discharges, or the taint of the autopsy, and you have puerperal septicaemia or phlebitis. It matters little, except for scientific interest, whether epidemic child-bed fever is a disease of multiform character, or whether its varieties are determined by the manner of its production, for all have more or less a fatal tendency under the most approved treatment; but it concerns us to determine how to protect the patient by precautionary and prophylactic measures.

ANATOMY AND PHYSIOLOGY.

SORBY ON A MICROSCOPE SPECTRUM APPARATUS.—Though Sorby's paper (*Monthly Microscopical Journal*, May, 1875, p. 198) has no direct medical bearings, we refer to it on account of the method recommended for expressing the position of absorption-bands, which is equally applicable to spectral analysis when used for physiological or for medico-legal purposes. Mr. Sorby's well-known method of measurement is to compare the position of the bands in the absorption-spectrum with the dark bands produced in light passing through a quartz plate interposed between two Nicol's prisms, the thickness being so regulated as to give twelve bands in a convenient position. This method was open to several objections [especially, we think, the difficulty of obtaining scales strictly comparable with one another.—*Rep.*] Mr. Sorby now proposes to express the position of all bands by a number representing the actual wave-length at that part of the spectrum. For this purpose he has constructed a table giving the wave-lengths of every one-eighth division of his quartz interference-scale so that, after having measured the position of any part of the spectrum by means of this scale, he can by the use of the table at once express everything in terms of millionths of a millimetre of wave-length. He proposes to publish this table and give with it the means of correction, so that, in case anyone should have a quartz scale not accurately corresponding with this, the measurements may still be expressed in accurate wave-lengths.

[The reference of absorption-bands in the spectrum to wave-lengths, though not new (see Jäderholm, *LONDON MEDICAL RECORD*, April 14, 1875, p. 234), has apparently not been made practicable before in microscopic researches. If systematically carried out, it would greatly increase the value of the micro-spectroscope; the want of a satisfactory scale of reference having been the chief objection to the use of this instrument.—*Rep.*]

RICHARDSON ON DIAGNOSIS OF BLOOD-STAINS.—Dr. J. B. Richardson (*Monthly Microscopical Journal*, May, 1875, p. 213, and *American Journal of Medical Sciences*) refers to Dr. Woodward's criticisms on his alleged microscopical distinction between human blood and that of the dog (*LONDON MEDICAL RECORD*, March 17, 1875, p. 165). Dr. Richardson fully admits the force of Dr. Woodward's criticisms, and only urges, as before, the danger of publishing truths of which an improper use might be made in the defence of criminals. He also contends that alterations of size or form due to drying are much less obvious in the case of a thin film of blood than in large masses. J. F. PAYNE, M.B.

OTT ON THE ACTION OF LOBELINA ON THE CIRCULATION.—Dr. Ott has performed some experiments with the alkaloid of *Lobelia inflata* in Professor Bowditch's laboratory at the Harvard Medical School. It was a dark oily liquid, heavier than water, with a tobacco-like taste and smell. He dissolved it in water acidulated with acetic acid, the solution being carefully neutralised before injection. Six experiments were performed on curarised rabbits; the inference drawn from them being that lobelina, in small doses, raises the blood-pressure by exciting the peripheral vaso-motor system; the pulse being

temporarily reduced in frequency, and subsequently quickened. [The inevitably complex conditions of the experiments, which are fully described by Dr. Ott, render it necessary that they should be repeated and varied before even this limited inference from them can be regarded as established.—*Rep.*]

E. BUCHANAN BAXTER, M.D.

PATHOLOGY.

TUKE ON AFFECTIONS OF THE NEUROGLIA.—Dr. Batty Tuke, in the sixth Morisonian lecture (*Edinburgh Medical Journal*, April, 1875), considers the different forms of disease of the neuroglia. Having previously considered the cerebral disturbances due to variations in the blood-supply, he states that the idiot, whether the well-recognised imbecile or merely the subject of that form of idiocy which manifests itself by perversions of the moral sense, is so in consequence of derangements in the cells and fibres of the brain; that in many instances the brain is defective and on a par with the half-withered limbs. Simple melancholia without excitement, and those cases where there are found torpor and stupidity, thick speech and a slobbering mouth, with loss of reflex action, and general anæsthesia, and conditions of true primary dementia, are due to lesions or changes in the neuroglia. In the latter cases, often spoken of vaguely as cases of organic brain-disease, there are to be found either sclerosis or a colloid degeneration of the neuroglia.

The neuroglia is subject to certain changes from congestion and blood-stasis in cases of chronic insanity. The different consistence of various brains, recognisable to the touch, is due to changes in the amount of this connective tissue or packing material. The different changes in the neuroglia may be grouped as follows:—First, a general increase of its protoplasmic material; second, a disseminated sclerosed condition; third, a form of sclerosis which has been termed miliary sclerosis; fourth, an increase of its finely fibrillated texture; fifth, a colloid form of degeneration; and sixth, atrophy. To the first form belong the enormous brains found in some idiots; the increase is simple connective tissue. Such a brain may weigh sixty ounces. In such a brain the nerve-fibres are seen lying in fasciculi, consisting of four, five, or six strands separated from one another by very clear plasma, in which are more than normally numerous nuclei, and a firm fibrillar structure. The second form has been described as grey degeneration, or as *sclérose en plaques disséminées*. Here there are light grey tracts, recognisable by the naked eye, of various shapes and sizes, which occasionally present themselves in the brains of chronic dementes. They occur mostly in the motor tract, in the pons and medulla, in the spinal cord, and in the white matter of the hemispheres, where they exist occasionally in widely spread areas. In transverse sections the axicylinders are indiscernible, and the field of the microscope is occupied by a finely molecular and fibrillated material embedded in a cloudy homogeneous plasma. Miliary sclerosis is a disease of the nuclei of the neuroglia. There are three stages of the malady; in the first the nucleus becomes enlarged, and throws out a homogeneous plasma of milky colour. In the centre of these semi-opaque spots the enlarged nucleus can still be detected. In the second stage the morbid plasma becomes distinctly molecular

in character and permeated by fibrils. In well advanced cases, the plasma seems denser at the circumference of the spots than at the centre, and a degree of absorption of the contiguous nerve-fibres is evident. In the third stage, the molecular matter becomes more opaque and contracts on itself, the boundaries become puckered and irregular in outline, and the material often falls out of the section, leaving ragged holes. These holes can not be mistaken for the smoothly rounded or oval perivascular spaces. The very fine fibrillar stroma of the neuroglia, which in health can with difficulty be distinguished by the aid of most powerful lenses, often presents itself in sections of the brains of the insane as a distinct mesh-work under comparatively low powers. The spider-like cells of Deiters show themselves with great clearness. In colloid degeneration, circumscribed semi-translucent spots, with well defined edges and molecular contents, show themselves in the white matter contiguous to the cortical substance. In extreme cases, the appearance under the microscope resembles that of a slice of sago-pudding. This is a degeneration of the nuclei of the neuroglia. The amyloid bodies of Virchow are a modification of the granules of the granular layer. After explaining that the other forms of disease of the neuroglia must, for want of time, stand over till another year, Dr. Tuke concludes by stating: 'It is in the mortuary and the workroom that the arcana of cerebral pathology will be disclosed; the section-knife and the microscope will, at no distant period, lay open secrets which the iteration of theory by the abstract philosopher can never discover.' J. MILNER FOTHERGILL, M.D.

MIERZEJEWSKI ON CEREBRAL LESIONS IN GENERAL PARALYSIS.—Dr. Mierzejewski, of Petersburg, in the first place (*Archives de Physiologie*, March and April, 1875) goes over the opinions of various writers upon the normal elements of brain-structure, and then passes in review the lesions of the vessels, of the interstitial substance, and of the nerve-elements in individuals attacked with general paralysis.

The muscular changes, he states, are more constant and more profound than those of the nerve-substance. They are not uniform, but are more obvious in some than in other parts, and at different stages of the affection. In the early stages the most distinctive appearance is the presence of an increased number of nuclei on the walls of the vessels, constituting a subadventitial extravasation;* at a more advanced stage miliary aneurisms, with rupture of vessels, thickening of their walls, and fatty degeneration of the vessels, are observed. Dr. Mierzejewski holds also that there is a new formation of capillaries in this disease, and gives drawings illustrative of his opinion as opposed to those observers who regard these appearances as simply cellular prolongations.

Hæmorrhage into the tunica adventitia is an appearance that the author has frequently noticed in cases that have run a rapid course. The vessels around which it was found had not undergone any change. In cases more advanced, the presence of extravasation is often accompanied with the multiplication of oblong longitudinal nuclei (middle coat

of vessel) and of transversely oblong nuclei (median coat), distinguishable from the elements of the extravasation.

The blood-corpuscles, if few, may disappear; but if more abundant, those left from the extravasation undergo a retrogressive change, leading to disorganisation of the vessels or a chronic inflammation. A curving of the vessels on themselves within the tunica adventitia is noticed also by the author—as it has been by Sankey and others.

The true miliary aneurisms, Dr. Mierzejewski remarks, are always preceded by 'periarteritis;' the coats of the arteries are fused together, the muscular coat being deficient. The contents of the aneurisms are blood-corpuscles and leucocytes, fat-granules and hæmatoidin when the change is further advanced.

Extravasation of blood in the cerebral substance has also been observed by the author around the capillary vessels. Fatty degeneration of the vessels is also described as occurring under the influence of inflammation—the 'inflammation interstitielle' of M. Magnan. This inflammation may be divided into three stages; in the first there is a marked proliferation of the nuclei of the connective tissue. The author describes several forms and sizes of these proliferated nuclei, and then notices, in the second stage, numerous opaque spots, of a homogeneous aspect, irregular in size and form, and presenting distinct outlines, taking the carmine-dye deeply, and in many instances sending off irregular processes, or filaments which form a network. These filaments Dr. Mierzejewski regards as coagulated fibrine. Branching cellules are also noted as existing in the brain-substance, differing from those found in healthy structure. A case recorded by M. Charcot is quoted as confirmatory of the opinion that ramifying or spider-cells are pathological. In this case, one of syphilitic paralysis, M. Charcot found a centre of grey degeneration in the pons Varolii, in which were found cells resembling those described by Dr. Mierzejewski. These cells are regarded as being made of connective tissue fused by coagulated fibrin.

With reference to changes in the nerve-elements themselves, Dr. Mierzejewski has observed that the more obvious changes are to be found in nerve-cells (*cellules ganglionnaires*). Where these present a pathological condition, he states that there is generally an accumulation of the cell-elements near or around them. In advanced disease the nucleus becomes disintegrated, and the cell is filled with pigmentary granules which do not take the carmine tint. In some, this granular matter has been soluble in ether. The axis-cylinders resist the change, except that they are supposed to be susceptible of hypertrophy, and present oval enlargements, giving to their course a beaded appearance.

[The author's observations are accompanied by three plates, containing forty-six coloured illustrations, which amply explain the text.—*Rep.*]

W. B. KESTIVEN, M.D.

ORTH ON TUBERCULOSIS.—Orth's lecture (*Berliner Klinische Wochenschrift*, no. 12, 1875) is in answer to the objections brought by Friedländer against Buhl's view of the secondary infective character of tuberculosis, and against the evidence from experimental production of tubercle (*LONDON MEDICAL RECORD*, January 27, 1875, p. 51.) Orth maintains, in opposition to Friedländer, that the relations of caseous masses and tubercles in the body accord

* The author notes that he employs the word subadventitial to point out that there exists no lymphatic spaces in the brain but the adventitial coat; quoting Dr. Batty Tuke for this view (*Brit. and For. Med. Chir. Rev.*); see also the same opinion urged in the *St. Barthol. Hosp. Reports*, 1872.

perfectly with Buhl's theory, and that tubercles produced by experiment are true tubercles. The former position is, he thinks, specially supported by the local occurrence of tubercles around caseous masses, either at one spot only or as a part of general tuberculosis. The tubercles in such cases are found evidently older the nearer they lie to the caseous foci, and thus appear as if produced by an infective process gradually spreading outwards. In four cases (three being infants), caseous masses in the lung were thus surrounded by miliary tubercles in the pulmonary tissue and pleura. In another, an adult, there was thick cheesy pus in bone and adjacent muscle, with tubercles in the surrounding tissue. In another case there was no general tuberculosis, but extensive ulcers in the bladder and colon were connected with eruptions of miliary tubercles on the serous covering and in fibrous adhesions which had formed between the affected parts of the bladder and rectum. He also quotes a case of pulmonary phthisis where both pleurae were thickly covered with tubercles, and these had spread apparently by local infection through the diaphragm to the adjacent parts of the peritoneum, but to those parts only. In all these cases, Orth urges that the origin of miliary tubercle by local infection from the caseous or ulcerative foci is the explanation that naturally suggests itself, and is not a forced interpretation, as Friedländer contends. He also gives reasons to show why, in these cases at least, the hypothesis that the caseous masses were originally tubercular is inadmissible. The local process of infection he believes to be closely connected with the lymphatic system, while the more general infection, leading to general tuberculosis, takes place, on the other hand, through the blood, and only when the conditions are especially favourable and a considerable quantity of infective matter passes into the circulation.

Orth then criticises Friedländer's objections to admitting the nodules produced by experimental inoculation to be true tubercles. All nodules resulting from inoculation may not be tubercles, but some certainly are so; and, though they may not have giant-cells, those elements are not constantly present in true tubercles. The experimental tubercles possess, in fact, the same typical structure as genuine tubercles, though showing similar variations.

MEDICINE.

LANDOUZY ON SCIATICA AND CONSEQUENT MUSCULAR ATROPHY.—In the March and April numbers of the *Archives Générales de Médecine*, this subject is discussed at length by M. Landouzy. His chief object is to show that the varieties of sciatica may be divided into two classes; the first of which consists of cases of disease of the function of the sciatic nerve, or neuralgia proper; and the second

of disease of the substance of the nerve, or neuritis, using this word to include all changes and not only inflammation. Of the characteristics of the second class, muscular atrophy is the chief, but hitherto its value in diagnosis and prognosis has not been felt, and it has not been carefully observed. It is generally explained as consequent on the intensity and duration of the sciatica; but M. Landouzy does not accept this explanation as satisfactory, and he cites a case in which a fortnight after the beginning of the disease the circumference of the thigh was found to have diminished one and a half inch, a diminution as great as in any case noticed of atrophy after long continued acute sciatica. Nor is the atrophy dependent on the want of exercise of the limb, for it sometimes occurs in patients who find their only relief in movement: nor does the theory of reflex action explain it, for that has been confuted by the experiments of M. Vulpian (see preface to Weir Mitchell on Nervous Diseases). M. Landouzy explains it as the result of such changes in the substance of the nerve as can hinder the transmission to the muscles of the trophic influence of the nerve-centres. Granted that such an explanation is correct, muscular atrophy may be taken as diagnosing disease of the substance of nerves from disease of their function, neuritis from neuralgia. M. Landouzy admits that this division is one rather of convenience than of essential difference, for he suspects that there is a change of substance of the nerves in all cases of neuralgia as well as of neuritis, but that in the former it is not sufficient to hinder the transmission of nervous influence. One frequent result of sciatica is the thickening of the skin and the superficial fascia in the limb affected.

This may conceal the slighter cases of muscular atrophy, and account partly for the representation of its rarity, which we find in Axenfeld and other authorities. As a rule, the superficial fascia is less firmly attached to the underlying muscle than is normal, and its thickness may easily be estimated by raising and pinching it.

The histological observations on the nerves in cases of sciatica with attendant muscular atrophy are too incomplete to furnish a certain explanation, but they tend to show that there is atrophy of the cylinder-axis and hyperplasia of the sheath of Schwann. This is the result common to all injuries of the nerve, whether from wounds, cold, rheumatism, lead-poisoning, or inflammation propagated from adjacent tissues (see M. Vulpian, *Archives de Physiologie*, 1871-1872, 'Influence des Nerves sur les Muscles'). What, however, is the condition essential to produce this atrophy, must be left, in M. Landouzy's opinion, to the histologists of the future. The pathology of the muscular atrophy is analogous; the fibrillae are atrophied, and there is hyperplasia of the areolar sheath. For this morbid condition of the muscle, M. Landouzy prefers to use the term dystrophy, and to reserve the word atrophy for the simple lessening of the diameter of the muscular fibres, such as is consequent upon want of exercise.

The review of twenty-six cases, of which an account is given at length, leads M. Landouzy to adopt the following classification in sciatica.

A. *Cases of Neuralgia Proper*.—In these the pain is sudden in its invasion, darting and intermittent; it is referred at first at least to one or more limited spots, and does not accompany the whole course of the nerve. The nerve is not swollen or painful when touched, and there is no muscular atrophy.

B. Cases of Neuritis.—In these the disease comes on slowly: its first stage is marked by a dull aching pain and numbness; afterwards there may be the acute intermittent pain of neuralgia proper, but there is also the continuous severe numbing pain following the course of the sciatic nerve; the nerve itself is swollen, and any pressure upon it is painful. Lastly, there is muscular atrophy roughly proportionate to the duration of the sciatica, and occasionally herpes or some cutaneous disease arising from defective nutrition.

That the sciatic beyond other nerves should be liable to this neuritis is the result, M. Landouzy says, of its being especially exposed to pressure in sitting, to chills owing to its superficial course, and to inflammations originating in the pelvic viscera. The same continuous pain and muscular atrophy which characterise neuritis are sometimes observed in some of the nerves which run from the brachial plexus, especially in the ulnar.

If neuritis be diagnosed, the prognosis is less favourable than in neuralgic sciatica; but cases of M. Vulpian are cited to show that nerves which have degenerated may regenerate completely both the cylinder-axes and the sheaths of Schwann; and on their recovery the recovery of the muscles follows.

The therapeutics of sciatica M. Landouzy does not discuss fully, but he is anxious to say a word in favour of the use of leeches to subdue the pain, and of continuous currents to restore the nerve to permanent health.

J. B. BRADBURY, M.D. (Cambridge).

SALES-GIRONS ON THE MODE IN WHICH THE CIRCULATION OF FÆCAL MATTERS IS RE-ESTABLISHED AFTER LIGATURE OF INTESTINE.—*La Revue Médicale* for March 22, 1875, contains a paper of extreme interest, which in the absence of any name we suppose must be attributed to the editor. He states that, whilst making experiments on the way in which temperature is affected by ligaturing the intestine, he was surprised to find that most of the dogs experimented on, after vomiting and obstruction of the bowels, and refusing their food, began gradually to recover after the fifth day; and about the tenth day they resumed their normal appearance, and all the functions of life seemed carried on as before. He thought at first that the ligature was not properly tied. This led him to make fresh experiments—with a similar result. He thinks the mechanism of recovery deserves special notice. When a segment (anse) of intestine is ligatured with silver wire, so as completely to obstruct its calibre, if the animal survive and be killed after ten days, it will be found that the portion of intestine is adherent to the abdominal wall, and to adjacent coils of intestine, by false membranes, which are easily torn, and often circumscribe little collections of pus. If, without disturbing the relations of the parts, sections are made above and below the portion ligatured, we can easily demonstrate, by injecting water, that the bowel is once more pervious. There is no perforation of the bowel, but a circular cicatrix shows where the ligature was applied—the two surfaces of intestine brought into contact by the ligature are, so to speak, welded or soldered together [sont soudées l'un à l'autre]. The calibre is normal, except that at the level of the cicatrix there is a slight circular constriction of the mucous membrane. The metal ligature is found attached to one side, and floating loop-like in the calibre of the bowel. It is easy to

understand that, under the influence of the peristaltic action of the bowels, the intestine is cut through by the ligature; but during cicatrization of the external coats, the mucous membranes have succeeded in separating, and thus the patency of the calibre is re-established. Two things help to bring about this result. The first is the thickness of the walls of a dog's intestines; and the other, the nature of the mucous membrane preventing the adhesion of two mucous surfaces.

This is, then, a true recovery. The cicatrix is a genuine cicatrix, made up of the three tunics; and is demonstrated to be so by microscopic examination. Similar results were obtained with hemplasties. It was once found that one of these was burst by the intestinal juices. An India-rubber ligature was found encysted, its elasticity doubtless causing this result. If, instead of including a loop of intestine, the ligature was simply tied round the bowel [en travers de l'intestine sans prendre un anse], the results were similar, but more rapid, five days sufficing for the process. [These observations appear to the reporter of extreme interest, as illustrating the probable mode of recovery in some cases of intestinal obstruction in the human subject; and as explaining the circular [annular] cicatrices sometimes seen in the intestines in *post mortem* examinations.—*Rep.*]

W. BATHURST WOODMAN, M.D.

LINCOLN ON A RARE FORM OF SPINAL PARALYSIS.—Dr. D. F. Lincoln relates in the *Boston Medical and Surgical Journal*, of March 25, an interesting case of spinal paralysis in an adult, closely resembling what is generally called 'infantile paralysis.'

The patient was a gentleman, forty-nine years of age, who had generally enjoyed good health, and whose habits were regular. The attack began one morning with a feeling of numbness and tingling, soon followed by weakness in the legs; this increased so much during the day, that towards evening he had to be helped into bed. In the course of the next two days, the weakness spread to all the voluntary muscles of the body except those of the face and eyeballs, and of the feet. There was not absolute paralysis of any muscle, but, as the patient lay in bed, he could not raise his head from the pillow, nor bend his knees, and the grasp of his hand was very feeble indeed. The paralysis was more marked on the left side than on the right. The muscles of respiration were not affected; he could speak and swallow well, and the bladder and rectum performed their functions as usual. There was no spasm or rigidity of any of the muscles affected, and no pain. Sensation, after the first day of the attack, was everywhere normal. The electric contractility of the muscles rapidly diminished, and at the end of three weeks was almost extinct; forty cells of a Daniell's battery only produced a feeble contraction of the rectus femoris, whilst faradisation produced no effect at all; there was considerable wasting of the paralysed muscles. Slight signs of improvement began to show themselves about six weeks after the invasion, but the recovery, though tolerably complete, was very gradual: the patient was confined to his house for six months, and it was some time longer before he was able to resume his business.

Duchenne was the first to recognise the fact that a disease, identical with what is ordinarily called 'infantile paralysis' may occur in adults; he pub-

lishes four such cases in the last edition of his 'Electrisation Localisée.' The subject has also been treated by Drs. Bernhardt and Westphal, of Berlin (LONDON MEDICAL RECORD, February 4, 1874); cases have also been recorded by Dr. Frey, in the *Berliner Klinische Wochenschrift* (see LONDON MEDICAL RECORD, 1874, pp. 83 and 778), and by Dr. Seguin in the *Transactions of the New York Academy of Medicine*. In some of these cases the invasion of the disease was accompanied by fever, and permanent paralysis and wasting of some of the muscles resulted, thus rendering the resemblance to the infantile disease even more marked than in that just recorded.

SURGERY.

MAZZONI ON FIVE CASES OF RESECTION OF THE STERNUM AND RIBS.—Professor Mazzoni relates the following cases in his *Anno Secondo di Clinica Chirurgica*, Rome, 1874 (abstract in *Annali Universali di Medicina*, March, 1875).

Case 1. *Myxosarcoma in the Sternal Region: Extirpation*.—A countryman, aged fifty-five, a year previously perceived a small hard painless tumour over the middle of the sternum. In five months it acquired a circumference of nearly sixteen inches. The skin covering it was normal; it was adherent to the bone, and presented fluctuation at some points, being hard and painless to pressure in others. In removing it, it was found necessary to excise the sternum from the manubrium to the ensiform cartilage, along with portions of the second, third, and fourth costal cartilages. The mediastinum was exposed, and the pulsation of the heart could be seen. The wound was at first dressed with carbolic oil, afterwards with permanganate of potash. A diarrhoea which the patient had having been suppressed, the wound appeared to be healing favourably, when, fifteen days after the operation symptoms of pulmonary congestion set in, and passed into hypostatic capillary pneumonia, which ended in death. At the necropsy, the base of the wound was found covered with healthy granulations, and the posterior and inferior parts of both lungs presented indications of broncho-pneumonia.

Case 2. *Caries of the Sternum and of the First Right Rib*.—A young man, aged twenty-three, of lymphatic temperament, had three abscesses, one

over the anterior surface of the ensiform cartilage, another on the middle and internal part of the clavicle, reaching downwards as far as the third rib, and a third on the middle of the sternum towards the right side. After opening them, caries of the sternum was found to exist. Professor Mazzoni exposed by a semilunar incision the central part of the sternum, and removed it, the periosteum being preserved. The right end of the incision was prolonged as far as the end of the first rib, which was found to be carious, and was removed. The result of the case was successful; the healing was, however, impeded somewhat by the formation of a sinus passing from the sternum to below the breast.

Case 3. *Necrotic Caries of the Fifth, Sixth, and Seventh Ribs*.—A girl aged thirteen, of cachectic habit, had four years previously received a blow over the seventh right rib. She had an abscess, which, after opening, left a fistulous sinus through which were removed several pieces of bone. The opening did not close, and three years later she was taken into hospital. The right side of the chest, from the first to the ninth rib measured an inch more than the left, and the cutaneous veins were dilated. Professor Mazzoni removed about 0·8 inch of the fifth rib, 1·6 inches of the sixth, and 0·8 inch of the seventh. The wound was dressed with carbolic oil. The reaction was moderate, and ceased on the fifth day; nothing abnormal ensued and recovery was complete.

Case 4. *Caries of the Fifth Right Rib*.—A scrofulous boy, aged ten, who had already had enlarged glands, had caries of the fifth right rib in the axillary line. Dr. Mazzoni excised about 1·2 inches. There was considerable febrile reaction, but at the end of about a month healing was complete.

Case 5. *Caries of the Sixth and Seventh Costal Cartilages and of the Margin of the Sternum*.—A countryman, aged forty-four, who had not previously had an illness of importance, was attacked, after a fever which was believed to be rheumatic, with pain in the region of the sixth and seventh cartilages. An abscess of the size of a hen's egg formed, and, after opening, left a sore which refused to heal; besides which, there was a fistulous opening, leading to carious cartilage. The fistula having been dilated, the cartilages were resected. The wound cicatrised without general or local reaction; but not completely as a sinus was left, through which the edge of the sternum was felt to be denuded. This was removed, with the gouge, and the actual cautery was applied; after which, recovery was complete.

A. HENRY, M.D.

VOLKMANN ON THE TREATMENT OF FALSE JOINT.—Dr. Volkmann (*Berliner Klinische Wochenschrift*, April 26, 1875) describes a case in which the false joint was in the lower part of the left thigh, and resulted from non-union after complicated fracture.

About six months after the accident, the ununited fragments were exposed by an incision through the skin about five inches in length. The bones were found to be cylindrical and firm, the upper surface covered with rough osteophytic laminae, their ends as they overlapped being bound together by a loose membrane; moreover, from the apex of the upper and posterior fragment proceeded a strong fibrous cord about half an inch long, binding it to the underlying and anterior fragment. The extremities of both fragments were next removed by means of a 'keyhole' saw, so that the two portions of the thigh-

bone overlapped each other for about two inches. Then the hinder half of the anterior (under) fragment and the front half of the posterior (upper) fragment, in their long axes, were cut through for the same extent (two inches) with a chisel, so that these two extremities became step-shaped, and were easily and neatly adapted to each other.

The fragments so placed were bored through, and riveted together by means of two ivory pegs.

The external wound was brought together by sutures enclosed in a strong plaster of Paris bandage, with a trap-door, and the wound dressed by Lister's method. The pegs were removed seven weeks afterwards; they had become thinned and eroded. Eleven weeks after the operation the consolidation was such that a mechanical appliance could be fixed to the knee-joint. Beyond a shortening of about four-fifths of an inch, no deformity is to be observed.

EDWARD BELLAMY.

DELENS ON FRACTURE OF THE CLAVICLE.—In the March number of the *Archives Générales de Médecine*, M. Delens draws attention to certain cases of fracture of the clavicle in its middle third, caused by muscular contraction.

There is nothing original in the paper, which simply gives the histories of several cases which have been published from time to time, and summarises from these.

Nineteen facts are reported, and one instance is mentioned of fracture at the outer extremity of the bone, to show at the same time the possibility and the rarity of the occurrence. The right was in eleven, the left in five instances, the side injured. Owing to the periosteum remaining unlacerated, the displacement was inconsiderable, the bone bending forward at the site of its fracture. Of seventeen cases in which the sex is mentioned, eleven were men and six were women. In ten of the instances the patients were between twenty-five and sixty years of age. In most of the cases debility, scrofula, or syphilis seemed [as the author terms it] to have predisposed to the fracture. The muscular effort occasioning the lesion was often slight, as in closing a door or in playing at battledore-and-shuttlecock; or the fracture occurred during the convulsions of epilepsy. The precise mechanism of the lesion is unknown. The injury [as might be expected] is easily diagnosed; and, owing to the slight displacement from the non-laceration of the periosteum, rapid repair and little deformity result.

OBSTETRICS AND GYNÆCOLOGY.

TRASK ON INJECTION OF TINCTURE OF IODINE INTO THE CAVITY OF THE UTERUS IN HÆMORRHAGE AFTER DELIVERY.—The *American Journal of Obstetrics* (February, 1875) contains an interest-

ing article on this subject by Dr. James D. Trask. After referring to the diversity of sentiment entertained as to the safety of injections of the solution of the perchloride of iron in *post partum* hæmorrhages, he ascribes to Dr. Dupieris, of Havana, the credit of first employing injections of tincture of iodine for that purpose. (See *N. A. Medico-Chirurg. Review*, vol. i., Philadelphia, 1857.)

The following is a brief summary of what Dr. Trask seeks to prove.

1. A very considerable proportion of cases in which the injection of salts of iron has apparently saved life, has been those in which it accomplished this end not in virtue of its local styptic action, but because of its power to excite reflex action when cold, friction, pressure, etc., have failed.

2. When it produces coagulation of blood in the orifices of the blood-vessels, there is danger that the coagulation may follow the vessels into the substance of the uterus, producing dangerous thrombi, and that the blood already collected in the cavity of the uterus also may become converted into a hard, intractable coagulum which the uterus cannot expel, and which may, after a few days, decompose and give rise to septicæmia.

3. There is reason for believing that, as an excitor of dormant reflex action, tincture of iodine may be substituted for the iron with positive advantage, from its efficiency as an excitor and from its antiseptic properties.

If these points be established, the use of iron salts in a solution sufficiently strong to induce coagulation of blood in the uterine vessels should, at any rate, not be resorted to until tincture of iodine has been tried and failed.

Dr. Trask disavows the position of claiming positively for iodine a superiority over the iron. More facts are needed to warrant this. He has, he says, simply sought to present the considerations that render it extremely probable that the one will be found an advantageous substitute for the other, when it shall have received at the hands of the profession a sufficient trial.

KRUMPTMANN ON A CASE OF COMPLETE CONGENITAL CLOSURE OF THE VAGINA AND OF THE EXTERNAL OS UTERI, WITH CONSEQUENT HÆMATOMETRA AND ACUTE PERITONITIS.—Herr Krumpmann relates (*Medicinisch-Chirurgisches Centralblatt*, April 16) a case that came under his observation in a girl sixteen years old, who presented symptoms of acute peritonitis when first seen. On the subsidence of the urgent symptoms, an ovoid movable tumour was perceptible in the hypogastric region. As she had not menstruated, although the monthly menstrual molimen was present, an examination was made; the external genitals were well developed and normal; the hymen was imperforate; the vagina could not for a certainty be ascertained. The hymen was perforated with a trocar; a rudimentary vagina could be felt; but no menstrual flux came away on the removal of the trocar. The vagina was then dilated with sponge-tents, and the cervix, which was low down, could be readily felt. No external os could be found, although its position could be recognised. An opening, half an inch long, was made by a bistoury into the cervix, and about five and a half pints of grumous material expelled. A sponge-tent was placed in the wound; but the pain could not be borne, and it had to be removed. The patient made an excellent recovery, the uterine opening not closing.

She married two years afterwards, became the mother of four healthy children, and eventually died, fourteen years later, of cancer of the womb.

FLEISCHER ON THE INTERNAL AND EXTERNAL APPLICATION OF CHLORAL HYDRATE IN CARCINOMA UTERI.—Herr Fleischer (*Medicinisches-Chirurgisches Centralblatt*, no. 9, 1875, strongly advocates the use of this drug in this affection. He is in the habit of applying it locally in the following manner. The vagina being first of all well washed out with water injections, a piece of cotton-wool is dipped into a solution of chloral hydrate (two drachms to three ounces), and passed up to the carcinomatous surface; this is repeated every two hours; after the second, or third at the most, the character of the pain becomes altered, and the discharges less offensive. Its internal administration he prefers *per rectum*, as it is not so liable to become abused by the sufferer, and its effect can be better regulated, as it loses its effect much more slowly than by the mouth. Its chief advantage over morphia is that it has no confining effect on the bowels.

[Dr. Goodell, of Pennsylvania, also speaks highly of the local application of chloral, especially in reducing the offensiveness of the discharges.—*Rep.*]

ZAUNSCHIRM ON ELECTRICITY IN THE ASPHYXIA OF NEW-BORN INFANTS.—Dr. Zaunschirm (*Medicinisches-Chirurgisches Centralblatt*, April 16, 1875) reports a case where, failing to resuscitate an infant after delivery by the forceps, by the usual methods, he bethought himself to apply electricity. Having obtained an induction-instrument, he applied a feeble current, gradually increasing in strength, principally to the sympathetic nerve. With the first application of the pole, inspiration was produced; one pole was then applied partly to the larynx and partly to the neighbourhood of the neck; the second pole to the thorax. Soon the heart's action became stronger and more rhythmical, and the breathing changed and more natural. By the end of ten minutes, the child was completely resuscitated. He strongly recommends the adoption of this method in cases of severe asphyxia. W. C. GRIGG, M.D.

WILHITE ON TRISMUS NASCENTIUM.—Dr. Wilhite (*American Journal of Medical Sciences*, April, 1875) gives fourteen cases of this affection in support of the theory put forward many years ago by Dr. Marion Sims, that the disease is due to mechanical pressure on the medulla and nerves by an inward displacement of the occipital bone. This depression is liable to occur in cases of protracted labour, and too well ossified state of the fetal cranial bones, and is subsequently aggravated by the dorsal decubitus in the cradle and in the mother's arms.

The affection is described as of two forms, viz., acute 'trismus,' in which death takes place in two or three days or even less; and chronic, or 'trismoid,' in which the child wastes away gradually. In both the first symptom is inability to suck, which is stated to be pathognomonic of the disease. Of the fourteen cases related five were of the acute form, nine chronic. Of the former three, and of the latter five, recovered under treatment; the remainder died without it. Treatment consisted in keeping the child lying on one side or the other, instead of on its back, thus relieving pressure on the occipital bone.

OPHTHALMOLOGY AND OTOTOLOGY.

GROSSMANN ON SYMPATHETIC OPHTHALMIA.—In the *Berliner Klinische Wochenschrift*, April 5, will be found a concise historical sketch, by Dr. Grossmann, of the phenomena which make up what is now termed sympathetic ophthalmia. According to this writer, the nature of the affection was first recognised by the Vienna School in the early part of this century, although it was Mackenzie who in 1844 first described a variety of sympathetic iritis. The writings of later surgeons, and especially those of Von Gräfe and Mooren, agree in the doctrine that the starting-point of the disturbance in the second eye is to be found in the presence of cyclitis in the eye originally injured or affected. In accordance with this, Dr. Grossmann gives a very complete clinical sketch of the symptoms of cyclitis, and enumerates at length the many circumstances under which it may take its origin, such as injuries of all kinds, with or without any external wound; also certain intraocular causes, such as tumours, detachment of the retina, anterior synechia, extensive posterior synechia, and the varieties of anterior staphyloma, most of which are not generally recognised as possible causes. As regards treatment, when once any structural alteration has taken place in the second eye, the removal of the offending eye must be promptly carried out. If performed sufficiently early, Grossmann has found that iridectomy will be of great use to the second eye, provided it be completely executed and to a considerable extent; otherwise it will prove of no service; and if its performance be delayed till the iris has contracted adhesions, or has become extensively altered in texture, the operation will be impracticable owing to the impossibility of removing any of the iris, and the probable result of such unsuccessful interference will be degeneration and atrophy of the entire globe. Should, however, the iridectomy be performed early enough, in the course of time, it may be of many months, the eye may regain some considerable amount of useful vision, although it is probable that extraction of the lens will have to be undertaken to bring about even this partial recovery. From many cases of the kind Dr. Grossmann chooses as an illustration of his remarks, the case of a man, aged twenty-three, who was struck in the left eye with a small splinter of iron; for this injury the man was under treatment for nine months, at the end of which time he resumed work,

but was compelled to discontinue it at the end of a week in consequence of the ciliary irritation which made its appearance in the right eye. These symptoms rapidly ripened into those of iritis, and he now came for the first time under the author's care. The left eye, which was blind, shrunken, and painful, was removed, and at once the symptoms in the other eye were alleviated; at the end of a month a large iridectomy was successfully performed, and a steady and still further improvement took place; in the result, the natural and healthy appearance was restored, and the patient regained very useful vision = $\frac{3}{8}$. Examination of the enucleated eye revealed a splinter of iron embedded in the ciliary region. Dr. Grossmann insists on the importance of publishing such cases in great detail, in order that those members of the profession who are not practising ophthalmic surgery may be sufficiently alive to the danger and to the insidious nature of this form of ophthalmia. BOWATER J. VERNON.

SIMROCK ON A NEW MODE OF PERFORATING THE MEMBRANA TYMPANI.—Dr. Simrock states, in the *New York Medical Record* (March 27), that he has been in the habit for some time past of perforating the membrana tympani, in most cases by means of strong sulphuric acid, instead of the ordinary needle. If the end of a fine probe, covered with a thin layer of cotton-wool and dipped in the acid, be applied to the drum membrane, an opening is produced almost instantaneously, and by rubbing the end of the probe over a larger field an aperture of any size can be made; in the latter case, the membrane quickly becomes dry and brittle, like tissue-paper, and can be readily removed. The application causes but little pain; in many cases the perforation may be effected without the patient being aware that any operation has been performed. Care must be taken not to use too much acid; a mere trace suffices. The advantage which Dr. Simrock claims for this mode of operating is, that the aperture remains patent for a much longer time than after an ordinary puncture. The latter generally closes in two or three days, whilst, of seventeen perforations produced by the acid, three remained open for four months, and none closed under a month; by a second application, the tendency to close is still further diminished. As regards the result of the operation, Dr. Simrock reports that, in seventeen cases, tinnitus disappeared in five; in nine it was so much diminished that the patients were no longer troubled by it; three were not benefited. Hearing was greatly improved in six cases, less so in four, and not at all in seven. J. W. LANGMORE, M.D.

POLITZER ON ADENOID VEGETATIONS IN THE PHARYNGEAL SPACE.—In nos. 3 and 4 of the *Allgem. Wiener Medizin. Zeitung* for 1875, Professor Politzer, in the report of a clinical lecture, describes the methods he employs for the removal of these adenoid vegetations which are found especially on the upper wall of the pharyngeal space, and which often complicate affections of the middle ear. As a means of diagnosis, he considers the index finger superior to the use of the pharyngeal mirror. The instrument which he uses for their removal is a ring knife with the cutting edge towards the centre. The knife, held in the right hand, being passed through the nasal cavity nearest the vegetation to be operated on, the left index finger is introduced into the mouth, and the ring placed by it on the swelling and firmly

pressed against it. The knife is now drawn towards the operator, cutting off the protruding part of the growth. The bleeding after the operation is not important, and quickly ceases under the injection of cold water through the nasal cavity. The operation is repeated till all the vegetations which can be felt by the finger are removed. Another method which he employs, is the application of fused nitrate of silver placed on a roughened silver probe. The pain occasioned by it he removes by the injection of a solution of common salt through the nostril.

DELSTANCHE-SOHN'S NEW FORCEPS FOR KEEPING THE EUSTACHIAN CATHETER IN POSITION.—For those who desire some means more than the fingers afford of keeping the Eustachian catheter in position, the forceps described by Dr. Delstanche-Sohn, of Brussels, in the *Archiv für Ohrenheilkunde* for March, may be useful. It consists of a flat piece of fish-bone of about two millimètres thick and one centimètre broad, bent while heated over a lamp into the shape of the letter M, with the ends of the long arms approaching each other, and then dipped into cold water. The ends are covered with small pieces of caoutchouc tubing, and placed so that one end presses on the side of the nose furthest from the catheter, and the other presses directly on the catheter, thus fastening it against the nasal septum. Dr. Delstanche-Sohn thinks this instrument has the following advantages. (1) It costs nothing, is easily applied, is of simple construction, and preserves for a long time, even with daily use, the necessary amount of elasticity; (2) it presses directly, and in the most advantageous direction, upon the catheter; (3) on account of its lightness and elasticity it causes no inconvenience to the patient; (4) it is prevented from slipping by the caoutchouc covering the ends; (5) it does not interrupt the breathing of the patient through the nostrils. W. LAIDLAW PURVES.

REVIEWS.

Notes d'un Journaliste sur la Médecine et la Chirurgie contemporaines. I. Nos Chirurgiens: MM. Péan, Ollier (de Lyon), A. Guérin, Amussat, Dolbeau, Jules Guérin, Maisonneuve, Chaisaignac, Dieulafoy. Par M. le Dr. B. J. LAPEYRÈRE. pp. 240: Paris, 1875.

The object of this little book is to circulate an admiring biography of the eminent surgeons named on its title-page, in conjunction with an equally admiring description of the special invention in surgery in connection with which each has rendered himself famous. Thus the chapters are headed—'Mons. Péan and the spread of Gastrotomy,' 'M. Ollier and Subperiosteal Resections,' etc. And, in addition to the description and praise of the principal inventions of each surgeon, a list is given of his entire publications.

The objections to a publication of this kind are obvious at first sight. They are mainly two. In the first place, the journalist bestows his patent of immortality on his friends or favourites, whilst he denies it to his enemies or to strangers; in the second place, the method of puffing an individual by indiscriminate laudation of some single invention is one which neither gives an exalted view of surgery and the surgeon, nor tends to any intelligent judgment as to the surgical methods themselves. We cannot,

therefore, recognise in Dr. Lapeyrère's work a valuable addition either to the biography or to the surgical tuition of the day; and we should greatly deprecate the extension of the plan into this country, which its author appears to hint at. We can conceive few works less likely to please the sounder judgment of the profession, to give solid instruction to the reader, to elevate the character of British surgery, or to promote the real renown of its subjects, than one composed of chapters lettered like the sandwich-men at election time—"Spencer Wells and Ovariectomy," "Lister and Disinfectants," "Thompson and his Lithotrite," "Mackenzie and his Laryngoscope," etc. The great and solid fame of the English school of surgery has always rested on its success in curing disease rather than on the ingenuity of its members in devising specialities, which are too apt to degenerate into something bearing an uncomfortable likeness to the patents of the charlatan. The tendency of this pushing, advertising, press-ridden age, is too much in that direction as it is, and works like the one before us have an influence in fostering this tendency which it is well to repress as far as our judgment can do so.

Dr. Lapeyrère seems to have seen the objections to which his scheme is open, and he thus endeavours to meet them in his preface.

'Our work, which is destined for the multitude, will preserve throughout the character of that true publicity, which consists in photographing (so to say) the ideas which we have acquired. Our only care then has been to attain exactitude along with impartiality. As regards individuals, twelve years of journalism have taught us sufficiently, that of all the means of making them known, the best is not to criticise them, with more or less of authority, but simply to relate their story.' That is, if we understand the idea rightly, the journalist is to abandon the task of the critic altogether, and confine himself to simple narration. But as this narration must, from the nature of the case, be friendly (otherwise there would be no use in introducing the man at all), the whole thing becomes a kind of puff, the more insidious because the favourable opinions with which the book is, as a matter of fact, full, would, we suppose, be characterised by the journalist, as simple accounts of what his author may be supposed to say in favour of his invention, though the reader of course takes them for the results of the author's own reflection.

Further, with reference to the topics he has chosen, Dr. Lapeyrère speaks thus.

'In this first gallery, exclusively devoted to French surgery, perhaps the absence of accredited names will be regretted.' [This certainly was our feeling in looking at the title-page.] 'Let us explain ourselves. The "Concours," by drying up the sources of originality, has created with us a peculiar situation, characterised by an equality of mediocrity' [what a singular opportunity to choose for a biographical sketch of the school], 'and the experimental method has done the rest. By its principle, which saps all tradition, it has crumbled authority, so that the great masters are gone the same way as gods and kings have gone in the present day. Bouillaud and Piörri survive. Claude Bernard has had to submit to the law of his own principle. In a word, no masters and no scholars; revolutionists in medicine; conservators in surgery. That is where we are now; so that our task is singularly simple. We have only to occupy ourselves with the improvements

or the discoveries to which particular names will remain attached' (pp. 2, 3).

We have seldom read a more lugubrious description of the decadence inseparably connected with that pseudo-liberality which renounces all reverence for the past, and by which a school is reduced from the dissemination of great principles and from the struggle after true perfection to a clique of petty specialists, each with his little invention, and each trying who shall shout out its praises loudest. Far indeed be it from us to say that the great school of France has fallen to this, and we trust to see M. Lapeyrère's judgment of his compatriots refuted by some higher authority; but if it were so, this book would be a very fitting hand-book for such a school. It is well done, with as little vulgarity and as much honesty as are compatible with its plan; the inventions it describes are well described, and much that it says about them is true. We are far indeed from charging on its author any mean or improper motive; but the work embodies a low view of the art of surgery in general, and a still lower, and we hope an altogether inadequate, estimate of the French school in particular.

We shall pass very rapidly over the details of the work. In his chapter on M. Péan, the author describes minutely and well that surgeon's operation for removing fibrous tumours of the uterus, along with portions of the uterus itself, by gastrotomy—an operation followed by recovery in fifteen cases out of twenty-one. This surgeon is said also to have performed ovariectomy 120 times with a mortality of only 25 per cent.—a real and solid advance in French operative surgery. Next comes the chapter on M. Ollier and his method of subperiosteal resection, in which we find little that is new; and the few critical observations which the author allows himself (if we are right in putting them down as his own, and not as furnished to him by M. Ollier or his scholars) are not distinguished for accuracy. Thus he says that regeneration of bone is only possible after the subperiosteal method (p. 65), ignoring altogether the fact that very considerable growth of bone constantly follows resection performed in the ordinary way, of which Mr. Syme's case, published and figured in the *Lancet* for 1855, vol. i., is a striking, though not an unusual example. Again, in quoting M. Ollier's statistics of deaths and recoveries, which are certainly less favourable than those obtained in England and America, he explains this partly by saying that English and American hospitals are more healthy (which is true enough; but there seems no reason why the admitted defects of French hospitals should not be remedied), and partly by the utterly unfounded assertion that the English and Americans hardly practise excision except in childhood (p. 69). The judgment of surgeons is still in suspense as to the practical value of M. Ollier's method; and we have no evidence here one way or the other beyond the vague assertion that patients of M. Ollier have been exhibited in whom the elbow seemed to have been reproduced and had regained all its movements. Restoration of motion after the ordinary operation is so common, and often so complete, that this vague statement is of little value.

The third chapter is devoted to M. Alph. Guérin and his method of dressing wounds with cotton-wool. In this chapter we find the lamentable fact related, that during the first siege of Paris only a single amputation was successful, and that one only a case of amputation through the malleoli. M. Guérin

thought it, therefore, a mark of signal success that in the second siege of Paris he had saved nineteen out of thirty-four 'operations' (p. 87). What the operations were is not stated; but assuming, as from the context we may, that they were amputations of all kinds for gunshot, this would not strike English military surgeons as a remarkable ratio of recoveries. However, it may be taken as a presumptive proof of the foulness of the hospital wards in Paris, and of the necessity for fresh air and cleanliness, which, we are confident, would effect a greater revolution than any surgical invention. The following chapter treats of the connection of M. Amussat, fils, with the galvanic cautery; a chapter which, we think, would have been more complete if the name of Middeldorpf had been rather more prominently mentioned, and the connection of that and other electricians with the method had been more fully discussed.

M. Dolbeau and the method of perineal lithotomy is the next subject. Here we have the description of a combination of median lithotomy with lithotripsy, which is said to have been very successful; the total number of M. Dolbeau's own operations being twenty-six with five deaths, and the whole number of operations performed on his plan fifty-five, with nine deaths. But, as no data are given of the age and general health of the patients or the size of the stones, the figures are worthless.

The next chapter is headed 'M. Jules Guérin and the Subcutaneous Method,' in which the additions which this eminent surgeon may have made to the application of the method of tenotomy are spoken of, we submit, rather too much as if he had been the discoverer or inventor of an art which, after all has been said, he only carried somewhat further than its inventor. It seems strange, even in a French work, to read a chapter on the subcutaneous method in which Stromeyer is not even mentioned, and from which a reader new to the subject would infallibly conclude that tenotomy was devised by M. Jules Guérin. M. Maisonneuve's plan of urethrotomy is next described, which consists in introducing through the stricture (if one can) a perfectly flexible filiform bougie, at the top of which is a head containing a screw. When the bougie is passed into the bladder, a director, or grooved staff, is screwed on to the head of the bougie, and the latter is pushed on before the staff, to which it therefore serves as guide. As the filiform bougie passes on, it rolls itself up in the bladder. When the surgeon has got his grooved-staff in position, he pushes down its groove a half-sharp lancet-headed knife, which will cut or rupture the stricture, but is not large enough to injure the normal urethra. Every degree of praise is lavished on this proceeding, while the objections which have prevented its coming into use are, of course, unnoticed, viz., that in cases where urethrotomy might really be required, *i.e.*, in very dense, extensive, impassable strictures, or in formidable strictures, complicated with false passages, the surgeon generally finds himself foiled in the attempt to pass his filiform bougie, whilst the cases in which he can pass it can generally be cured without any such dangerous operation. We need only mention that the same surgeon's caustic arrows, M. Chassaingnac's écraseur and drainage-tubes, and M. Dieulafoy's aspirator form the other subjects, all useful and meritorious inventions, yet hardly, one would think, sufficient to give a title to their inventors to appear as the heads of a great school. Yet the introduction of the aspirator is the only

performance which seems to have raised M. Dieulafoy into the rank of 'Nos Chirurgiens' at the age of thirty-five.

We need only add that a biographical sketch of each surgeon is added, in a style corresponding to that of the rest of the articles. T. HOLMES.

A Manual of Diet in Health and Disease. By T. KING CHAMBERS, M.D., F.R.C.P. Pp. 352. Smith, Elder & Co., 1875.

In compiling this small but comprehensive manual, Dr. Chambers has laid the profession under a debt of gratitude to him. He writes on the subject like one who has given his mind to it, and therefore is entitled to speak with authority. It is not quite up to the present position of physiology, and in some points should be improved in a future edition; but if it has some defects here, they are amply compensated for by the wide range of personal knowledge on the matter testified to in every chapter. The author has travelled far and made careful observations during his wanderings, especially on the subject here treated. His account of various foods, their value, and the best means of selecting them, is brief but comprehensive. Then he gives an account of the preparation of foods, which reveals his personal interest in the subject of which he writes. There is ripeness in his information, which impresses the reader as he goes on. He advocates the free use of fruit by adults as well as children, but does not approve of their being eaten only at dessert. When speaking of rice, he is in favour of its more widespread use, except in exhaustion and rapid cooling after severe exercise. The second part is devoted to the special dietetics of health; and Dr. Chambers has much to say to the point about the requirements of different ages, of commercial and literary life, and of travel. In these chapters there is much that may be read with advantage, both by professional and by lay readers. The remarks as to the diet to be adopted by travellers are judicious, and specially appropriate. There are many valuable hints given about other matters than food which are well worth remembering. In part third, we find the dietetics of sickness detailed at some length. In this section there is much that is valuable, and it is a step in the right direction, but still there is something left to be desired. We must not be too exacting about efforts which are new, and as a pioneer Dr. Chambers deserves much credit; he has opened up a new field of which others will no doubt avail themselves. Nevertheless, many of the chapters are too meagre, and might have been dealt with at greater length, as, no doubt, they will be in a future edition. As a rule the remarks are sound and well chosen, but there are exceptions, as, for instance in advising the loss of albumen in albuminuria to be met by a diet rich in albumen—advice of questionable utility when we remember the destination of most of the albumen consumed. Taken altogether, this work is one which gives, in an agreeable form, much valuable information on a most important subject, and ought to have a large sale both in the profession and out of it.

AN ANACHRONISM.—The monastery of Altenburg, in Lower Austria, advertises for a resident medical attendant. He is not only to treat those inmates who are ill, but to shave the beards and cut the hair of the holy brethren. For these duties he is to receive free board and residence and 200 florins (20*l.*) yearly.

MISCELLANY.

THE new Anatomical Institute at Leipzig was opened on April 27.

DR. G. L. CARIUS, professor of chemistry at Marburg, died on April 26, in the forty-sixth year of his age.

THE Cross of Commander of the Norwegian Order of St. Olaf has been conferred on Professor Sigmund of Vienna.

AMONGST the works of art in the Paris Salon are portraits of Dr. Noël Gueneau de Mussy, painted by M. Benjamin Constant, and of Dr. Oulmont, by M. Blanchard.

MORGAGNI.—A colossal statue of the celebrated Giovanni Battista Morgagni, by Salvini, has been placed in a public place at Forlì, and is to be publicly unveiled during the present month.

CARLSBAD.—A recent list of the visitors of Carlsbad gives some statistics of that celebrated watering-place from 1765 to 1874. In 1765 there were 247 visitors, and the number increased yearly until 1778, the year of the Bavarian war of succession, when it fell to 59. The place was also unfavourably affected in other years of war. In 1809 the number of visitors fell to 155, and in 1812 and 1813 to 782 and 629. In 1848 the number fell from 3,435 in 1847 to 1,718; and during the Italian war in 1859 to 4,545, the number in 1858 having been 5,776. In 1866 the number of visitors fell from 7,969 in the previous year to 3,009, and in 1874 it was as high as 14,616.

ANOTHER VICTIM TO DUTY.—The *Indipendente* of May 5 records the death of Dr. Carlo Ferreri, a young physician of Turin, at the early age of twenty-seven. In February last, an epidemic of typhus fever broke out at Torre-Pellice, and Dr. Ferreri was sent to the place to afford professional aid—two physicians, Drs. Malan and Laura, having already fallen victims. Mainly through the intelligent and assiduous labours of Dr. Ferreri, the disease was stamped out in two months, and he returned to Turin on April 15. Shortly after his return, he was seized with the disease against which he had combated, and died on April 30.

CRIME AND AUTOMATISM.—Dr. Despine, in his *Psychologie Naturelle*, gives a striking analysis of the mental status of the criminal classes. Attracted by the singular want of emotion displayed by most criminals, Dr. Despine was led to a thorough examination of court-records and other sources of information. He arrives at a belief in the entire absence of moral sense in this class. He says that free-will, which in the normal man is only controlled by the sense of duty, in the criminal has no such counter-balance, this sense being wanting. His acts are therefore mentally automatic, the result of the strongest instinct, appetite, or passion prevailing at the time. Most criminals are therefore morally irresponsible, no matter how great the crime as against society. Like brutes, savages, and idiots, they yield to natural appetites and passions, unrestrained and unapproached by any feeling of impropriety, although intellectually cognisant of the moral standards of society. Hence their remarkable *sang froid*, and the superficial character of any apparent reformation or conversion. Dr. Thomson, resident surgeon to the General Prison for Scotland, at Perth, finds his experience confirmatory of the views of Despine, and, in a paper published in the *Journal of Mental Science* for October, 1870, recognises various degrees of 'moral insensibility.'

MEDICAL INSTRUCTION IN COPENHAGEN.—The following are the courses of instructions given during the spring term this year in the Faculty of Medicine in Copenhagen. Professor M. H. Saxtorph, surgical clinical lectures and exercises, one hour daily. Professor P. L. Panum, lectures on the functions of vegetative life, and on

the nutrition, growth and repair of the tissues and organs, four hours weekly; colloquial examinations on the subjects of the lectures, one hour; for senior students, repetitive examinations on selected subjects from the whole range of physiology, two hours; practical course of medical chemistry, twice a week, three hours each time. Professor C. E. With, medical clinical lectures, five hours weekly; practical, clinical medicine, one hour daily for three months; lectures and demonstrations on internal diseases, one hour weekly. Professor F. Th. Schmidt lectures on the muscular and vascular systems five hours weekly; examination on topographical anatomy, once weekly, for an hour and a half; elementary exercises in microscopical anatomy, once weekly, for two hours; dissections. Professor C. M. Reisz lectures on acute infectious diseases two hours weekly; examination (from Niemeyer's Therapeutics) on individual chapters of diseases of the air-passages and of the organs of circulation (after an introductory lecture on the examination of the thoracic organs) two hours weekly; practical clinical medicine, one hour daily for three months. Professor A. Stadtfeldt lectures on the physiology and pathology of labour, two hours weekly; clinical exercises and demonstrations in midwifery and in the diseases of women and children, for senior students, three hours weekly; exercises in the examination of pregnant women, one hour weekly. Professor T. S. Warncke lectures on pharmacology, two hours weekly; exercises in writing prescriptions, two hours weekly. Professor Gædeken lectures on forensic medicine, two hours weekly; written exercises and examinations, two hours; clinical lectures on mental diseases, one hour weekly. Lector P. Plum exercises on practical surgery, four hours weekly; examinations on the surgical diseases of the female urinary and genital organs, two hours. Lector C. Lange (in the absence of Dr. Rasmussen through illness), demonstrations in pathological anatomy, three hours a week; *post mortem* examinations, three hours. Provisional teacher, S. Engelsted, gives clinical lectures on diseases of the skin and venereal diseases, one hour weekly; and exercises in the diagnosis and treatment of these diseases, two hours weekly. Drs. A. Brünniche, F. Trier, and L. J. Brandes, give practical clinical instruction on internal diseases; and private teacher, E. Hansen, gives practical clinical instruction on diseases of the eye once weekly, for two hours.

ERRATUM.

The second paragraph of the article on Auditory Vertigo (p. 287) of last number, should be in quotation marks, as it was taken from Dr. Brown-Séquard's lectures.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d. Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each. Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, MAY 26, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

THIERSCH ON LISTER'S ANTISEPTIC METHOD, AND ON THE SUBSTITUTION OF SALICYLIC FOR CARBOLIC ACID.

The following abstract of a paper published by Professor Thiersch, of Leipzig, in nos. 84 and 85 of Volkmann's *Sammlung Klinischer Vorträge*, is taken from the *Allgemeine Medicinische Central-Zeitung*, nos. 31, 32, 33, and 34, 1875.

That the atmosphere surrounding patients plays an influential part in the treatment of wounds, is a conviction which has long been entertained, even before any proof was afforded of the presence of minute fermentative particles in the air. Lister regards the action of these ferments on a wound as the cause of accidental traumatic diseases, and the object of his treatment is to eliminate this influence from the course of healing of the wound, so that an aseptic course may be ensured and all danger arising from zymosis warded off.

In former times, the traumatic inflammation, so far as it could be regarded as a mechanical result of the injury, was made the central point of treatment, and endeavours were made to reduce it by anti-inflammatory measures. Now, however, the chief importance is attached to septic processes; all dangerous increases of the traumatic inflammation are attributed to them, and antiphlogistic measures are looked on as without effect against these processes. Minute vegetable organisms, bacteria, belonging to the atmospheric dust, are specially regarded as producers of putrefaction and as disease-poisons.

Unfortunately there are still many unsolved questions in connection with this subject; and the opinions of special observers are too often contradictory. In any case it is established, that the atmospheric ferments exert a special influence on putrefiable fluids, to which belong the fluids of wounds; and that these fluids, among which the author reckons the discharges from the parenchyma of the wounded part, act in various ways on the organism according to their composition. All beyond this is matter of conjecture.

Dr. Thiersch agrees with those who believe that the conditions for septicæmia, hospital gangrene, and pyæmia are afforded by the operation of the atmospheric ferments; he supposes that poisonous materials are set free by chemical decomposition under the influence of the ferments, but that the ferments themselves are not poisonous. He regards Lister's method of treating wounds, which he has until very recently used with much benefit, as an experiment correctly based on the preceding supposition.

In March, 1874, Professor Kolbe placed at his disposal for therapeutic experiments a considerable

quantity of salicylic acid, which he had prepared by a cheap process.

This acid dissolves at the ordinary temperature of a room, in the proportion of about one part in 300 of distilled water; and this solution, which the author calls salicylic water, possesses distinct antiseptic properties. Urine, to which salicylic acid has been added in this or in greater proportion, does not pass into decomposition, although exposed to the air. A specimen which had been kept in this way nine months still contained urea and showed no turbidity. A similar effect is produced in blood and pus. On the addition of salicylic acid, blood assumes a dirty violet colour, probably dependent on the iron which it contains. Salicylic water throws down from pus-serum a greater quantity of albuminates than a one per cent. solution of carbolic acid in water does. Recent and granulating wounds do not suffer any inflammatory irritation on being irrigated with salicylic water; and if, after the solution has remained long in contact, a white layer of coagulated matter be formed by precipitation from the pus-serum, the granulation-tissue remains unaffected beneath it. After irrigation of the wound for some time, salicylic acid can be found in the urine; and in many cases its presence in this excretion is shown by an olive-green colouring. No poisonous effects were observed during the passage of salicylic acid through the body, after its administration in doses of half a gramme (seven and a half grains) or more daily. The colourless blood-corpuscles and pus-corpuscles retain their form, probably from gradual hardening of their protoplasm; while in the red corpuscles the colouring matter is aggregated in the peripheral layer, giving them the appearance, when the circumference is brought into form, of a yellow ring with a clear centre. The molecular movement of the protoplasm-granules of fresh pus-corpuscles and colourless blood-corpuscles continues some time, in spite of the presence of salicylic acid.

The action is otherwise when we have to deal with a wound which is already charged with the products of ichorous or gangrenous decomposition. When the surface of the wound is carefully cleaned and sprinkled with salicylic acid in substance, the effect is to prevent a return of the foul odour; but if the ichorous or sloughing process have reached a certain extent, being $\frac{1}{8}$ to $\frac{1}{2}$ inch in thickness, as in suppurating cancer, and in frost-bite and senile gangrene, the action of the remedy does not extend deeply enough, and the smell soon returns. Under some circumstances the application produces burning pains, which last from a quarter to half an hour.

It being established that a solution of salicylic acid (1 in 300) prevents the putrefaction of blood and of exudations from wounds, that this solution exerts no detrimental irritation on fresh and granulating wounds, and that evil consequences from the passage of the acid into the circulation are not to be feared, Dr. Thiersch used salicylic acid methodically in cases of recent wounds.

As, in Lister's method, the access of atmospheric ferments to the wound during operation is said to be rendered harmless by the use of carbolic acid, it was expected that a similar result would follow the use of salicylic acid; and at the same time that the continued retention of a sufficient quantity of the antiseptic in contact with the discharges would act on the products of decomposition that were independent of atmospheric ferments, by arresting

their formation or changing them. This occurred under the use of salicylic water and cotton-wadding impregnated with salicylic acid, which Thiersch calls salicylic cotton. Of the latter, some was prepared with a three per cent., and some with a ten per cent. solution; the latter being coloured with carmine to distinguish it. The salts of salicylic acid were found to possess but slight antiseptic power. As salicylic acid is not volatile at the ordinary temperature, like carbolic acid, it appeared at first doubtful whether it was capable of rendering atmospheric ferments harmless when used in the form of spray; it has been found, however, that the moisture deposited from the spray on the wound fulfils the antiseptic object, so that the salicylic spray may be used with as much security as the carbolic. The salicylic acid spray is without smell; but it produces sneezing and coughing; the same effect is produced by the fine dust set free in handling salicylic cotton. Cotton which does not produce this effect does not contain a sufficient quantity of free salicylic acid. This acid also, like carbolic acid, makes the surgeon's hands rough.

In order to accumulate a sufficient store of the antiseptic in the vicinity of the wound without changing the dressings, two ways were possible. Either dressings of cotton-wadding thickly strewn with salicylic acid could be applied, and covered with a fresh layer of salicylic cotton as soon as blood and exudations appeared on the surface of the dressing; or the cotton might be charged anew with salicylic acid by irrigation with salicylic water. As it was to be expected that, if the dry dressing were used, the layers of cotton nearest the wound would become impervious to the exudation through the stopping up of the interspaces, and thus the object of the antiseptic would not be attained, Dr. Thiersch began his experiments with the moist plan. In the course of his observations, he ascertained for what cases the dry dressing and the irrigation were respectively fitted; and to these is added as a third variety the open treatment of wounds by irrigation with salicylic water, in the same way as is done with carbolic acid in Bardeleben's practice in the Charité hospital.

All the operations were performed by Dr. Thiersch, whenever possible, according to Esmarch's method, after previous careful disinfection of the part to be operated on, under the protection of antiseptic spray, and with disinfected hands and instruments. Especial importance was attached to arresting arterial bleeding as much as possible before applying the dressings; and for this purpose Lister's carbolic catgut was exclusively employed.

Of the twenty-two cases reported, four were amputation of the thigh, with fatal results; and in two cases of amputation of the forearm, three of amputation of the leg, four of the hand and six of the arm, the course was not remarkable; three successful cases of amputation of the thigh and leg occurred in children. Dr. Thiersch has arrived at the conclusion, from a consideration of the unsuccessful cases, that, although salicylic acid may not prevent all decomposition, and although offensively smelling products of decomposition may be formed, it prevents that form of decomposition which leads to pyæmia. In four cases at least, the special conditions for the production of pyæmia appeared to be present.

In order to give a clear exposition of the practical value of antiseptic treatment, Dr. Thiersch has

summarised the 160 cases treated antiseptically in the Leipzig Hospital during the last ten months, commencing with April, 1874, when he made his first experiments with salicylic acid. Much of the success which he met with is, however, to be attributed to the newness and remarkably good arrangement of the new Jacob's Hospital in which the author obtained his results. The hospital, which lies in a high open position at the north of the town, extends over a large area. It is divided into two parts, one of which consists of barracks. There are 348 beds, eighty of which in the hospital and nine in the barracks are for surgical uses. The hospital is easily ventilated; in winter, warm pure air is introduced and the impure air is pumped out; each department has a supply of hot and cold water. All the excreted matters are disinfected by Süvern's method. Infected linen and bed-clothes are removed from the wards and not brought back until they have been thoroughly purified; and great attention is paid to cleanliness. The nursing is managed by the Dresden deaconesses; the institution possesses a very good dispensary, and most liberal provision is made by the town authorities for the expenses of treatment of the patients.

(To be continued.)

A CASE OF CONIUM-POISONING.

The *New York Times*, of April 13, gives a long report of the scientific evidence tendered, and of the verdict returned, in a singular case of poisoning by conium, of which Dr. Walker was the victim. According to the evidence previously given by those around Dr. Walker when he died, he had minutely observed every sensation and dictated them to his wife, who took them down in writing. He died quite suddenly, speaking and making muscular movements almost to the instant before expiration. In consequence of the singular circumstances of the case, the inquest and verdict attracted much attention.

Dr. J. C. Shaw was the first witness called. He gave an account of the *post mortem* examination. In the brain, which weighed fifty-seven ounces, there was much venous congestion. The arachnoid and pia mater were thickened and vascular, but readily removed from the brain-substance. The crura cerebri were slightly softened. The cerebral arteries were much degenerated; the vertebral, of unequal size, the basilar, the posterior and middle cerebral arteries, all bore marked evidences of calcareous degeneration. 'A small foreign growth was found on the pia mater, just in the fork, at the commencement of the crura cerebri.' The lungs were very much congested; not mere hypostatic congestion. The heart weighed nineteen ounces; the valves were perfect; its structure was healthy. The coronary arteries were normal, and the aorta contained only one point of atheroma. The abdominal viscera were sound; there was much fat.

Dr. Agnew stated that the extract of conium, prescribed by himself and Dr. Webster, was of ordinary strength. As it was ineffectual in giving relief, they advised Dr. Walker to procure some of Dr. Squibb's extract, which he did.

Dr. Squibb gave his evidence from a careful written statement. He stated that he had given up ordinary practice for the preparation of medicinal agents. [For which Dr. Squibb has a high and

widely spread reputation.—*Rep.*] The deceased came to him on April 3, sent by Drs. S. Agnew and Webster, with a written prescription. Their conium had failed to affect the deceased or to relieve his facial spasms. He had taken 180 drops without effect. He then gave him a fluid extract of conium-seed, directing him to take it in fifty-minim doses, at intervals of half an hour, and told him that the effect to be watched for was a kind of intoxication, which was usually accompanied by dizziness, with muscular weakness and relaxation. In four hours the patient died, having taken three fifty-minim doses. He agreed with Drs. Agnew and Webster as to the propriety of giving conium in the deceased's complaint. The most careful instructions were given to the deceased; and the medicine, though potent, was not prescribed in either a deadly or a dangerous dose. The dose he took was not a large one; and the cases on record, where conium has been most successful in overcoming muscular spasm, have, on the average, been treated by doses much larger. In the cases published by Dr. John Harley, of London, one of the highest and best authorities on the use of conium, the average dose exceeded by one half that taken by Dr. Walker; while many of the doses, though not considered exceptionally large or at all dangerous, exceeded the whole quantity taken by the deceased in his three doses. These circumstances made it doubtful if the deceased had died from conium alone. The preparation was made according to the United States *Pharmacopœia*, and was no better or stronger than it ought to be made; it was only carefully prepared. There was no secrecy nor great difficulty about the preparation. Measure-glasses were not always absolutely accurate.

Mr. Charles L. Walker, son of the deceased, deposed: 'On Saturday evening I came home, about twenty-five minutes to seven; mother called me and said father had been taking his medicine, and she wanted me to come upstairs. I went into the room: father was sitting on the edge of the bed leaning against my mother. He recognised me, and I sat down, and he pressed my hand: I fanned him, and he seemed relieved; I sent for coffee, but he said, "by-and-by," pointing to his throat; he called for electricity by the Faradaic system; he tried to apply it, but he fell back heavily. Dr. Gilfillan was summoned, and on his arrival said my father had been dead some little time. When he fell back it was about a quarter to seven; his mind appeared clear.' This testimony was corroborated by John H. Walker, another son of the deceased.

The Coroner then charged the jury, saying, 'There are three questions you have to answer: How, when, and where the deceased came by his death.' He read to them, at length, the description of the action of hemlock from Dr. John Harley's book. The jury returned the following verdict: 'The deceased came by his death by the medical use of the fluid extract of conium. He first took 180 drops of the extract of the leaves, in divided doses, in two hours, and then after an interval of four hours 150 minims of the extract of conium seed, in fifty-minim doses every half-hour, and suddenly died in about one hour and a half after taking the third dose. Moreover, we find that, from some inappreciable cause to us, the medicine acted with unwonted potency.'

Dr. John Harley comments on this case as follows. 'Having used Dr. Squibb's fluid extract of

conium, received direct from him, and ascertained its medicinal value as compared with other preparations of hemlock (See *Practitioner*, Dec. 1870, p. 332), I fully concur in Dr. Squibb's statement that 150 minims is not a deadly or even a dangerous dose to a person in a fair state of health, such as Mr. F. W. Walker was assumed to be in. In a healthy individual, the quantity would have caused only a moderate degree of coniumism, and such as would be appropriate to the treatment of the inveterate form of spasm of the facial muscles with which the patient was afflicted. The evidence, indeed, shows that the specific action of the drug was not excessive in Mr. Walker's case. He was not, in fact, under the complete influence of the drug at the time of his death; for, if he had been, he would have been incapable of the acts evidenced by his sons during the last five minutes of his life. His son states that he "recognised" him, "pressed" his hand, "pointed" to his throat, called for electricity, and was able to articulate the difficult word "faradaic" clearly enough to be understood. And it is further stated, in the evidence of his sons, that he tried to apply the current a few moments before he fell back dead. A person under the mortal influence of hemlock would be incapable of speech and motion. Further, this condition of complete palsy of the voluntary acts would precede death by a considerable interval.

'Nevertheless, the finding of the jury is in strict accordance with the evidence; and it is discriminative, as well as just. But the "inappreciable cause from which the medicine acted with extraordinary potency" is sufficiently obvious to the pathologist. Mr. Walker's wife regarded him as in good health; but the *post mortem* examination revealed the fact that he had nearly come to the end of his days, and that very little was needed to precipitate him into the grave. Apart from the extensive degeneration of the great arteries of the brain, and the softened condition of the crura cerebri, which must have weakened and retarded the motor impulses conveyed by them—apart from these factors of apoplexy, there was grave mischief in the chest. The lungs were exceedingly soft, so much so as to tear in places during their removal; and here is an explanation of the abnormal susceptibility to the action of hemlock. The greatly enlarged heart (at least one-third heavier than it should have been in a man of the patient's age) speaks of feebleness of the pulmonary circulation, and no doubt the blood-vessels of the lungs were, to say the least of it, as extensively degenerated as were those of the brain. With such a predisposition to pulmonary congestion, a little exciting cause was sufficient to determine the event. The hemlock undoubtedly contributed to this, because, by depressing what must have been previously a feeble respiratory function, it would cause increased cardiac pressure, and thus give a tendency to syncope, of which the patient died. But there were other influences at work besides the hemlock, and these, I glean from the evidence, were scanty food and nervous prostration. It appears that he took no refreshment for nine hours, purposely refraining from food in order to promote the action of the medicine. His nervous system had been on the strain of expectancy of subjective symptoms for as many hours, and this would be a powerful adjunct to the other two depressing influences. The impulsive and apparently reckless character of the man must also be taken into account, as well as the deterioration of the organic functions.'

[With a heart weighing nineteen ounces, twice the weight of a normal heart, without valvular disease, there is a very strong probability of chronic renal disease, though there was no special allusion to the kidneys at the inquest.—*Rep.*]

J. MILNER FOTHERGILL, M.D.

EULENBURG ON HEMIPLEGIA FROM LIGHTNING.

There is an original paper on this subject by Professor Eulenburg of Greifswald, in no. 17 of the *Berliner Klinische Wochenschrift* [April 26, 1875], in which he remarks on the small number of published cases of partial paralyses through lightning-stroke, and the scanty details we possess as to their nature and seat. This is especially the case as regards hemiplegia. Dr. G. R. Barnes ('The Deaths from Lightning at Ewell,' *Medical Times and Gazette*, June 20, 1868, p. 671), narrates the death by lightning, of a man on horseback, at whose necropsy a blood-clot was found in the left cerebral hemisphere; but it is not certain whether the hæmorrhage was due to the lightning or to the fall from his horse. Bugge (*Deutsche Klinik*, June 20, 1874), speaks of 'a nerve-affection as the consequence of being struck by lightning' in a delicate girl, who was so struck in a room. At first there were only headache, dilatation of pupils, dyspnœa, and palpitation; after twelve days a systolic and diastolic murmur in the cardiac region; after six days more paralysis on the right side; and death on the thirty-third day. There was no *post mortem* examination. Bugge maintains that there was first a neuro-paralytic (?) endocarditis, followed by cerebral embolism. In any case, the lightning was not the proximal cause of the hemiplegia. It thus contrasts with the case Eulenburg now puts on record.

Carl Z., aged forty-two, was on duty as a pointsman on the Berlin-Stettin railway, near Stralsund. On the night of August 4 to 5, 1873, he went along the rails during a heavy storm, in order to wind up the clock used in the signal department. He had scarcely inserted the key with his left hand (always used by him in his work), and made the first turn in the winding, when a flash of lightning flew along the telegraph wire into the clock, thence to the key, and thence into the left half of his body. He immediately lost consciousness, and lay so for about an hour, till restored to consciousness by the heavy rain which followed, soaking in, and dropping on his face. He tried to get up, but found that he was perfectly paralysed on the left side. With great difficulty he dragged himself to the room allotted him, where he spent the time till relieved. Next morning a local surgeon verified a total loss of motor power in the left arm and leg, with considerable loss of sensation; pricks of pins were not accurately localised, and sense of weight was almost lost in the leg, whilst heat and cold were felt pretty much as in health. Headache, insomnia, giddiness, slight muscular tremors, constipation, and retention of urine were felt for a few days, and then gradually vanished. But the patient complained for some time of dyspnœa, of a 'weight on the chest,' and of a slight degree of tenesmus of the bladder. After some time, and local faradisation, the leg gained some power, but the arm remained as before. Ten months after the accident (end of May, 1874), the patient came under Dr. Eulenburg's care. Slight want of

symmetry of the features was evident; the left side of the face was a little flattened; the left ala of the nose moved less in respiration than the right; the left angle of the mouth was slightly drawn towards the paralysed side, and was almost immovable when he laughed. There was at times slight tremor of the eyelids. All his special senses were perfect; and, except that he complained of great loss of memory, the sensorium appeared free from any disorder. The paresis of his left arm was almost complete; it hung down quite limp, and all movement seemed abolished, except that he could do a little in the way of moving his fingers, especially in flexing them; and he could partially abduct and oppose the thumb. There was no hindrance to passive movements, the joints being movable. Sensation (tested in various ways) and electro-muscular sensibility were almost the same as on the sound side. The skin was generally pale, but on the back of the hand darker, and almost cyanotic; the temperature of this hand was a trifle lower than on the sound side. There was not much apparent wasting, or difference in measurements. There may, however, have been more than was visible; since, as he was left-handed, the left arm was no doubt originally the larger. The left leg, though still weak, could be moved in various ways. The muscular sense was little affected; but cutaneous sensibility, tested in different modes, was decidedly defective in the foot. Sensibility to pressure was slightly so. The skin was more mottled, darker, colder, drier, and less supple than that of the healthy leg. The epidermis was thrown off more rapidly. The growth of the nails was not affected. The thigh and calf-muscles were rather flabby, and slightly smaller than those of the right side [measurements gave four-tenths and eight-tenths of an inch decrease]. The left half of the thorax did not move so well as the right in inspiration. The left pectoralis major was somewhat smaller than the right. The nerves in both upper and lower extremities showed entirely normal reactions, with faradisation. The excitability of the muscles, in accordance with the slight loss of bulk, was a little diminished. The galvanic irritability of the nerve-trunks was perfectly normal [first cathode closing-contraction, then anode opening-contraction, and anode closing-contraction]. There was one exception. On irritating the left bronchial plexus in the neck, in the supraclavicular fossa, when the different electrodes were applied to the plexus, one electrode being on the sternum, it was found that contraction of the left arm followed first, on removal of the cathode, then with opening and closing of the anode, and only much more slowly with closing of the cathode [on the left side this latter required thirty-five to forty cells; whilst ten to fifteen cells were sufficient on the right side]. Galvano-muscular contractility seemed almost unaffected. During June and July, peripheral faradisation and galvanisation were used alternately to the brachial plexus, peripheral nerve-trunks, and paralysed muscles of the arm; this was then interrupted for some months, resumed again in November, and continued till December 15, with continuous improvement. He can now raise, flex, and extend the whole arm; but it is still comparatively weak, and rotatory movements of the arm, with pronation and supination of forearm, are still imperfect, as is the action of the pectoralis major. There is no more anomaly of the nervous irritability. All differences in sensation, temperature, and

nutrition of the paralysed side have vanished almost entirely. In commenting on this case, Professor Eulenburg remarks that there must almost certainly have been a central cerebral lesion—apparently of hæmorrhagic character. The hemiplegic type, slow recovery, beginning in the leg, slight disturbance of nutrition, and almost absolute integrity of the faradic and galvanic reactions, all point to this. The slight amount of facial mischief points to the right cerebral hemisphere [nucleus lentiformis, corpus striatum]. Probably the optic thalamus and adjacent parts suffered slightly, at least in their blood-supply. Admitting, however, the patient's statement (and there seems no reason to doubt it), why was the right side of the brain affected, whilst the current must have traversed, first the key, then the left arm, etc? There seems no satisfactory explanation. The peculiar and anomalous alteration of the galvanic reaction of the brachial plexus noted above, which was repeatedly observed for a considerable time, seems also very difficult to explain by the light of recorded facts. [Reference is made to Erb's *Entartungs-Reaction*, and to Burckhardt *Die physiologische Diagnostik der Nervenkrankheiten*, Leipzig, 1875.] We can only say with Burckhardt, 'that it appears that certain cerebral processes are able to modify and disturb all the normal conditions of nutrition, and thus to alter the reactions of remote [nerve] regions. [This case is so interesting in itself, and has been so carefully studied in all its aspects by Professor Eulenburg, that the Reporter feels but little apology to be necessary for the length of the present abstract.]

W. BATHURST WOODMAN, M.D.

ANATOMY AND PHYSIOLOGY.

DALTON AND OTHERS ON MOTOR CENTRES IN THE CEREBRAL CONVOLUTIONS.—The *New York Medical Journal* for March contains the report of a committee of the New York Society of Neurology and Electrology, consisting of Drs. J. C. Dalton, J. W. S. Arnold, Geo. M. Beard, A. Flint, Jr., and John M. Mason, on the above subject.

'There is no doubt that there are certain limited spots upon the surface of the cerebral convolutions which, when subjected, in the etherised animal, to a weak galvanic current, will cause distinct momentary contraction of separate muscles, or groups of muscles, on the opposite side of the body.

'The same galvanic stimulus, applied to other points, not more than five millimètres distant, will be entirely without effect; and, when reapplied to the former spot, will again produce the same contractions as before.

'The number of the repetitions of particular contractions following galvanisation of particular points leaves no question as to the reality of the connection between them.

'In repeated instances, corresponding points upon the right and left sides of the brain act experimentally as centres of motion for similar groups of muscles on the left and right sides of the body. We cannot say that in all cases this bilateral correspondence of the cerebral centres of motion is complete; although it may be so in reality, since the two sides of the brain in the dog are never exactly symmetrical, as regards either the fissures or the convolutions.

'The action of the cerebral convolutions in pro-

ducing muscular contraction, when this contraction is definite and limited, is always a crossed action; galvanisation of the convolutions on either side of the brain exciting movement in the muscles, both of the limbs and face, on the opposite side of the body.

'Galvanisation of the dura mater, or other sensitive parts, produces, on the contrary, by reflex action, muscular twitchings on the same side of the body.

'This is especially illustrated in an experiment, where, the dura mater being exposed but unopened, application of the electrodes to its exterior surface produced, twenty-four times, muscular twitchings on the corresponding sides only, namely, ten times on the left, and fourteen times on the right.

'But, after the dura mater had been removed, application of the electrodes to the surface of the convolutions, in the same experiment, produced, thirty-two times, distinct muscular contraction on the opposite side of the body alone; while once only it was followed by a slight contraction on the same side.

'In the same experiment, application of the electrodes to a small part of the dura mater left at a corner of the wound produced a distinct depression of the shoulder on the same side, while their application to the cerebral surface immediately adjacent was without effect; this result being obtained invariably in twenty applications, made alternately to the dura mater and to the brain.

'If we compare the total results of all the experiments, the preponderance of crossed action in galvanisation of the brain becomes very manifest. Fifteen different points of the cerebral surface, when galvanised, excited distinct movement on the opposite side of the body one hundred and sixty-nine times; two points excited slight movements on the same side with themselves four times only.

'Among these instances is not counted that of a special point, which usually excited a flexion of the head and neck in the median line; both sets of the muscles, right and left, being either called into action harmoniously, or else each one having the power to flex the head without deviating it toward the opposite side.

'All the centres of motion for the anterior and posterior limbs are situated in the convolution immediately surrounding the frontal fissure. This fissure, which is well-marked in the dog and other carnivorous animals, is a nearly transverse furrow running outward from the great longitudinal fissure, and situated at about the junction of the middle and anterior thirds of the brain, as viewed from above. The centres for flexion and extension of the anterior and posterior limbs the committee have always found in the external part of the præfrontal convolution, just anterior to this fissure, and in the post-frontal convolution just behind it. In a majority of cases those for the anterior limbs were situated more in front, near the outer extremity of the frontal fissure, and those for the posterior limbs more posteriorly and inward, but their exact position varied somewhat in different cases. The centre for flexion of the head and neck in the median line is in the lateral and anterior part of the præfrontal convolution, where it bends downward and outward; that for flexion of the head with rotation toward the side of the stimulus is in a part of the convolution situated still further toward the front and downward, so as to be invisible in a view of the brain taken from above. The centre

for the facial muscles is in a region situated on the lateral part of the hemisphere, immediately about the supra-Sylvian fissure.

These localities, as found by the committee, correspond in nearly all essential particulars with those given by Hitzig, and in some instances their identity was complete. This fact is of much value as testifying to the genuineness of the results in both cases—since the spots experimentally found to be centres of motion were all marked, as above stated, by the insertion of needles before killing the animal; but their location upon the hemispheres, and consequently their correspondence with those discovered by Hitzig, could never be seen until after the brain had been removed from the cranium.

With regard to the separate points for flexion and extension of the anterior and posterior limbs respectively, the committee are unable to fix these points more precisely from the results of their experiments. In some cases they varied in position more or less in different animals; and in some a single application of the electrodes would produce movement in more than one set of muscles. It is not possible, therefore, for the committee to indicate an exact or invariable locality for the centres of motion, by reference to the fissures or convolutions; but they are led to the conclusion that these centres exist, and that, when the galvanisation happens to be applied only to the spot which they occupy, they will produce movements peculiar to themselves.

Thus, in the experiments detailed above, sixty-four applications of the electrodes produced flexion in one limb only, and fourteen applications produced extension in one limb only; making seventy-eight isolated movements. In twelve cases there was flexion or extension of both limbs simultaneously, and in eleven cases flexion of one limb, accompanied by extension of the other, making in all twenty-three double movements of the limbs. That is, more than three-quarters of all these movements were isolated movements of flexion or extension of a single limb.

It is evident that a variety of circumstances influence the results of galvanising the cerebral convolutions. On several occasions the contractions produced in an opposite limb seemed to increase in intensity with the repetition of the stimulus at short intervals. A deeply etherised condition of the animal, on the other hand, will sometimes suspend altogether the phenomena of movement, which were well marked a short time before; and these phenomena may reappear after an interval of repose.

A weak galvanic current from eight cells, applied to a particular spot, may cause distinct movement in one of the opposite limbs only, while a stronger current from sixteen cells, applied to the same spot, may produce a confused motion in all the limbs at once.

PATHOLOGY.

BOURNEVILLE ON CERVICAL PACHYMEINGITIS.—Dr. Bourneville (*Le Progrès Médical*, Nov. 7, 1874) reports as follows, from the clinique of M. Charcot, with reference to one form of muscular atrophy of spinal origin. Hypertrophic cervical pachymeningitis, M. Charcot states, has occupied his attention for many years past, and has lately formed the subject of a monograph by one of his pupils, M. Joffroy.

It forms, observes M. Charcot, a type sufficiently distinct, its symptomatology being precise enough to facilitate its diagnosis. It is not necessarily incurable, as is shown by a case under observation.

Pachymeningitis consists in an alteration of the dura mater more especially. Its seat is variable, but its election seems to be for the cervical enlargement of the spinal cord. The lesion is confined at first to the dura mater, but extends subsequently to the cord itself and the nerves arising therefrom. It is probable that cases that have been reported as hypertrophy of the spinal cord have been of this nature, the cord being compressed by the thickened membranes. The pia mater becomes affected, but in a much slighter degree than the dura mater.

The spinal cord participates in the change, and presents the characters of an irregularly distributed myelitis, attacking both the white and grey matter. The peripheral nerves also become implicated, both in their anterior and their posterior roots—a circumstance to be borne in mind relatively to symptoms.

The symptoms which indicate this lesion have their early stage, or painful period, which lasts about three months. Pain of an extremely severe character occurs in the back of the neck, spreading up to the vertex and downwards to the shoulders. A degree of rigidity accompanies these pains, which are subject to irregular exacerbations. Coincident with the pain are formication and numbness of the upper extremities, and sometimes bullæ or pemphigus. These symptoms indicate an irritation of peripheric nerves.

The second stage of the malady depends upon the extension of the affection to the spinal cord and nerve-roots. The pain ceases in the limbs, which become paralysed, atrophied, and contracted in a manner which recalls the amyotrophic paralysis from lateral sclerosis. It is worthy of note that in the forearm the muscles supplied by the radial and median nerves suffer directly, while those that receive their influence from the radial (ulnar?) are less affected. Possibly this may depend upon the point of origin of the nerve-roots.

The lower extremities in their turn become paralysed, and later still become contracted, as in lateral sclerosis. The reverse, however, is here observable in the last-named affection. In pachymeningitis, the muscles of the lower extremities do not become atrophied.

The motor paralysis is produced by centres of myelitis occurring consecutively on the meningitis. The absence of amyotrophy is a feature which distinguishes the paraplegia which accompanies the lateral sclerosis from that which is associated with cervical pachymeningitis. In this last, bed-sores and disturbance of the functions of the bladder and rectum are rapidly developed, which symptoms are absent in the lateral amyotrophic sclerosis. In addi-

tion to the preceding differential features, is the rarity of implication of the medulla oblongata in pachymeningitis, which is one of the essential elements of lateral amyotrophic sclerosis.

[In the *Transactions of the Pathological Society of London* (1869, p. 354-57), Dr. Lockhart Clarke described and figured an enormous thickening of the membranes of the cord. Around parts of the cervical region of the cord the membranes resembled a layer of smooth leather, and were inseparably adherent to each other. The posterior roots of the nerves, on each side, appeared through the membranes, like thick cords firmly bound down to the surface of the white columns. The large size of the nerve-roots was due to hypertrophy of the pia mater and the connective tissue around them, and between their bundles. Instead of being separated from each other by only a small quantity of connective tissue, the bundles of nerve-roots were kept widely apart by an enormous quantity of this tissue, which abounded in round and oval nuclei of different sizes —*Rep.*] W. B. KESTIVEN, M.D.

MITCHELL ON SPINAL ARTHROPATHIES.—In a paper in the *American Journal of Medical Sciences* for April, 1875, Dr. Weir Mitchell expresses his concurrence with the views of Charcot as to the two forms of joint lesions of spinal origin. The one is acute, or subacute, accompanied by redness, swelling, and sometimes with more or less violent pain. The chronic form is of slow growth. The general clinical characters which distinguish them from common rheumatism of joints are their limitation to the joints of the members afflicted with palsy, their relation in time to hemiplegia, and the co-existence of other trophic troubles. There is also something in the status of a palsied limb which favours the increase of an already present rheumatism. The arthropathies which result from injuries to nerve-trunks, as well as those due to some more central lesions, seem due rather to irritative states than to absolute defects of power. It has been shown that they are caused neither by vascular palsies nor by vasal spasm, nor yet by inertia, which is competent to cause, in limbs long at rest by splints, certain chronic forms of joint-disease. 'I have certainly seen,' says Dr. Mitchell, 'neuro-traumatic joint-disease break out suddenly, and with terrible severity, within three days of a nerve-lesion, which but slightly affected either motion or feeling, and which certainly gave rise to no atrophies, so that it seems unfair to attribute them to defects of nutrition in this sense or that direction. Even very slight lesions of nerves affect the cutaneous secretions; and it seems fair to infer that disturbances in the chemical balances of the deeper tissues may likewise arise from as slight neural causes. When the lesion is in the nerves, it is associated rather with partial sections of one nerve than with complete sections. Is the effect carried directly along the injured peripherally distributed fibres and so affects the joint; or does the local irritation influence the centre, and through it, and the still entire nerve-threads, act upon the joint to disorder its nutritive life?' Dr. Mitchell inclines to the latter view. Hitherto, in all the reported cases of neural arthropathy, there has been a passive central or peripheral nerve-lesion, and usually there has been also precedent symptoms not related to the joints, such as atrophy, paralysis, anaesthesia, or hyperaesthesia. In three of the four histories related here, the joint-lesion came first, existed alone

for a time, and was followed by other nutritive, sensory, and motor conditions of the limbs, which reveal the spinal column as the organ upon which the whole chain of phenomena depended.

J. MILNER FOTHERGILL, M.D.

KNOX ON DEFECT OF THE CORPUS CALLOSUM.—In the April number of the *Glasgow Medical Journal* Dr. Knox records, and illustrates by a lithographic plate, a case of defective corpus callosum in the human subject. This occurred in a female idiot, about forty years of age. During life there had been no paralysis, and the special senses were all present, but how far defective could not be determined. Her muscular development was good, but she seldom walked, generally preferring to roll on her back on the ground. On examination of the brain after death the corpus callosum was not discoverable, and the fornix, moreover, was completely divided in the middle line [the patient being thus, *quoad* her brain, reduced to the level of a bird.—*Rep.*]. The anterior pillars of the latter could be traced to the corpora albicantia. It was not determined whether the soft commissure was present or not. The convolutions were numerous, but small.

The value of the paper is much enhanced by an exhaustive bibliography of the subject, no fewer than fourteen authors having recorded similar cases. As regards the etiology of this defect, dropsy of the ventricles would seem to be the most frequent, if not the sole cause. Dr. Knox concludes (1) that when the commissural system is wholly absent, or very rudimentary, idiocy or imbecility prevails; (2) that when the corpus callosum is only partially defective, while the other commissures are present, an intelligence slightly below the average, together with dullness or childishness, will be characteristic of this condition. J. C. GALTON.

FRUA ON A CASE OF PROLAPSE OF THE URINARY BLADDER IN AN INFANT.—Dr. G. Frua writes in the *Annali Universali di Medicina* for March, 1875, that an infant six months old was brought to hospital, supposed to have been suffering for a fortnight from prolapse of the rectum. Instead, however, of rectal prolapsus, there was found in the region of the vulva a substance of the size of a small nut, having a very slightly rugose mucous surface, and a wine-red colour. On raising the tumour, or pressing it towards the upper angle of the vulva, the vaginal opening was rendered distinct; and when the rectum contracted, urine was seen to escape from two small apertures at its lower part, corresponding to the ureters. The prolapse was considered to be irreducible. The bladder had escaped through the urethral canal, which encircled it like a paraphimosis, and if it could have been reduced, it would have been again prolapsed by the dysenteric forcing with which the child was affected. The child died fifteen days after admission, a month after the condition was first observed. A *post mortem* examination confirmed the diagnosis; the ureters were much dilated, and probes introduced into them passed out through the openings observed in the prolapsed bladder. A. HENRY, M.D.

MEDICINE.

CARPENTER ON THE RATIONAL TREATMENT OF SOME FORMS OF HEMIPLEGIA.—In the *Practitioner* for May, Dr. Alfred Carpenter gives a summary of several cases of hemiplegia with the treatment adopted. He gives as a typical case the following. 'A man, aged fifty-six, has had for some time a feeling of malaise and discomfort, with an increasing feeling of weakness, and an inaptitude for either mental or muscular work. For this he takes more stimulants than usual to keep him up to the mark. "Pick-me-up" is the favourite expression when taking the dram. The patient is off his appetite; he eats but little, and that little must be rich and uncommon; he requires to have his appetite tempted. Then he has a sudden attack of giddiness, becomes faint, either falls or quietly lapses into a state of unconsciousness for a time; sometimes he is convulsed. On recovery from his comatose or semi-comatose state it is found that one side is weak; it then becomes gradually paralysed, speech is affected, the mouth is distorted, and there is more or less perfect hemiplegia, both sensation and motion being altogether lost, or motion alone being interfered with. If the patient recover from the shock or surprise, the hemiplegic symptoms gradually decrease, and at length altogether disappear; the unfavourable symptoms pass away in a year or two, and if a proper course is followed they need not recur.' In the majority of such cases, in which absolute recovery has taken place, Dr. Carpenter has come to the conclusion that they were due to a condition of blood similar to what is found in suppressed gout. As soon as the patient begins to recover, his talk is of debility. If he do not impress this view of the case upon his medical attendant, his friends do. Then comes the great error of treatment. Liberal supplies of animal food, so much wine, and so much tonic are insisted on, until the gouty condition is again established, and the patient goes down again. On the other hand, it is more rational to remember the damaged tubes and to take off as far as possible the pressure upon them, so as to obviate a second attack. For this end a restricted diet is very desirable; and fish, farinaceous food, milk, and vegetables should form the staple of the patient's diet. The bowels should be kept gently open by saline purgatives freely diluted, and the circulation may be kept quiet by some vascular depressant. In addition to this, the muscles of the affected side are to be well exercised by an attendant. They should not only be well kneaded, but they should be firmly grasped and the blood squeezed out of them regularly. By such means the muscles are kept in good condition, and are ready to act on any slight nerve-stimulus. As the patient recovers, the appetite often becomes very keen, and it is rather difficult to restrain it; if, however, the above dietary be strictly adhered to, no evil comes of it. If the dietary be such as to allow a return to the original condition, then future attacks will follow. A fish-diet, judiciously combined with other articles of food, appears to have been the means of restoring to perfect health many men who were thought to be past recovery. It has enabled many to use their brains again without injury. A certain amount of intellectual activity is beneficial.

[These remarks of Dr. Carpenter's, taken with the

experiments of Dr. Parkes, at Netley, as to the effects of a non-nitrogenised diet in lowering blood-pressure (*Lancet*, May 23, 1874) indicate the proper line to adopt in cases of hemiplegia occurring in gouty individuals or the subjects of chronic Bright's disease, where such paralysis is very common.—*Rep.*]

MORRIS ON THE USE OF ALCOHOL IN DISEASE. In the *Philadelphia Medical Times* for April 10, Dr. J. C. Morris has an article on this subject. After giving the most recent views of the action of alcohol, and of some other stimulants, together with some statistics of cases of typhoid fever treated with varying quantities of alcohol, he concludes thus. 'Three things should ever be borne in mind in the administration of alcohol, except in cases of shock or hæmorrhage. 1. It should be given in small, definite quantities, at intervals of three or four hours generally, so as to produce repeatedly the primary effects, and avoid the second or third stage of its action. 2. It should always, if possible, be accompanied by food, which may thus aid in the permanent invigoration of the patient. 3. It should be withdrawn gradually, but steadily, as the patient regains strength, and no patient should be left to the continued use of it after recovery. While the disease or debility continues, large quantities will often be necessary; but as the powers of the system are restored, the desire for it will lessen and disappear, unless an unnatural appetite or craving is awakened. It has been my experience that patients generally as readily and gladly assent to its withdrawal as to that of other medicines, when the need for it has ceased; and after a practice of more than twenty years, I have yet to have upon my conscience the knowledge that one fellow being has fallen into habits of intemperance (so far as I know) from my prescription. One word as to its abuse. It was a severe definition, but one, unfortunately, not farther from the whole truth than such definitions usually are, which was given by the late Rev. Dudley A. Tyng, when speaking of the habitual use of alcohol: 'The man to whom even one glass of liquor a day is a necessity is a drunkard.'

J. MILNER FOTHERGILL, M.D.

ANDRAL ON GLYCOSURIA.—At a late meeting of the Académie de Médecine of Paris, M. Andral read a note based on the analysis of eighty-four cases of diabetes observed by him, of which we reproduce the principal passages. Glycosuria in these eighty-four cases had not attacked all ages indiscriminately; at the time they came under M. Andral's observation two only were under six years of age (three and five years old), three were from ten to twenty years old, twelve from twenty to thirty, twenty from thirty to forty, and the same number from forty to fifty, thirteen were from fifty to sixty years old, twelve from sixty to seventy, one seventy-three, and one seventy-eight years of age. It hence follows that glycosuria, which is a very rare occurrence before twenty years of age, becomes less so from twenty to thirty years of age, acquires its maximum of frequency between forty and fifty years; would be somewhat frequently met with from fifty to seventy years of age, and after that age would only be the exception; that is to say, the greatest frequency of the disease would coincide with that epoch of life when the organic powers are in the most active condition, but these times of life are not those in which diabetes had first made its appearance. M. Andral could only be cer-

tain of this fact in sixty out of the eighty-four patients, and he found that in them diabetes had made its first appearance in twelve cases before thirty years of age, in forty between thirty and sixty years of age, and so on. The two sexes were not equally represented, there being fifty-two men to thirty-two women in the eighty-four cases. Amongst these eighty-four cases, there were several which were useful in showing the influence of the nervous system on the production or aggravation of the disease. In fact, in several of these cases the urine was suddenly seen to become loaded with glyose after severe mental disturbance. Thus, under this influence, urine, which only contained twenty grammes of sugar to the litre, four-and-twenty hours later contained ninety-six. In more rare cases, the first manifestation of diabetic accident quickly followed a similar cause. We know that the density of the urine is more considerable in glycosuria than in any other disease. Whenever the urine contains more than twenty-nine grammes of sugar to the litre, M. Andral has seen the ureometer mark more than 1,030, keep itself in a great number of cases between 1,032 and 1,038, often also between this last figure and 1,042, then rise in fewer cases from 1,042 to 1,045 and once mark 1,047, which is the maximum observed by him. M. Andral, from comparative observations he has made, believes himself to be able to come to the conclusion that, when the density of the urine is greater than 1,036, the existence of glycosuria may be affirmed. The general treatment adopted in these eighty-four cases consisted in the use of alkaline drinks, and in an alimentary regimen, principally but not exclusively composed of animal substances, to which M. Andral added some green vegetables and bread. In the course of this treatment the sugar disappeared in the case of a few of the patients without re-appearing; in others it also disappeared, but to again make its appearance; finally, in other cases it remained equally abundant, and even increased. When this was the case, M. Andral absolutely prohibited the use of starchy food, and nourished the patients exclusively on animal substances, taking special precautions to assure himself that this regimen was strictly observed. Nevertheless, the sugar continued to make its appearance in the urine. Besides, it was impossible to continue this regimen indefinitely, seeing that at the end of a certain time the patients found it so distasteful that there was no choice left as to giving it up. And here there occurred a remarkable fact in the case of a patient whose urine during this regimen had contained a larger and larger proportion of glyose, rising from fifteen to twenty, thirty, forty-four and forty-nine grammes to the litre; it gradually contained less, until it diminished progressively to the original quantity of fifteen grammes, so soon as M. Andral allowed him to take eggs, milk, a little bread, and vegetables. But this desirable change was not lasting. On the continuation of this regimen, the glyose again increased and rose to fifty-four grammes per litre. Another patient, also placed under a regimen of exclusively animal food, still showed eighty-two grammes of sugar per litre of urine. These facts only serve to confirm the results obtained by M. Claude Bernard, who found a considerable quantity of sugar in the blood of the hepatic veins of animals fed on albuminoid substances.

SIMONIN ON THE INFLUENCE OF ANÆSTHETICS ON THE TEMPERATURE.—M. Simonin has

arrived at the following conclusions (*Bulletin de Thérapeutique*, April 30) on the temperatures induced in the human subject by the different stages of anæsthesia produced by chloroform. During the period termed excitation, the temperature was heightened by eight-tenths of a degree. During the surgical period, the temperature was twice again increased by a tenth of a degree; but it generally showed "a recoil varying from two to eight-tenths of a degree. During the stage of collapse, the lowering of the temperature was found to be nine-tenths of a degree below the acme. On investigating the totality of the manifestations, the temperature was found to have risen during the anæsthesia from one to nine-tenths of a degree (Centigrade) above the starting-point. Taking the totality of the manifestations, the temperature was found to be from one to two-tenths below the starting-point, sometimes even from one to four-tenths.

The temperature at the awakening was sometimes observed to be similar to the temperature of the outset. Sometimes it was from about two to five-tenths higher; sometimes it was found to be from one to six-tenths of a degree lower than the temperature at the outset.

In some cases the lowered temperature seems to have been explained by hæmorrhage; sometimes, however, as there was no hæmorrhage, this interpretation could not be entertained. The age, etc., of the patients, do not appear to have modified the results recorded.

It does not seem that the increase of temperature during the period of excitation and the commencement of the surgical period should be attributed to a paralysis of the vaso-motor nerves. The theory of a special and primary excitation of the nervous organic origins by anæsthetic agents appears very plausible.

D'AZAMBRYA ON OZÆNA AND ITS TREATMENT. Dr. D'Azambrya sums up in his *Thèse de Paris*, December, 1874, no. 465, the results obtained in special aural and nasal practice at La Pitié Hospital. His conclusions are the following. 1. Ozæna is a chronic fetid coryza; in other words, where ozæna exists there must be chronic inflammation of the pituitary membrane or the subjacent tissues, and fetidity of the breath. 2. Ozæna is almost always of a scrofulous or a syphilitic nature; occasionally it is met with without any known cause, or after traumas, foreign bodies or calculi of the nasal fossæ, or destructive lesions supervening as complications of the decline of, or the convalescence from, acute fevers; still more rarely is ozæna of an herpetic nature. 3. There is a simple and non-ulcerous ozæna without osseous lesions, which is owing either to scrofula or syphilis. The ulcerations of scrofula proceed from the superficial to the deep parts, and are more irregular than those of syphilis. Syphilitic ulcerations are constituted by two different processes:—(1) By eruptions analogous to those observed in the skin, and which on this account should be called syphilides of the nasal fossæ; (2) By softening and opening of syphilitic gummata. 4. The most serious ozæna is that which commences by primitive lesions of the bony structure (caries and necrosis). Necrotic ozæna at the first onset is more common in syphilis than in scrofula. Ozæna always accompanies the disease described under the name caseous coryza. The treatment of ozæna ought to be at once general and local. The

general treatment is the same as that of scrofula and syphilis. The best local method of treatment consists : 1. In douches and nasal irrigations ; 2. In the direct cauterisation of the ulcerations. This method gives excellent results even in cases of necrotic coryza. The surgical treatment by the method of Rouge of Lausanne gives more rapid results, but it has its dangers—phlebitis, purulent infection, incomplete operation—and should only be employed in cases where the disease is intractable to non-surgical treatment employed continuously and methodically.

LONDON ON THE ENDEMIC FEVER OF JERUSALEM, AND ITS ETIOLOGY.—Dr. London, during an eight years' stay in Palestine, in a professional capacity, had a good opportunity of observing the diseases of that region. He states, in the *Report of the Session of the Gesell. der Aerzte zu Wien, in Allg. Med. Cent.-Zeit.*, March 13, 1875, and *New York Medical Record*, that the prevailing disease at all seasons of the year in Jerusalem is fever of the intermittent, remittent, and pernicious varieties. He attributes their occurrence to the cistern-water in common use. This is collected principally in the winter, and in the course of the summer becomes exceedingly foul and full of organic impurities, from standing so long in the imperfect and filthy cisterns. To fifty patients suffering from intermittent fever he gave quinine in large doses, but at the same time allowed them to drink the ordinary cistern-water. To another fifty he gave no quinine, but simply took pains to have them supplied with drinking-water brought from a well two miles distant from the city. The latter promptly recovered from their intermittent fever, while the former fifty either did not get rid of it, or had frequent relapses. The cases of fever are much less numerous during winter, when the water is fresh. Dr. London also believes, that the dysentery and cholera, which likewise prevail, are referable largely to the same cause. He found that these cases were benefited by quinine.

SURGERY.

MADELUNG ON DUPUYTREN'S CONTRACTION OF THE FINGERS.—Dr. Madelung, of Bonn, in an article on the etiology and operative treatment of contraction of the fingers (*Berliner Klinische Wochenschrift*, no. 15, 1875), states that, having had many opportunities of observing this affection, he agrees with the majority of surgeons in Germany and other countries, in their views as to the uselessness and even the danger of its operative treatment as hitherto practised. The etiology of the so-called Dupuytren's finger-contraction is discussed, and a description then given of the treatment carried out in such cases by Dr. Busch, of Bonn, which treatment seems to have been invariably attended by good results. The statement of Dupuytren, that this affection occurs only in men, and in those who obtain their living by hard manual labour, is contested by Dr. Madelung, who has seen contraction of the fingers in merchants and persons in good circumstances, and in one case, in an old woman who had not at any period of her life used her hands in any kind of hard work. Of considerable etiological import, according to Dr. Madelung, is the fact that in many cases of finger-contraction the affection has been preceded at a distant period, by inflammation, generally of a chronic form, in the palm of the hand. In most old people, males and females, there may be found, it is stated, a tendency to contraction of the fingers, so that complete digital extension, whether passive or active, is no longer possible. This senile condition, and the affection known as Dupuytren's contraction, are supposed by Dr. Madelung to be both due to the absorption of the numerous small deposits of fat which in healthy, young, and middle-aged subjects, exist between the connective tissue bands of the palmar fascia, and the short fibres which connect this fascia with the superjacent integument. The presence of this adipose tissue in the palm of the hand is well known to dissectors, from its giving so much trouble in anatomical preparation of this region, especially of that portion between the linea mensalis and the roots of the fingers. This deposit of adipose tissue disappears in old age, and after any injury to the palm of the hand, which may result in acute or chronic inflammation or in suppuration. The soft structures of the palm being no longer well protected against the effects of pressure from without, and the connective tissue of the palmar fascia being compressed between the heads of the metacarpal bones and any hard external body grasped by the hand, this fascia falls into a state of chronic inflammation and hyperplasia, and becomes contracted so as to cause permanent flexion of the fingers. When once any portion of the palmar fascia has become tense and prominent, the contraction rapidly becomes more marked, in consequence of the more ready exposure of the affected portion of the palm to the exciting causes of chronic inflammatory action. This view of the causation of finger-contraction serves better than any other hitherto proposed, to account for certain facts in connection with this affection ; such, for instance, as that of the symmetrical occurrence of the digital contraction in both hands, and that of the frequent appearance in persons who have gone through much and severe manual labour.

The operation performed by Dr. Busch for the cure of contracted finger consists in excising the retractile portion of palmar fascia. In a case, for example, of contraction of the little finger, the patient having been put under the influence of chloroform, an angular flap of skin with its base at the root of the finger, and at its apex at the inner margin of the hand towards the wrist, is taken from the palm. The skin, with as much as possible of the subcutaneous connective tissue is then dissected up, and the contracted portion of palmar fascia exposed. This tense fascia, as the finger is being gradually straightened, is cut away bit by bit with the point of a small scalpel until there is no longer any impediment to complete extension. The flap is then replaced and retained in position by sutures. The raw surface left near the angle of the flap may, if not very wide, be closed by bringing together with sutures the edges of skin. The finger is allowed to remain free for some days after the operation; but when granulation has been established, a cylinder of wood is placed in the palm of the hand for its support, which cylinder, in the course of a few more days, is removed, and the finger is then kept extended by means of a small straight splint applied to the back of the hand. This straight splint is removed every day in order to permit change of dressing to the wound, and movement of the previously contracted finger. On complete healing of the wound, which takes place usually in three or four weeks, the hand is left free, and the patient is instructed to complete the treatment by frequently exercising passive and active movements of the finger. In a case where several fingers are contracted, it is not thought advisable to free them all by one operation, as too large a wound would thus be formed in the palm of the hand. Still, where no more than two fingers are contracted, a single operation may be performed. Dr. Madelung states that in his experience Busch's operation has never been followed by any bad results, and that he has never seen after it diffuse suppuration, inflammation of a tendinous sheath, or even trismus.

This operative treatment, in Dr. Madelung's opinion, is to be preferred to Guérin's operation for dividing the flexor tendons of the contracted fingers, to Dupuytren's practice of dividing the palmar fascia by a transverse incision made near the root of the fingers, to Sir A. Cooper's practice of dividing subcutaneously the retractile bands of fascia, and to Goyrand's operation by which the fascia is divided transversely after its exposure by deflecting on either side the lips of a long wound made from above downwards on the palm of the hand. These proceedings are based, in Madelung's opinion, on a mistaken idea as to the etiology of the affection, and will therefore nearly always fail. They all necessitate the subsequent application of orthopaedic treatment and the use of costly and complicated apparatus. The success attending Dr. Busch's treatment seems to have been due in great measure to the fact that the previously contracted finger is not interfered with for some days after the operation; and that movements, whether passive or active, are not made, and extension not maintained, until granulation has been well established in the wound of the palm.

W. JOHNSON SMITH.

AZAM ON A CAUSE OF THE PERSISTENCE OF HERNIARY STRANGULATION AFTER REDUCTION.—At the meeting of the Paris Academy of Sciences

on April 12, M. Azam read a paper on this subject, of which the following are the conclusions (*Bulletin de Thérapeutique*, April 30). By taxis or reduction after operation, the intestine may be pushed back under the detached peritoneum or inside an epiploic cord. This accident is mortal, for it is unobserved, and the strangulation continues without, as a general rule, the surgeon being able to intervene in time to be of any use. The backward and inward direction generally given by the surgeon to his efforts is the cause of this complication. In order to avoid it, the operator should perform the reduction, placing himself on the side opposite to the tumour, and should direct his efforts upwards and outwards, almost parallel to the axis of the body. If an operation have taken place, he should not neglect to keep the sac outside to avoid the transversal folds of the neck.

MATERIA MEDICA AND THERAPEUTICS.

PLANAT ON PICROTOXINE AS A REMEDY FOR EPILEPSY.—To M. Felix Planat's work on this subject has been awarded one of the premiums under the foundation of the Prix Barbier at the disposal of the Paris Academy of Medicine. M. Planat's researches, as recorded in his *Recherches physiologiques et thérapeutiques sur la Picrotoxine*, have been directed to the endeavour to find some remedy for epilepsy. To this end he proposes, not as a specific, but as a really useful medicine, picrotoxine, the active principle of *cocculus indicus*. He administers it in the following way: *Cocculus indicus*, 200 grammes; alcohol, 1,000 grammes; allowed to macerate for three weeks. Give two to three drops of the alcoholic tincture, increasing from two drops daily, then diminishing. The treatment should be prolonged for several months, or even a year. According to M. Planat, the anatomical seat of epilepsy is in the spinal marrow; the contraction of the sanguineous capillaries brings on a bulbar ischæmia, and this ischæmia in its turn produces convulsions. The picrotoxine acts on the bulb; it is a convulsant poison, therefore, in accordance with the axiom 'similia similibus,' it will cure epileptic convulsions.

The commission appointed to adjudge the Barbier

prize, however, neither guarantees M. Planat's theory nor his experiments, although he asserts that he has by the administration of picrotoxine brought on convulsions, with foam at the mouth, in a rabbit, a kitten, and in animals of a lower organisation, as frogs, crabs, and even in snails and slugs. Neither does the commission guarantee the veracity of the numerous cures with which M. Planat credits himself. The Academy, however, has shown its estimation of meritorious work carried on through twelve years, by the award of a premium of five hundred francs to M. Planat.

ROUBAND ON THE BROMIDE OF LITHIUM.—In a recent memoir on this substance, M. Rouband arrives at the conclusions (*Bull. de Thér.*, April 30) that bromide of lithium is a drug having two actions. It possesses in a high degree the lithotropic qualities generally recognised as appertaining to the salts of lithia. It affects the reflex sensibility in a stronger manner than the other bromides, without having the objectionable action on the heart of bromide of potassium. Consequently, its place in therapeutics is marked out in the first order of antilithic and sedative drugs, and its action is particularly valuable in those accidents of the uric acid diathesis which are accompanied by painful symptoms, and in the neuroses which are often complicated by the presence of uric acid.

PSYCHOLOGY.

FOTHERGILL ON CEREBRAL ANÆMIA.—In the fourth volume of the *West Riding Asylum Reports* (1874), Dr. Milner Fothergill considers the subject of general cerebral anæmia, with its different causal conditions. He then takes up the subject of local cerebral anæmia, as in melancholic states where the intellect is unaffected. He follows Schröder van der Kolk and Laycock in regarding the occipital lobes of the cerebrum as the seat of the systemic sensations. He then points out how these parts are supplied by the posterior cerebral arteries, which are branches of the basilar artery, with the small posterior communicating branches of the circle of Willis. This inosulation by the circle of Willis, Dr. Fothergill holds to be less perfect than is usually credited, and that there is often an anæmic condition of the parts supplied by the vertebral arteries, when no such condition exists in the ante-

rior and parietal portions of the brain, fed by the branches of the internal carotid arteries. Not only is the blood-supply of the occipital lobes different from that of the rest of the hemispheres, but the vaso-motor nerve-supply of their blood-vessels is also differently derived. The internal carotid is supplied by the ascending branches of the superior cervical ganglion; while, on the other hand, the vertebral arteries are supplied with vaso-motor fibrils from the inferior cervical ganglion, which receives the ascending branches of the thoracic ganglia, including the fibres of the splanchnics which ascend from the abdomen. Cyon and Aladoff have shown that the vaso-motor nerves of the liver actually run down the vertebral arteries, through the lower cervical ganglia, after which they form the annulus of Vieussens, and then pass on to the first dorsal ganglion, and thence through the gangliated cord of the sympathetic, down the splanchnics, to the coeliac ganglion, and along the hepatic vessels of the liver. Hence, he contends, we can see that there is a direct anatomical association betwixt the nerves of the liver and those of the vertebral arteries; and from this we can comprehend the condition of melancholia existing along with derangement of the liver without the intellect being affected. Dr. Fothergill holds that in the vaso-motor supply of the vertebral arteries from which the occipital lobes of the brain are fed, we may find the explanation of the association known to exist betwixt a melancholic or depressed condition—anæmia of the occipital lobes—and abdominal disturbance, as a displaced uterus, an accumulation of fæces, Addison's disease, or irritation in the reproductive organs. In a case related by Schröder van der Kolk, melancholia came on immediately after displacement of the womb, and as suddenly passed away on its replacement. Melancholia is due, he holds, to anæmia of the occipital lobes; while loss of intellectual power follows when the anæmia is general, as in acute dementia. The motor and ideational centres may lie upon one vascular area, while the systemic sensations may occupy a vascular area of their own. At least, such association is found in the combination of motor and intellectual disturbance in the general paralytic, where the anterior and middle lobes are chiefly implicated; while in emotional disturbance associated with abnormal systemic sensations, commonly found together in the melancholic, according to Schröder van der Kolk at least, the morbid changes are found in the posterior lobes.

OPHTHALMOLOGY AND OTOTOLOGY.

PONCET ON OPACITIES OF THE VITREOUS HUMOUR AS THE RESULT OF ARTERITIS.—In the *Annales d'Oculistique* (March, 1875) is an elaborate record of the case of an officer, aged forty-five, who had been for some years the subject of cerebral disease, with failing vision, followed by opacities in the vitreous body and total blindness. Death occurred rather suddenly, and, as the necropsy showed, apparently from thrombosis of the basilar artery. The condition of the eyes was thoroughly examined, and is elaborately illustrated in the present article. The state of both eyes was much the same, and the feature presenting most interest was the extensive infiltration of the layers of the retina, and of all

the other tissues, with pigment-granules. As the case could hardly be classed as one of retinitis pigmentosa, as generally understood by that term, the author gives a concise sketch of the various opinions which are held by pathologists as to the mode of origin of the pigmentation in cases of this kind. He considers that the case cannot be correctly termed retinitis pigmentosa, because there was a general infiltration of the retina with coloured particles, and along the course of the vessels; there was no atrophy of the optic nerve, and the central artery presented no lesion.

According to Landolt (*Annales*, 1873, vol. lxi.), the characteristic signs of this affection are a chronic inflammation, situated principally in the neighbourhood of the retinal vessels, which arises in the ciliary zone, and eventually involves the other layers of the retina, the pigment-granules spreading along the course of the newly formed fibres of connective tissue.

Leber (*Annales*, 1871, vol. lxi.) has found it impossible to range under one head all the varieties of retinitis attended with deposition of pigment, and he is obliged to admit, and accordingly he enumerates, no fewer than nine varieties.

Poncet considers that the primary lesion in his case was an arteritis; and, in explanation of the mode in which the pigment of the chœrea had made its way into the substance of the retina, he argues that it could not have been, as Landolt has described, by means of newly formed connective tissue, inasmuch as no such formation occurred; but it occurs, he believes, by nuclei which travel from cell to cell, and thus make their way between and into different layers of the retina which have not been previously disorganised by inflammation. Poncet does not agree with the opinion expressed by Schweigger, to the effect that pigment-granules are inoffensive to the tissues into which they filter; he admits that under certain circumstances they may not interfere with the functions of the cell which they inhabit; but, as regards the tissues of the eye, he believes that pigmentation never occurs without undoubted evidence of structural disease, and when the pigment-granules have made their way to the vitreous humour, the result is a proliferation of the tissue of the latter, and a subsequent opacity.

In cases such as this, Poncet believes the mischief to have its starting-point in the disturbance of the choroidal pigment by inflammation; and as he demonstrated, in the present instance, evidence of arterial mischief in the choroidal network, he considers that he is entitled to the opinion that the case was one of arteritis, and all the more because it was this same arterial lesion, when localised in the basilar trunk, which had caused the patient's death.

During the life of the patient an iridectomy was performed, and, on examining the scars which resulted from the operation, they were found to be infiltrated in the same remarkable manner as the tissues within the eye. Taking this as evidence of the free passage of fluids from within the eye, Poncet is of opinion that it lends some support to those who consider that the benefit conferred by an iridectomy is due to the drainage which the operation establishes, and which it for some time maintains.

BOWATER J. VERNON.

SCHWARTZE ON MEMBRANOUS CLOSURE OF THE EXTERNAL AUDITORY MEATUS.—Professor Schwartz gives, in the *Archiv für Ohrenheilkunde*

for March, a report of a case of membranous closure of the external auditory meatus with caries of the temporal bone, in which the careful removal of the membrane from the wall of the meatus and the subsequent employment of cylinders of laminaria were followed by the complete restoration of the lumen of the meatus, which, on a *post mortem* examination being made, was found to have an epidermal covering of normal thickness, and showing no trace of the membranous growth. This is the first case of the kind in which he has obtained a satisfactory and permanent lumen.

SCHWARTZE ON THREE CASES OF NECROTIC EXPULSION OF THE COCHLEA.—In the *Archiv für Ohrenheilkunde* for March, Professor Schwartz relates the cases of Dr. Parreidt of Cologne, Dr. Bœck of Magdeburg, and Dr. Cassells of Glasgow. In the first of these cases deafness was complete on the affected side, but neither during the whole course of the affection, nor afterwards, was there a trace of paralysis of the facial nerve. In the second case paralysis of the facial was present. In the third case, after the removal of the necrotic cochlea, the hearing was improved both for speech and watch, and the patient was able to distinguish without difficulty all the notes of the scale of the piano. Should this latter case have been properly observed and reported, the theory as to the function of the cochlea by Dr. Verney, and lately revived by Helmholtz, must be thrown aside.

W. LAIDLAW PURVES.

DERMATOLOGY.

PINCUS ON BALDNESS.—Dr. Pincus read before the Medical Society of Berlin (*Berliner Klinische Wochenschrift*, nos. 4 and 5, 1875), a paper on this subject, of which the following is an abstract.

Nineteen out of twenty cases of ordinary chronic alopecia, affecting the forehead and vertex, belong to a group described as alopecia simplex (*A. furfuracea*, *Calvities senilis*, *C. præmatura*), excluding the baldness caused by parasites, alopecia areata, and defluvium capillorum from syphilis and other constitutional diseases. It is usually supposed that this affection is a passive kind, an involution, or atrophy, depending either on primary degeneration of the blood-vessels of the scalp (*Veiel*), or on atrophy of the peripheral nerves (*Voigt*, *Hebra*, and *O. Simon*). Hence the remedies employed have always been of an excitant, stimulant, or 'strengthening' character.

Careful examination, however, of the skin of the scalp, before the hair has begun to fall, shows that the naturally open and loose texture of the subcutaneous fascia has become dense and adherent; the bundles of fibrous tissue are thinner, closer, and shorter, and contain less soft areolar interstitial tissue and much less moisture.

Then follows the first stage of the disease, in which the hairs gradually lose their normal length, though each one is still as thick as before; they have no longer the glossy appearance of health; and the number which fall out daily is slightly increased, while, instead of only about a quarter of these being under six inches long, half or more of the hairs which collect upon the comb are found to be short ones; lastly, the secretion of the sebaceous glands is increased and altered in quality, constituting the pityriasis capitis, or as Hebra more correctly terms

it, seborrhœa sicca, which precedes baldness. The author regards this glandular affection rather as the result of thickening and tension of the cutis than, with Neumann, as a common result with it of some more remote cause, such as exhaustion from mental emotions, from excesses, from fatigue, etc.

The second stage of the disease is marked by decided decrease in the thickness of the individual hairs. This seems to depend upon a shrinking of the hair-follicle, just as when the thin and delicate hair of a boy's chin is converted into a beard by the hair-sacs dipping deeper down and leaving the papillary layer of cutis for its deep part, and at last for the loose and vascular subcutaneous adipose tissue. The contraction and dryness of the skin in alopecia squeezes the hair-bulb at its neck, and so the deeper parts of the follicle gradually atrophy; and, instead of reaching below the cutis, it becomes at last a shallow pit, scarcely deeper than the papillary layer, and, of course, producing a hair of corresponding short and slender dimensions.

The usual limitation of baldness to the forehead and vertex is ascribed by the Vienna school of dermatologists to its dependence on a change in the trophic influence of the supra-orbital branch of the fifth nerve. Of this Dr. Pincus sees no proof, and ascribes it to the fact that the gradual thickening, hardening, and adhesion of the cutis and subcutaneous tissue of the scalp above described normally begins on the forehead, then spreads backwards in the middle line, and finally to the occiput, and even in old men leaves the temporal regions unaffected.

[The difference in quantity and character of the connective tissue uniting the skin and deep fascia along the middle of the head from that below the occipital superior curved line and the temporal curve, is familiar to practical anatomists; but the writer does not explain why baldness is usually more advanced over the junction of the parietal and occipital bones than at the vertex.—*Rep.*]

The rarity of baldness in women is similarly explained by the fact that in the tissues of the scalp, as in many other regions, the female sex preserves the characters of childhood far more than men of the same age. But when alopecia does occur, the bundles uniting the cutis to the periosteum have been found to be short and thick in a woman's scalp.

One effect of baldness is diminution of the sensibility of the skin. This was tested both as to tactile discrimination (Weber's experiment with blunt compasses) and as to recognition of degrees of pressure. The former test is more accurately appreciated from the tenth to the fifteenth or eighteenth year; from the twentieth to forty-five or fifty there is little change, and after that time the power of discrimination decreases (independently of baldness). The smallest distance at which the two points can be distinguished on the normal scalp of an adult is twenty-five millimètres (half what Weber himself found), the points being placed transversely, except over the temples, where they are better felt when applied parallel to the long axis of the skull. Here, and on the occiput, the discrimination is most acute; next on the vertex, where the points must be thirty-one millimètres apart; next comes the frontal region; and, lastly, the part between the vertex and forehead, where the distance must be thirty-five millimètres. The difference in appreciation of pressure (tested by Eulenburg's apparatus) between the parts of the healthy scalp is much less; but here

also the part over the coronal suture seems to be least sensitive.

In the first stage of alopecia there is no change in sensibility, but in the second the points of the compasses must be more widely separated to be felt as distinct; and still more striking anæsthesia is shown by the bald scalp to the effect of pressure.

This change in the nerves of the part is not a primary one, but due to the thickening and contraction of the cutis and subcutaneous fascia. It may probably explain some cases of neuralgia of the vertex.

The microscopical appearance of a section of a bald scalp is very different from that of senile skin. [See Neumann's *Hautkrankheiten*, S. 286; and a fuller account in Dr. Pullar's translation of the second edition, p. 226. The changes in brief are: Thinning of the horny cuticle, which becomes dry and brittle; thinning of the Malpighian layer of epidermis, with increase of pigment; atrophy of papillæ; loss of fibrous bundles in the deep layer of the cutis, those which remain being therefore wide apart, thick, and granular, while the connective tissue between is either œdematous or infiltrated with a homogeneous hyaline material, like coagulated gelatine—not 'coagulated lime' (*loc. cit.* p. 227)—described as colloid degeneration by Rokitsky, and probably in some cases a true lardaceous degeneration beginning in the cutaneous blood-vessels; the subcutaneous fat is atrophied, and its cells turned into serous vesicles; the entire skin loses its elasticity, and is thrown into folds; the sebaceous glands dilate, the sudoriparous shrink, and the hair-sacs atrophy.—*Rep.*] But a microscopic section of a prematurely bald scalp shows little or no granular degeneration of the cutis, and no atrophy of the epidermis; but increase in size and closeness of the elastic and white fibrous bundles of the cutis, with atrophy of hair-sacs and sebaceous glands alike; and, instead of presenting a thin, dark, wrinkled appearance, the skin is hard, shining, smooth, and cannot be lifted into folds.

Lastly, Dr. Pincus offers some remarks on the treatment of premature baldness in the first of the stages above described—recognised by a daily loss of under fifty hairs, and among these a fourth or fifth less than six inches long, by diminished sensibility to pressure, and, after this has gone on some time, by commencing hardness and immobility of the scalp. If weak alkaline washes be applied to the hair in this state for a year or more, the progress of baldness is arrested, and in some cases the mischief already done is restored. Dr. Pincus recommends a solution of caustic potash or soda in the proportion of 1 to 250 to 1 to 500 (equal to one fluid drachm of liquor potassæ B.P. diluted with from an ounce and a-half to two ounces of water, or the same quantity of liquor sodæ diluted with from an ounce to two ounces) or solutions of the alkaline carbonates (15 to 20 grains of bicarbonate of potash or soda to an ounce of water) to be rubbed into the scalp for from three to five minutes daily, using not less than two or three drachms of the solution each time. After a time this may be done every other day, and then only once a week. 'This treatment is not inconvenient to the patient and is very convenient to the doctor, for he can say all that is necessary at the first visit, and need not see his patient again, or only three or four times in the year.' The only objection is, that the colour of the hair becomes paler during the process.

When the second stage of the affection is fully established, neither this nor any other treatment is of the slightest use. Cantharides and the other stimulants recommended have been found, Dr. Pincus thinks, to cause the still healthy hair to grow more quickly than usual and then to fall out faster than before, but they have no effect on the lanugo, and none, of course, on the empty follicles. In the early periods, however, even of this second stage, Dr. Pincus has found good results in about a third of his cases from the use of stronger alkaline washes, and of solution of corrosive sublimate (0.02 to 150, nearly six and a-half grains to an ounce). Even then the treatment must extend over months, and the result is that the progress of further mischief is stopped. Application of the continuous current has been without result; nor have local subcutaneous injections of alkali or perchloride proved more efficacious.

HOMOLLE AND OTHERS ON LUPUS.—M. Georges Homolle contributes to the *Archives Générales de Médecine* (April, 1875) a careful criticism of the views of German pathologists on the histology of lupus, with his own microscopic observations of a nodule of ordinary lupus, of an epithelioma growing on the scar of healed lupus, and of noma of the vulva. He maintains with Alibert, Bazin, Hardy, and most French dermatologists, as well as Fuchs in Germany and Mr. Wilson in England, that lupus is a 'scrofulide,' opposes Friedländer's theory that the 'granulations' of the disease are miliary tubercles, supports the statement of Virchow, Gustav Simon, Neumann, Auspitz, and all other unprejudiced observers, that, whatever its true pathology, a section of the affected skin shows the epidermis unaffected and the cutis, both papillæ and deeper layers, swollen by infiltration of small, round, nucleated 'embryonic' cells, 'leucocytes,' 'granulation' corpuscles or 'wandering cells.' He supports the conclusion of Dr. Gedding of New York and Moritz Kohn (Kaposi) that the lupus erythematosus of Cazenove is an affection of the sebaceous glands, and does not find, with Rindfleisch, that the same is true of the 'tubercular' (nodular ulceration or evident) form. His case of epithelial cancer seemed histologically unconnected with the preceding lupus, as in former cases reported by Hebra, O. Weber and others. Noma (esthiomène) of the vulva approached ulcerative lupus very closely in its histological characters. Dr. Homolle gives an excellent list of recent observations on the minute anatomy of the disease, and it may be useful to transcribe the most important of these. Pohl (Virchow's *Archiv*, 1854, vi. 190) Virchow's *Krankhaften Geschwulste*, xx. 1863; Auspitz (*Zeitschrift der Wiener Aerzte*, 1864, ii. 229, and *Archiv für Dermatologie und Syphilis*, 1871, p. 119). Kohn (ib. 1872, p. 72). Rindfleisch's *Handbook*, p. 269. Gedding (pamphlet on Lupus erythematosus, reprinted from reports of *Akad. der Wissenschaften in Wien* (1868) Volkmann's *Klinische Vorträge*, 1871. Friedländer (Virchow's *Archiv*, 1874, lx. 17).

A recent number of *Le Mouvement Médical* contains a comparison of the treatment of this disease as recommended by Devergie with that practised by M. Lailler. The former authority, as is well-known, advises internal treatment as of first importance, combining cod-liver oil in large doses, with iodide of iron, iodine of potassium, and gentian. To this he adds, in rebellious cases, bichloride of mercury and Fowler's solution. 'Quelle macédoine!'

exclaims M. Lailler (and he would find a similar hotch-potch among the prescriptions of some successful skin-doctors nearer home). He contents himself with ordering cod-liver oil and iodide of iron, with a little quinine or gentian wine, to which he adds iodine of potassium when he suspects a syphilitic taint. Treatment by sulphur externally and internally, especially at such houses of correction as *Eaux Bonnes*, is admitted in the milder cases. In others local means must be employed—tincture of iodine, juniper oil ('huile de cade,') goujon oil ('huile de noix d'acajou') as recommended by M. Bazin, iodoform, mercurial ointments, Vienna paste, etc. [There seems really no advance on the plan of treatment practised with great success by Professor Hebra, and described by his pupil, Kaposi, in the volume last translated for the Sydenham Society. Iodoform is said to be as efficient as other destructive applications, and not to cause pain. Goujon oil was tried by the reporter in one case of leprosy, and it has no effect at all; but probably its composition is variable.—*Rep.*]

FROMMEL ON ERYSIPELAS.—In the *Medicinisch-Chirurgisches Centralblatt* of Vienna (Feb. 1875), Dr. Frommel relates a case of 'erysipelas migrans.' The illness began with shivering, vomiting, and pyrexia, head-ache and giddiness. On the fourth day the patient, a healthy country girl, had ordinary erysipelas of the face with bullæ already formed. On the sixth day the shoulders and upper part of the chest were invaded, and the patient was unconscious, after having been violently delirious. Treatment was by low diet, purging, and ice to the head. Two days later the bullæ on the face had dried up, and the sharply defined edge of the eruption had descended to the epigastrium, crossing without hesitation a line which had been drawn with nitrate in the hope of stopping it. On the twelfth day of the disease the general condition of the patient was much improved; her faculties were normal, the fever gone, and the face almost well. Thick scabs had now formed on the neck and thorax, and the redness of the back and abdomen was diminishing. But in a slighter degree the disease had now spread to the hypogastrium, again unimpeded by a line of lunar caustic. A week later there was only some desquamation visible on the face, the scabs were being thrown off on the neck and chest, the redness about the waist was fast diminishing; but the skin of the buttocks and groin was red and swollen, though without vesication. At the same time the general condition of the patient kept on improving, her appetite increased, and by another week the erysipelas had disappeared without having attacked the lower extremities, and nothing but the weakness of convalescence remained. Throughout the four weeks' duration of the attack there was more or less diarrhœa.

MISCELLANY.

THE Cambridge Board of Natural Science Studies announce that applications by members of the University, desirous of availing themselves of the facilities for study at the Zoological Station at Naples during the ensuing season, are to be sent to Dr. M. Foster, Trinity College, on or before October 20.

ARRIVALS AND DEPARTURES.—The new reptile house in the Jardin des Plantes, Paris, has sustained some heavy losses. A large turtle died from the shot it had received many months ago when captured in the Atlantic Ocean, and a large serpent from a wound inflicted by a rat. The rat having been offered as living food, resisted violently, and bit his adversary so deeply that he died a few days afterwards. The above heavy loss will be to a considerable extent compensated, as the Jardin des Plantes will receive in a very few days a boa more than eight yards in length, which has just arrived at Havre. It is said that this animal requires a goat or a sheep to appease its appetite at one time.

MEDICAL QUALIFICATIONS FOR FOREIGNERS IN BRAZIL.—M. Jaccoud, of the Paris Faculty of Medicine, has addressed some inquiries to the Emperor of Brazil relative to the conditions imposed on foreign medical practitioners who desired to practise their profession in the empire of Brazil. In answer to these queries, M. Jaccoud has since received an official assurance from the Brazilian Prime Minister, to the effect that the Brazilian Faculties of Medicine are authorised to allow medical men, natives of other countries, to answer the questions addressed to them in the course of the examinations indispensable to the exercise of their profession in Brazil, in their native tongue.

POSTHUMOUS OVERCROWDING. — According to M. Maxime du Camp's last and recently published volume of *Paris, ses Organes, ses Fonctions et sa Vie*, out of 45,780 deaths registered in that city during 1872, 14,987 were owing to diseases of the respiratory passages, including 7,436 from phthisis, 2,018 from intestinal disorders, and 1,966 from meningitis. The question of the interment of the dead has become one of great importance to the city of Paris. The twenty cemeteries belonging to it are encumbered with bodies, and the earth is saturated with their decomposing remains. The subject of cremation has been mooted, but with no great success, and it appears probable that the present difficulty in disposing of the Parisian dead will be met by the formation of the vast suburban cemetery at Méry-sur-Oise; a project which originated with Baron Haussman.

LOVE AND JEALOUSY.—It has, we believe, been generally held that 'our poor relations' are not subject to the influence of those passions which imply some use of the reasoning faculties. Such a conclusion, however, would appear to be invalidated by the following anecdote, if it be as authentic as the respectable source whence it is derived, the *Lyon Médical* for April 18, would seem to guarantee. It is there related that M. Cherville has seen a mare refuse her food and kick her stall to atoms from jealousy, because her groom petted and coaxed a horse, her stable companion. The same authority also states that in a stable where a cow and a donkey were stalled together, when the dairymaid came to milk the former, she was no sooner seated on the milking-stool than the donkey would leave its stall, come close to the woman, and rest its head on hers until she had finished the milking; as if the poor animal would also claim a share of her attention and affection.

AMMONIA AND SNAKE-BITES.—Professor Halford's plan of injecting ammonia into the veins of persons suffering from the effects of the bite of Australian snakes was brought forward at a late special meeting of the Medical

Society of Melbourne. The president, Mr. Bowen, read a paper on the subject, in which he gave the results of the operations hitherto performed upon those who had been bitten in the colony, and offered some observations upon that part of the report of the Indian commission in which it is laid down authoritatively that the intravenous injection of ammonia is not only useless but injurious. Mr. Bowen pointed out several sources of fallacy in the conclusions from the Indian experiments with a few Victorian snakes, and hinted at the loose and unscientific way in which the commission had generalised upon insufficient data, and without taking all the known facts into the calculation. In the discussion which followed, the general feeling of the profession was decidedly in favour of the ammonia treatment, and adverse to many of the views put forth by the Indian commission. At the same time, it was conceded that the Indian experiments with the virus upon dogs had been conducted with greater care, precision, and completeness, than those made here many years ago. The discrepancy as to the fatal results of the poison in the two countries was, however, inexplicable. Whereas inoculation with the virus in Calcutta seems to have killed a small proportion of the animals operated on, almost every dog died in Melbourne after the snake had been made to bite. An independent set of experiments was made by Dr. M'Crea, the chief medical officer, long before Professor Halford came to the colony, with precisely similar results to those arrived at by the professor subsequently. Every dog Dr. M'Crea caused to be bitten died. How, therefore, the Indian commission failed to kill their dogs with the same kind of snakes, has yet to be explained. It has been suggested that the sea-voyage and the difference in climate and food may have lowered the quality of the venom of the Australian snakes sent to India. It was finally resolved to appoint a commission of the members of the Medical Society, independently of Professor Halford, to investigate the whole subject, and especially to go through all the experiments of the Indian commission on animals in a precisely similar manner—the inquiry to stand over until next summer, as the cold season, during which the snakes are neither so lively nor so venomous, is close at hand.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

WEDNESDAY, JUNE 2, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

A REMARKABLE CASE OF CATALEPSY AT THE COCHIN HOSPITAL, PARIS.

The case of catalepsy which has been under observation at this hospital, and which has been attended with sufficient publicity to allow the most satisfactory verification, cannot fail to afford interesting matter for thought to the physician as well as to the philosopher and historian. There is here no question of those facts which mysticism, fanaticism, or credulity, have often shrouded in mystery by attributing to them a miraculous or supernatural aspect, turned to profit according to the requirements of the moment; here there is only question of a pathological fact of an exclusively scientific nature. A patient, Marie Lecomte, who had come into Dr. Desprès' wards for a surgical affection, was soon afterwards attacked with dysmenorrhœa and uncontrollable vomitings; these complications were followed by nervous aphonia and suppression of the urinary excretion, then supplementary derivation of urine by vomitings. At the beginning of April the urinary function, which had long been suspended, was re-established, when on April 5 the patient fell into a lethargy; her breathing was imperceptible, her lips were pink, and her complexion rather roseate than pale. The trunk and limbs were in a complete state of relaxation; the pulse was normal; involuntary motion was quite abolished; the finger, placed through the half-opened mouth, on the glottis, the most sensitive point in the whole animal economy, neither provoked cough nor any other movement. M. Desprès, therefore, ordered that no food whatever should be given to the patient, even with the cannula used to feed paralytic patients, for fear that any attempts at giving nourishment should produce asphyxia. On April 6 the whole of the patient's muscles were tense and hard; they were contracted. It was cadaveric rigidity, *minus* death, for the pulse registered seventy pulsations, and the temperature of the body, taken with a thermometer placed under the armpits, measured 100.4° Fahr. At this time the patient was cataleptic, and the lethargy continued. This condition lasted six days, during which the patient remained apparently dead, and took no nourishment. During this attack the facts observed were, in the first place, muscular rigidity. The limbs were in a state of extension, the arms fixed tightly to the body gave the patient a resemblance to a mummy, it was necessary to use force to change the position of a limb. The limbs, hands and fingers remained for many hours in the very fantastic positions in which they were placed, and then gradually returned by jerks to the position whence they had been removed, and so remained in the same previous state of

contraction. There was not the slightest relaxation of the muscular contraction. The patient was seen every hour of the day and night and her condition was always the same. Many attempts were made to awaken the patient, such as pricking the most sensitive points, introducing rigid stems into the nostrils; but nothing had any effect, and the physicians who used these means were convinced that the abolition of the reflex movements was a certain fact.

M. Desprès again tried an experiment, tending to show that the muscular contraction was involuntary, as a conclusive proof. The muscles of the abdomen contracted like those of the rest of the body, and retained the form imparted to them. By forcibly applying the hand to the abdomen, the muscles were depressed, and the imprint of the hand remained visible during three minutes at least. These muscles remained contracted in the position imparted to them, a thing which could never be obtained by the effort of the will under any circumstances. On the seventh day of the crisis, the patient murmured some words and asked for something to drink; she drank a small quantity of coffee and broth, which she partly vomited some hours after. On the eighth day the patient fell back again into the cataleptic condition, the fresh crisis lasting forty hours. On the twelfth day, there was a fresh partial awakening. The patient called her neighbours, the house-surgeon, and the sister of the ward, without recognising the persons she called, and without answering the questions addressed to her; she drank some more broth and coffee, which she vomited the next day. She had a relapse on the thirteenth day, with catalepsy and lethargy, lasting sixteen hours. On the fourteenth day there was partial awakening; then catalepsy, lasting about eight hours in the night. In the intervals of the crisis the patient drank broth and coffee; but, as she afterwards vomited a portion of what she had taken, the abstinence had markedly emaciated her, and the small pulse, marking 100, showed that want of food was producing its usual effects. From that time the cataleptic crisis ceased. The patient remained in a state of dreamy wakefulness—that is to say, of somnambulism. She did not recognise anyone; but was yet able to take drink, and specially coffee and milk. On the seventeenth day a fresh symptom made its appearance. The patient during her dream had complained of not being able to see, and believed herself to be blind. As a matter of fact, a shining object placed before her eyes, and even the light of day, did not seem to be perceived by her. By automatic movements, against which all efforts were useless, she got her fingers to her eyes, and rubbed them with a sort of febrile excitement to such an extent that it was found necessary to tie her hands. Finally her sight returned to her on the eighteenth day; she recognised some people in the ward; and was able to take liquid food in a regular way. On the twenty-fifth day, the patient did not vomit any more, but retained the nourishment she took; she was entirely convalescent, and only complained of pains in her limbs, which she compared to those caused by fatigue. On the thirtieth day, she was able to get up, and on May 5 she was entirely cured.

Cases like that which has occurred at the Cochin Hospital are not new, but they have rarely been well observed. The remarkable researches of Professor Lasègue have made known the intermittent catalepsy of hysterical subjects, of ecstatic maniacs, and even

of healthy persons. It is a condition which may be provoked at will or which overtakes patients somewhat suddenly; as in the case of the judge quoted by Fehr,* who, having been insulted on the bench and having risen to reply, remained with outstretched arm and open mouth in a state of catalepsy which lasted more than a quarter of an hour.

The catalepsy complicated with somnambulism of hysterical patients, which appears in crises of an hour or longer, is now thoroughly well known; if it be not simulated, it is at least kept up by the will of the patient, or by a tendency which they could resist if they would. This kind of catalepsy is almost exclusively the melancholy privilege of women and priests.† Cataleptics, who have taken advantage of religious superstition, and who have sometimes been encouraged by the Roman Catholic Church, belong to that group of cases in which catalepsy is complicated with somnambulism or ecstasy. Louise Lateau, an account of whom will be found at pp. 128 and 158 of the MEDICAL RECORD, is a cataleptic of this kind. The cataleptic of the Cochin Hospital presents another variety of catalepsy; the attack begins with lethargic coma, and generalised muscular contraction comes on twenty-four hours afterwards. When the patient awakes she is somnambulant. The catalepsy, accompanied by lethargy, lasts six full days, during which there is apparent death. After the awakening there are three relapses, and the disorder only seems to yield bit by bit, after alternations of awakening and lethargy for several days. Here is a case of a disorder which is now-a-days called neurosis, and connected with the hysterical temperament, in which nothing of the marvellous has been observed. Marie Lecomte is a foundling, four and twenty years old, who had never left the Foundling Hospital and the farm where she had been boarded out. A quiet and well-conducted unmarried woman, she neither had exaggerated religious ideas nor vicious habits. Both before and after her attack, during the state of ecstasy and somnambulism which followed the six days of catalepsy, she held no continuous conversation, said no prayer, nor pronounced the name of God; but asked for ice or water to drink, called those of her hospital neighbours whom she knew best; in fact, spoke naturally according to her tastes and habits. As the Paris hospitals, open to everyone, are usually given in charge to medical men who are accustomed to sick people and see things from a positive point of view, in accordance with science, no attempt was made to find any supernatural utterances in the words spoken by the patient. The case of Marie Lecomte, which should be published with all its details, becomes a scientific fact, with regard to its authenticity far above the facts reported in the sixteenth, seventeenth, and even eighteenth centuries. At those epochs, in fact, the hysterical cataleptics or insane devotees passed for the elect of God, and the ecstatic or somnambulant cataleptics who did not speak of the Divinity were exorcised and even burned. As regards lethargy and abstinence from food, Marie Lecomte is not the most remarkable type. Some maniacs have remained equally long in the cataleptic and lethargic state; but the relation of the facts is not clear, and it is not recorded if the muscular system was contracted during the whole time the fit seemed

to last, as it was with Marie Lecomte during six whole days.

It may not be unadvisable here to reply to a question which may arise in some minds. It is whether, in presence of this state of apparent death, it may not have not have been possible that ignorant persons may have believed death to be real and have interred the patient. The answer is easy; the most inexperienced practitioner who might have felt the pulse could not have had one moment's doubt on the subject, and there is ground for believing that if, since the beginning of this century, a cataleptic patient, in a state of lethargy, has been interred alive, the medical man could never have looked at the supposed corpse. This is clearly reassuring, and it may be deduced from the case of Marie Lecomte that, notwithstanding the appearances of death, the signs of life were so decided, that the most ignorant of practitioners could not have felt for an instant the slightest doubt as to the vitality of the patient.

THIERSCH ON LISTER'S ANTISEPTIC METHOD, AND ON THE SUBSTITUTION OF SALICYLIC FOR CARBOLIC ACID.

(Concluded from page 318.)

The hospital, however, is not free from accidental traumatic diseases. Hospital gangrene occurred once, under rather remarkable circumstances. In the end of March, 1871, the newly opened Jacob's Hospital was supplied with new furniture. The old furniture was deposited in the court-yard of the hospital, and here it lay for a week, exposed to rain, snow and wind. One day it disappeared, and it was said that it had been put in a better place. A few days later, without any trace of importation, hospital gangrene in its worst form appeared in two barracks lying far apart. There had been no case of the disease in the old hospital since 1868. In each barrack is an unoccupied ground floor, through which air reaches the wards. In this Dr. Thiersch found the old furniture stored—body-linen and bed-clothes, night-stools, mattresses, etc.—as if for an experiment with infection on a large scale. Fortunately only two cases occurred, neither of which was fatal.

Erysipelas has occurred sometimes more, sometimes less, severely. In 1873 Dr. Thiersch had seventy-five cases among 1,902 patients; in 1874, among 1,921 patients, the number of cases of erysipelas was not accurately known, but it was distinctly less than in the previous year. In both years, antiseptic treatment made no difference. As has been recognised on all sides, antiseptic treatment has no power to prevent the occurrence of erysipelas; it occurs under the use both of carbolic and of salicylic acid; sometimes frequently, sometimes rarely; sometimes in a severe, and sometimes in a mild form.

While no difference from the former conditions of the hospital has been observed as regards hospital gangrene and erysipelas, the case is different with pyæmia. When he first came to Leipzig in 1867, Dr. Thiersch found the disease remarkably prevalent in the old hospital. In the new hospital there has been a marked improvement, especially since Lister's method has been rigorously carried out. In 1873 Dr. Thiersch had ten cases of pyæmia among 132 deaths; of these four were imported two broke out

* Fehr, *Hiera picra, seu de Absinthia*, 1667.

† Rondelet speaks of a priest who fell into ecstatic catalepsy when the history of the Passion was read. (*Methodus cur. morb.*, ed. 1583, lib. i. cap. 20.)

in the hospital, and the remaining four occurred after amputation of the femur, amputation of the humerus, removal of the index finger under Lister's treatment, and in a case of severe injury of the thigh, laying bare the bone that was treated by open dressing. In 1874, out of 105 deaths, five were from pyæmia; in four of these the disease broke out in the hospital, all the cases being under Lister's treatment. The cases were, complicated fracture of the skull, severe complicated fracture of the leg, with laceration of the soft parts in the popliteal space, severe complicated fracture of both legs, and amputation of the humerus. The last case only occurred in the ten months specially embodied in the report.

Dr. Thiersch coincides in opinion with those who regard Lister's method of treating wounds as affording a fairly secure protection against pyæmic infection. Fresh wounds, especially operation-wounds, generally heal without fever, unless some extraordinary injurious influence acts on them; the plan favours healing by the first intention; if the secretions of the wound be retained, not much disturbance is produced. Suppurative and ichorous discharges generally undergo a change for the better in a few days; necrosis of sawn surfaces of bone and of portions of the skull that have been laid bare occurs rarely; and, thanks to the aseptic course, and the good properties of Lister's ligature, secondary arterial bleeding is rare.

Dr. Thiersch regards the antiseptic action of the salicylic dressing as certain as that of Lister's carbolic dressing. The salicylic acid also possesses two advantages; it is less irritating, and is not volatile. It can thus be incorporated with the dressing in greater quantity and remain for a longer time in contact with it, without endangering the result. Another advantage of salicylic acid is that it is inodorous.

Dr. Thiersch gives the following directions for the use of salicylic acid for the guidance of those who have not leisure to make experiments for themselves. For dressing with salicylic acid there should be kept at hand a supply of salicylic water—a solution of one part in 300; and of salicylic cotton, containing respectively 3 and 10 per cent. Dr. Blaser, the apothecary of the Jacob's Hospital, makes the preparations in the following way. *a.* For 3 per cent. salicylic cotton, 750 grammes are dissolved in 7,500 grammes of spirit of spec. grav. 0.830; the solution is then diluted with 150 litres of water, at a temperature from 156° to 176° Fahr.; and the mixture is used to saturate twenty-five kilogrammes of cotton-wadding freed from fatty matter. *b.* The 10 per cent. salicylic cotton is made by dissolving one kilogramme of salicylic acid in 10,000 grammes of spirit of spec. grav. 0.830, adding sixty litres of warm water (as above), and saturating with the mixture ten kilogrammes of cotton-wool. The saturation of the cotton is best done in a large shallow wooden tub; and it is best to use only a small quantity of cotton-wool (two or three kilogrammes) at one time, as in only this way an equal distribution of the salicylic acid is possible. The proceeding occupies only a short time.

In charging the cotton-wool with the warm solutions of salicylic acid, it is introduced in layers, moderate pressure being applied to each layer, so that it may be completely saturated before another is introduced. After the proper quantity of cotton-wool has been introduced and is perfectly saturated, the whole is inverted, and allowed to stand for a

short time (about ten minutes), so that the solution may be diffused as equally as possible. The cotton-wool is then laid in small heaps to cool, during which process the salicylic acid crystallises; and it is then allowed to dry in a moderately warm place for about twelve hours. It is not advisable to hang it up, as, in the process of draining, the equal distribution of the acid is disturbed. Such are the directions given. It is not to be expected, however, that the salicylic acid will crystallise in equal amount in all parts of the wadding; and, even after drying, the distribution of the acid may be rendered unequal by handling. Thus, in many parts there will be less than 3 per cent., in others more. An addition of 1 per cent. does no harm; but if in the 3 per cent. cotton-wool there be a deficiency of 1 per cent., or in the 10 per cent. cotton of 3 per cent., the deficiency should be made up from portions containing an excess.

As has been already observed, the salicylic cotton-wool does not allow the passage of the discharges of the wound so readily as Lister's carbolic gauze; and hence, when a dry salicylic acid dressing has remained for a week or two, pus is generally found in various quantities between it and the wound. Dr. Thiersch has made some experiments in order to find a more permeable material for dressing than cotton-wool. Hemp, flax, sawdust, etc., did not answer the purpose. His attention was then called by Dr. Von Mosengeil to jute; and, having obtained a supply of clean jute from the manufactory at Bonn, he charged it with 3 per cent. of salicylic acid, adding also 20 per cent. of glycerine to prevent the acid from falling off in dust. He introduced 2,500 grammes of jute into a solution of 75 grammes of salicylic acid in 500 grammes of glycerine and 4,500 grammes of water, at a temperature of 158° to 176° Fahr. In this way he obtained a soft material, resembling flax, giving off but little dust, which, when left on a wound for nine days, completely absorbed thick pus, which became equally diffused through it. At the same time, the dressing remained inodorous, and gave in every part the reaction of salicylic acid on being tested with chloride of iron. On account of the equal distribution of the discharges from the wound in the jute dressing, it is not necessary to apply a strongly charged layer internally; a four per cent. dressing is sufficient. Dr. Thiersch believes that jute will supersede cotton as a dressing for large suppurating wounds, although it is not to be compared with the latter as regards softness. Some comparative statements of the cost are given, to show that the salicylic acid dressing, especially when jute is used, is much cheaper than the carbolic acid dressing: the proportions, calculated for a case of amputation of the thigh, being:—Lister's dressing, 2.35 *mark*; dry salicylic dressing, 1.52 *mark*; dry salicylised jute dressing, 0.92 *mark*.

The cheapest of all is the jute dressing; and it is the more so, because it can be allowed to remain a longer time on the wound without danger of an accumulation of the discharges beneath it. Dr. Thiersch's experiments with the jute dressing are as yet, however, not sufficiently numerous to enable him to speak with absolute certainty about it. He does not think that it is of much importance whether a spray of carbolic acid (1 in 50 of water) or of salicylic acid (1 in 300) be used. Many give carbolic acid the preference, because it does not cause coughing and sneezing, and is readily removed from

the clothes by evaporation. Dr. Thiersch prefers salicylic acid, because it irritates the wound less. The sponges are kept in a solution of carbolic acid (1 in 20 of water); and, after being used, are washed with much warm water and again placed in the carbolic acid solution. Salicylic acid solution may also be used.

Lister's 'protective' is regarded as unnecessary, as the salicylic acid dressing irritates less than the carbolic acid; so also the macintosh, which Lister uses. To favour the escape of secretions from the wound, and at the same time to prevent the dry salicylic dressing from adhering, a piece of fenestrated gutta-percha membrane, or of waxed taffetas, is placed next the wound; or a piece of Lister's antiseptic gauze may be used for the same purpose.

In operating, chloroform is first given; and, if possible, Esmarch's apparatus for the prevention of hæmorrhage is applied. The part to be operated on is then shaved, if necessary, and cleaned by means of soap, water, spirit, and oil of turpentine, and is then rubbed by means of a nail-brush with a solution of salicylic water or carbolised water (1 in 20.) The operator's hands being disinfected and the spray-apparatus ready, the operation may be begun.

In amputation of a limb, such as the thigh, the arteries are secured by catgut ligature, the ends of which are cut off short. All bleeding having been arrested, the edges of the wound are accurately fitted together, and united by disinfected silk suture at both the most dependent angles. Solution of salicylic acid is injected into the wound at each corner; and at each angle a drainage-tube with several lateral openings is inserted as far as the bone, the outer projecting end being cut off. After again washing the wound with salicylic acid until the fluid escapes nearly pure through the drainage-tubes, the wound is covered along its whole edge with a strip of fenestrated gutta-percha or carbolised gauze three finger-breadths wide; over this is laid salicylic cotton-wool of the stronger form to the thickness of one finger, and of the weaker to that of two fingers, the whole reaching a hand-breadth beyond the edge of the wound. These layers of cotton-wool are then smoothly and equally covered with gauze. The application of the antiseptic spray is stopped as soon as the wound is covered with the salicylised cotton. If the temperature afterwards rise to about 101° Fahr. it is advisable to examine the wound, especially if the patient complain of pain in it. If there be no pain or fever, the dressing is left until the removal of the drainage-tubes appears necessary. Any spots of secretion that appear on the surface are covered with salicylic cotton. If all go on well, the dressings may be changed for the first time at the end of eight or ten days, the drainage-tubes being then removed; and the second dressing may remain until healing has taken place. If there be moderate retention of the discharge, the drainage-tubes are removed and new ones are introduced, and the wound is washed with salicylic water injected through them. If the wound becomes filled with coagula or if signs of sloughing appear, Dr. Thiersch opens the middle suture and applies moist dressing, with irrigation. If the arteries have undergone calcareous change, the wound is left open and covered with a thin layer of moistened weaker salicylic cotton-wool, and is irrigated with solution of salicylic acid.

A similar course is followed in resections of large joints, removal of tumours, etc.; provision being made by the introduction of drainage-tubes for the

escape of discharge at the most dependent part of the wound.

In large open wounds, Dr. Thiersch lays a thin layer of salicylic cotton-wool or antiseptic gauze over them, so that the irrigation may reach every part of the wound. The irrigation is effected by means of Esmarch's irrigator; or, if this be not at hand, the solution must be poured from time to time from a vessel. The skin around is protected from maceration by being rubbed with palm-oil. If abscess or retention-fever appear, the dressing is removed under the antiseptic spray, and drainage applied according to circumstances. When healthy granulations have appeared, the dry salicylic dressing may be used. The simultaneous use of ice-bags is often very useful.

In cases where there is advancing suppuration with insufficient escape of pus, generally attended with high fever, the suppurating cavity is washed with solution of salicylic acid; the necessary openings are then made, drainage-tubes are introduced, the part is placed in a proper position, and irrigated with salicylic acid. After a time, the dry dressing is applied.

In small or in congestion abscesses, incision and a drainage-tube are generally sufficient. In large deeply seated abscesses, especially if portions of sloughy tissue be present, a large opening is made and the part is washed with solution of salicylic acid; and then according to circumstances, one or more openings are made at the deepest and most dependent parts, so as to allow complete drainage. Dr. Thiersch thinks that the best plan is to introduce through each opening a drainage-tube, reaching as far as the centre of the cavity. The part may be washed with salicylic acid so long as the walls of the cavity remain ununited.

In concluding his paper, Dr. Thiersch considers the question whether salicylic acid is destined to become useful in military surgery. In the early period after a battle, the trouble and care attending the application of Lister's antiseptic render it impracticable, whether carbolic acid or salicylic acid be used. But, even though Lister's plan be not rigorously carried out, it may be advisable to use salicylised cotton in place of charpie, and to irrigate or moisten open wounds with solution of salicylic acid. Afterwards, when the lazzarets have been brought into order—and especially if salicylic acid should prove to be a prophylactic against hospital gangrene—the use of salicylic acid will facilitate the use of Lister's method in military surgery.

COULAND ON THE CONNECTION OF ERYTHEMA AND RHEUMATISM.

The *Archives Générales de Médecine* for January, 1875, contains ten cases of erythema papulatum occurring in the course of acute rheumatism, reported by Dr. C. Couland.

1. Male, aged twenty-nine. First attack of rheumatism. In April, 1874, he had an eruption apparently erythematous. June 2. He was admitted with an affection of the knees and ankles, fever, and an eruption on the trunk and limbs of minute injected points, arranged in circles and patches, fading on pressure, bright in colour, and unattended with itching or tenderness. June 3. Systolic bruit, probably pericardial. June 8. The eruption was nearly gone. July 10. He had left pleurisy with effusion:

joints almost well. July 17. Convalescent. July 20. He went out with no trace of his illness but bronchitis.

2. Male, aged twenty-three. First attack two years ago, in knees; it became chronic, and was accompanied by an 'erythematous' eruption, followed by desquamation. Present attack in knees and shoulders with slight pyrexia. Eruption appeared on the eleventh day of illness over the trunk and limbs like the last, but of a less vivid colour—approaching that of measles. A week later the eruption had disappeared without desquamation; the articular pains had diminished, and there was a systolic basic bruit, probably aortic.

3. Male, aged twenty-six. An uncle had had several attacks of rheumatism, and his fingers were now distorted (? osteoarthritis). Another uncle, said to be gouty, died, at forty-six, of 'pulmonary apoplexy.' The patient was first attacked in April, 1871, with pains in the knees and ankles, followed by a papular eruption on both legs, with three spots recognised at the time as erythema nodosum. A few days later he became suddenly anasarctous with urine containing blood and albumen, from which he recovered completely. In January, 1874, he had a slight attack of rheumatism, and a more severe one last May, which was not completely cured for six months. The heart was unaffected.

4. Male, aged twenty-one. June 2, 1873, attacked with febrile symptoms, followed in a week by erythematous patches on the hands and face, some of which assumed the form of erythema iris. On the 19th he had pains in the knees, and feet without redness or swelling; slight pleurisy. June 22. He had diarrhoea. On the 30th, he was well.

5. Male, aged nineteen. Ill a week with slight pyrexia and pains in the limbs. He had a morbilliform eruption on the face, with coryza and bronchitis. Next day (May 18, 1874) the eruption had spread to the body and legs, and caused excessive inflammatory oedema of the prepuce and scrotum. There were a soft apex bruit and a pericardial rub. May 19. The eruption was fading: he had albuminuria. Recovery took place with desquamation.

6. Female, aged twenty-four. Pregnant. Suffered from rheumatic fever at seven years old. A diffuse erythematous eruption, with oedema, appeared on the hands and cheeks, November 9, 1874. Next day it became more papular, with pains in several joints. By the 13th it had disappeared, and desquamation followed.

7. Female, aged seventeen. Father rheumatic. She had chorea at fourteen, with subacute rheumatism. January 14, 1874. She had an eruption on the elbows and wrists like a papular erythema, patches on both shins (E. nodosum?), and pains in joints, with a slight basic systolic bruit.

8. Male, aged twenty-nine. March 24, 1874. Inflammation of right knee, with papular erythema of both legs, and a systolic murmur at the apex of the heart. The eruption disappeared in six days, and the synovitis in a fortnight.

9. Female, aged twenty-one. She was perfectly well until the end of September, 1874. She was then feverish and poorly for a week, and her legs swelled, and in front of each tibia appeared small painful red elevations, which left behind them a bluish stain. On October 27 there was a fresh eruption of erythema accompanied by shivering, dyspnoea, and severe pain in the right shoulder and side, for which a blister was applied. She was then

admitted to La Charité, with dulness, bronchial breathing and ægophony of the right side, and a blowing systolic apex-bruit. By November 24 the eruption had disappeared, and the pleuritic effusion was absorbed, leaving a rub audible. A few days later she went out feeling perfectly well, but with the mitral bruit audible.

10. Female, aged twenty-six. Her father was gouty. She had suffered from scarlatina and enterica. The first attack of rheumatism occurred at twenty-three; it lasted six weeks, and was accompanied by erythema nodosum of both shins. A second attack of both affections occurred about a year afterwards, preceded by sore throat. She had a third attack of rheumatism when the case was reported, beginning with jaundice and angina, and accompanied by an eruption of papular erythema on the face, back, hands, and legs. The 'papules' were as large as half a franc, and itched very much, though they were also painful and tender to the touch. At the same time there were nightly shiverings, pyrexia, headache, and a furred tongue; general muscular pains were replaced by ordinary synovitis of the hand, knee, and elbow, and when this disappeared, the eruption had passed through a violet tint to the stage of desquamation. A few days after dismissal the patient came in again with a severe relapse of rheumatic fever, slight erythema of the legs and one arm, and acute endocarditis of both aortic and mitral valves.

Dr. Couland adds to this instructive series of cases the not unnecessary assurance that he has excluded cases of gout, because he believes that the identifications under the name 'arthritides' of gouty and rheumatic eruptions 'is contrary to the teaching of experience, and exceedingly inconvenient.'

In the same journal for the present month (p. 486), is a case of one of these curious erythematous eruptions with desquamation, which sometimes accompany articular rheumatism, described by the reporter, M. Percheron, as 'Dermatite exfoliatrice généralisée.'

P. H. PYE-SMITH, M.D.

ANATOMY AND PHYSIOLOGY.

CALORI ON ANOMALIES OF THE INFRAORBITAL CANAL AND NERVE.—The *Annali Universali de Medicina e Chirurgia*, for April, contains an abstract of a memoir by Professor Luigi Calori on the anomalies of the infraorbital canal and nerve, published at Bologna in 1874. The author confirms the observations of Wenzel Gruber, and adds some original remarks. The following are the anomalies observed in the infraorbital canal.

1. The conversion of the canal into a hollow cylinder or tube running within the antrum of Highmore as far as the middle of the orbital plane, where it ends in the infraorbital groove. The tube has on its inner side an accessory cavity of the antrum, a sort of diverticulum. This formation was met with in a fifth of the cases examined, and is analogous to the tubular infraorbital canal of the horse and other mammalia.

2. The existence of several infraorbital foramina or canals, arising either from subdivision of the ordinary canal by a septum, or from the presence of several granules opening on the face by distinct orifices, more or less distinct from the principal foramen (supernumerary canals of Gruber). But

there are also other infraorbital canals having no connection with the ordinary canal, and on the face or on the base of the orbit, or on the posterior surface of the superior maxilla; to these Gruber has given the name of anomalous infraorbital canals.

3. The infraorbital canal may be double. It is in very rare instances divided by a septum through its whole length; while in other cases the canal is bifurcated at a variable distance from its anterior extremity. Of the two trunks or canals, the outer one is always the continuation of the ordinary canal, and the inner one is supernumerary. This double arrangement has been long known, and has received the name of bifid infraorbital canal. The supernumerary canal always opens on the face on the inner side of the ordinary infraorbital foramen: the aperture may be on the same level as the ordinary foramen, but more frequently it is a little higher or lower, and is placed at a distance varying from one-fifth to half-an-inch, according to Calori's observations.

4. With regard to the frequency of the anomalies, Gruber found the infraorbital canal bifid in 116 out of 1,000 skulls, and Calori in 100 out of 1,000.

With regard to the infraorbital nerve, Dr. Calori says that he has, in three cases, while examining the second branch of the fifth pair, found passing out of a special canal, situated to the inner side of the ordinary infraorbital foramen at a distance of about one-third of an inch, a nervous twig of middle size which was distributed to the lower eyelid and the skin of the nose. This anomalous twig arose from the inner side of the trunk of the infraorbital nerve, at a distance of a quarter to a third of an inch from the projecting lower margin of the orbit, and either close to or a little behind the origin of the superior anterior alveolar nerve. In one case Dr. Calori observed two twigs escaping from two foramina, one above and the other below, lying to the inner side of the ordinary infraorbital foramen; the upper one was at two-fifths of an inch distant, the lower one-third. In this case also the twigs arose from the trunk of the infraorbital nerve, from one-fifth to a quarter of an inch from the margin of the orbit; the orifice was single, and the twig entered a canal which was supernumerary to the ordinary canal, and which bifurcated before reaching the face. The upper twig was distributed to the lower eyelid and the nose, the lower one to the nose alone.

In concluding his memoir, Dr. Calori comments on the practical utility of such anatomical researches in indicating the course which should guide the surgeon in dividing the infraorbital nerve.

A. HENRY, M.D.

OTT ON THE PHYSIOLOGICAL ACTION OF THEBAIA.—This has been studied by Dr. Ott in Professor Bowditch's laboratory at the Harvard Medical School. His conclusions are, in the main, confirmatory of those arrived at by previous inquirers. After furnishing a summary of existing knowledge on the subject, he describes ten selected experiments performed on frogs, pigeons, and rabbits, with Merck's thebaia, dissolved with the aid of hydrochloric acid, the solution being subsequently neutralised. He found that '0007 gramme ('01 grain) of the alkaloid produced tetanus in the frog, followed by recovery; '01 gramme ('015 grain) administered subcutaneously to a pigeon caused its death by tetanus in fifteen minutes. The tetanic spasm is of spinal, not of cerebral, origin; the sensory and motor nerves,

and the voluntary muscles, are not in any way affected by the poison. In rabbits previously curarised, thebaia caused some quickening of the pulse, and a marked rise of blood-pressure; the former phenomenon being probably due, not to paralysis of the inhibitory apparatus, but to stimulation of the cardiac ganglia; the latter to an action on the vaso-motor centre, since it was prevented by division of the spinal cord between the atlas and the occiput.

E. BUCHANAN BAXTER, M.D.

FALCK ON THE EXCRETION OF UREA IN A HUNGERED DOG.—F. A. Falck, *Habilitationschrift*, Marburg, pp. 22, 1874 (abstract in *Centralblatt für die Med. Wissenschaften*, no. 45, 1874) withheld from a well-nourished bitch, of 8,960 grammes weight, all solid and fluid food, and estimated every six hours, till the death of the animal, the quantity of urine removed by the catheter, its specific gravity, its colour, and the quantity of urea. The animal was weighed every six hours and the temperature taken. The author found that with continued inanition the body-weight gradually suffered less loss, that from the second hunger-day onwards the daily decrease in weight (reckoned as percentage of the body-weight) remained tolerably equal till death.

The animal died when it had lost 48·08 per cent. of its weight. The urine had always an acid reaction, the colour was reddish-yellow, and had a mean specific gravity of 1·051. During the first hunger-days the quantity of urea excreted sank considerably; afterwards it increased, so that for several days more urea was excreted than on the second hunger-day; during the last days of life the quantity of urea excreted was small. The author explains this change thus: that at first the fat was preferably oxydised for the sustenance of the temperature necessary for life, and, later, the albuminous bodies. The final diminution in the excretion of urea corresponds in time with the diminution in the temperature. From this it appears that the quantity of fat in the body of an organism totally deprived of food limits essentially the duration of life.

KRENCHEL ON THE CONSEQUENCES OF SECTION OF THE OPTIC NERVE IN THE FROG.—W. Krenchel (*Von Gräfe's Archiv*, 1874) says that Berlin found that after section of the optic nerve in the frog, degeneration of the nerve-fibres to their most extreme intracular terminations occurred. Berlin suggested that this was not due merely to the section of the nerves, but to the division of the blood-vessels by his method of operating. The author confirms Berlin's results completely, and shows further, by intracranial section (whereby the vessels are uninjured), the correctness of the above assumption. Krenchel found that in frogs, six months after the operation, no change in the eye either macroscopically or microscopically was to be detected; on the contrary, he found that several times in the almost always completely divided optic nerve, degeneration of the nerve-fibres for one to two millimetres from the point of section had taken place. It is very remarkable that the mobility of the pupil for the action of light is not in the least diminished by intracranial section of the optic nerve.

WALB ON TRAUMATIC KERATITIS.—Walb (*Centralblatt*, no. 7, 1875) employed the method of Lieberkühn, viz., the injection of a freshly prepared neutral solution of carmine into the cornea of the rabbit. This causes little or no disturbance, and if

the cornea be examined in from ten to eleven days, the corneal corpuscles are found splendidly coloured and lying in a perfectly colourless ground-substance. Afterwards the cornea can be irritated by chloride of zinc, nitrate of silver, etc., and the changes in the corpuscles, etc., noted. WM. STIRLING, D.Sc., M.B.

DEZAUTIÈRE ON HEART-SOUNDS.—M. Dezauière laid before the Paris Academy of Sciences, at their meeting of April 13, a note in which he says (*Bulletin de Thérapeutique*, April 30) that the sounds of the heart are produced by the rapid and violent contraction of the ventricles, each rapid and violent contraction producing a sound. If the expression may be allowed, it is a sound *à priori* and not *à posteriori*, primary, and not consecutive as is generally believed. The structure of the auricles does not allow contraction; besides, contraction of the auricles is not necessary, the blood descends naturally into the ventricles by its own weight. The contraction of the auricles would be dangerous, inasmuch as it might drive back the blood into the venæ cavæ and the pulmonary veins. The second impulse is produced by the contraction of the right ventricle.

PATHOLOGY.

KOSTER ON THE PATHOGENY OF ENDARTERITIS.—Koster's observations (*Verslagen en Mededeelingen der Koninklijke Academie van Wetenschappen*, 1874) were chiefly designed to investigate the origin of the numerous round or lymphoid cells, which all observers have found in the thickened inner coat of an artery affected with chronic endarteritis, or the atheromatous process. These were unhesitatingly set down by Virchow as the result of a proliferative process in the connective tissue cells of the inner coat, and this explanation was generally accepted, although it was difficult to show precisely what elements of the normal arterial wall were thus concerned. Moreover, since Cohnheim's observations on cell-migration in inflammation, it became just as natural to suppose that they might be leucocytes escaped from the circulating blood; a hypothesis which, first casually thrown out by Traube, has been adopted by Rindfleisch and others; and to it Koster decidedly commits himself.

His observations on the normal anatomy of the inner membrane led him to the conclusion that all arteries, even the human aorta, possess a complete continuous endothelial lining, in which are no stomata. The large branched stellate connective tissue cells described by Langhans, and seen in morbid (fatty) conditions by numerous pathologists, are not a normal constituent of the inner coat till after ten years of age; but they increase with the thickening of the inner coat, which takes place in old age, and in some morbid conditions constitute several layers.

Since these are the connective tissue elements of the inner coat, it becomes important to inquire whether they are the progenitors of the lymphoid cells above spoken of; but Koster, agreeing with Götze, fails to find any genetic connection between the two classes of elements, the stellate cells being unaltered, except by fatty degeneration, even when the lymphoid cells are most abundant; and the same holds with respect to the nuclei which are also sometimes abundantly present. He is thus driven to regard the round cells and nuclei as emigrant leuco-

cytes from the vessels, though he does not deny the possibility of proliferation occurring in such elements. In one point only, he qualifies the view already expressed by other pathologists; viz., he believes that the penetration of the wall by the corpuscles only takes place when the inner coat is already altered by fatty degeneration or hypertrophy. Further, this immigration of leucocytes, though secondary to the degeneration of the wall, is the chief factor in producing an actually atheromatous condition, and especially what was formerly called an atheromatous abscess, since the accumulation of such cells leads to 'necrobiotic decay.' These conclusions are supported by observations in a case of leukæmia, by an observation previously made by others that the young or lymphoid cells are most abundant in the superficial layers of the thickened lining membrane, and by a singular case recorded by Virchow, where an atheromatous cavity was found to be filled not with the usual degenerated materials, but with apparently young or newly formed cells, hardly to be distinguished from pus.

Koster holds with Virchow, that there is a simple fatty degeneration without hypertrophy; but thinks the more strictly hypertrophic form leading to sclerosis and deformity of the vessel, is only an extreme case of the chronic inflammatory process. The increase in thickness of the inner coat is due in great part to increase of its intercellular substance as well as to the formation of new stellate cells. A complete endothelium could always in recent specimens be found covering the sclerotic patches.

J. F. PAYNE, M.B.

FELTZ AND E. RITTER ON LIGATURE OF THE BILE-DUCT, AND ON THE BLOOD IN DIFFUSE HEPATITIS.—Messrs. Feltz and Ritter show, in a note laid before the Académie des Sciences, April 12 (*Bulletin Général de Thérapeutique*, April 30), from a series of nine experiments of ligature of the bile-duct, that the blood is more or less altered, in consequence of the resorption of the biliary salts and of their shorter or longer retention in the blood. The blood-corpuscles become diffuent; the hæmoglobine transudes, and even crystallises; fatty granules in considerable quantity, and crystals of cholestérine, accumulate in the serum. The change in the blood varies with the amount of biliary acid, shown by chemical analysis to be present in it. The jaundice does not depend either on biliary salts or on their transformation, but on the retention of the colouring matter. The absorption of the biliary salts has a limit, for the biliary secretion itself diminishes so soon as the dilatation of the secretory canals and canaliculi becomes considerable, and the epithelium of these tubules falls into a state of granulo-fatty degeneration, under the influence of the great increase of pressure within them. This modification of the secretion explains the rarity of nervous and hæmorrhagic accidents in hepatogenous icterus. In this respect, there is a great difference between acholic and poly-cholic icterus.

The authors have in one instance been able to produce the serious incidents of diffused hepatitis by artificial retention of the bile, and in this case they found an amount of biliary salts varying from ten to eleven thousandths in the blood. Taking clinical ground and comparing the pathological forms of icterus with those they have been able to produce artificially, either by biliary injections or the ligature of the

common bile-duct, the authors admit that there occurs in every icterus a moment in which the presence of biliary salts in the blood cannot be doubted, and that the nervous or hæmorrhagic accidents of diffused hepatitis depend in a great measure on the proportion of biliary salts accumulated in the blood. The general conclusion of all their experimental and clinical data is to establish unquestionably that the absorption of the biliary salts plays the principal part in all cases of diffuse hepatitis. Blood-poisoning is the characteristic of all so-called bilious states, whatever may be the multiple lesions of the splanchnic organs which give rise to or which depend on them.

In the future, morphological and chemical modifications of the blood should be sought for in diffuse hepatitis, and even in yellow fever. MM. Feltz and Ritter are entirely convinced that by this method it will eventually be rigorously demonstrated that every malignant bilious condition, of whatever nature, originates in the accumulation in the blood of a too considerable quantity of biliary salts, which act as destroyers of the red blood-corpuscles.

MEDICINE.

MOSLER ON ARTERIAL TRANSFUSION OF DE-FIBRINATED HUMAN BLOOD AFTER HÆMORRHAGE FROM THE BOWEL IN TYPHOID FEVER.—No. 20 of the *Berliner Klinische Wochenschrift* (May 17, 1875), contains a paper by Professor Fr. Mosler, of Greifswald, from which we abstract the following. He remarks that the general opinion as to the extreme gravity of intestinal hæmorrhage in enteric fever is confirmed by experience. If the blood flow rapidly, it is dark-red, syrupy, or clotted; but if it have remained some time in the bowel before being discharged, it is of a chocolate-brown or greenish-black [in the former case it is sometimes very florid and thin. A girl with typhoid fever, in the London Hospital, passed blood of a bright pink colour in the stools.—*Rep.*]. More or less collapse, often fatal, supervenes. The subjoined case was extremely severe. Mrs. G. L., aged thirty-seven, mother of six children, had previously suffered from chronic bowel and uterine complaints, and was attacked with typhoid fever in November, 1874. Under quinine, acids, and cold baths, her temperature became almost normal. On Thursday, November 31 [*sic*], Dr. Mosler was consulted on account of a sudden and unexpected pain in the ileo-cæcal region. He found the pulse 120, and small; temperature 108°7' at 5 P.M. Abdomen, especially where painful, extremely tympanitic. No lung complication. Thin, copious, liquid stools. As she had taken stewed whortleberries, the colour was not decisive. Local peritonitis was diagnosed. [Ice, externally; quinine in large doses, and enemata containing salicylic acid.] These means procured some amelioration of symptoms. December 5: morning temperature, 101°8' Fahr. December 8, in the morning, patient passed nearly a pint of dark blood from the bowel; in the evening still more. Altogether more than a quart was said to be lost. Next day she was in a state of extreme collapse, drowsy, with cold extremities. Seven-drop doses of liquor ferri perchloridi were given with wine and strong broth, and camphorated oil was subcutaneously injected at intervals of half an hour. In spite of these means, with warmth,

mustard, etc., the collapse deepened, and every one was surprised that she survived the night. Professor Mosler and Dr. Altdörfer resolved on transfusion, and asked the aid of Dr. Hüter. Meanwhile, she was given champagne, and the injection of camphorated oil was continued, for this seemed to do more good than anything else. The transfusion was commenced about 3 P.M. on the 10th. It was thought that transfusion into the veins would be dangerous in the weak state of her heart; probably paresis of heart, coagulation of blood, and death would occur, as Professor Möslér has seen in venous transfusion in collapse after diphtheria. [Möslér: 'Ueber Collapsus nach Diphtherie, vorgetragen in der Section für innere Medicin der Leipziger Naturforscher-Versammlung,' *Archiv der Heilkunde*, 1873.] Dr. Mosler took a pound and a half of blood from the left median vein of a strong labourer, whipped it and filtered in a water-bath at 104° Fahr.; Dr. Hüter, assisted by Dr. Wenzel, laying bare the very thin radial artery of the patient's right arm, opening it, and inserting the cannula, during the same time. Very cautiously eight syringefuls (of about twenty grammes [3vj.] each, were injected, about six ounces in all. The operation took about twenty-five minutes.

Except reddening of the forearm, there was very little immediate effect, but in a very short time the pulse became perceptible at the left wrist, and the impulse of the heart could be felt. After about half an hour there was a severe rigor, lasting about eight minutes. Champagne was given freely, and from this time her general condition rapidly improved. Her face became more natural, the skin began to perspire, and she slept the next and following nights. Next morning her pulse was 92, the temperature 101°1' Fahr. From this date, except for a carbuncle in the neck, recovery was uninterrupted. The wound in the arm healed well, and there was no return of hæmorrhage from the bowel. This case is the same reported in Dr. Kalusche's dissertation.

The other cases known to Dr. Mosler are: 1. One mentioned by Dr. A. C. W. C. Berns (*Beiträge zur Transfusionslehre*, Freiburg, Bd. I., Fr. Wagner, 1874, p. 27), in which Drs. Kussmaul and Czerny transfused 150 grammes (about four and a half ounces) of defibrinated blood, as a *dernier ressort* after hæmorrhage from the bowel in a typhoid fever case at Freiburg. There was a severe rigor half an hour later. In two hours there was a fresh, florid, and copious hæmorrhage from the bowel, under which the patient sank. During the transfusion borborygmi, indicating peristaltic action, were clearly heard—due to sudden overfilling of vessels? 2. The second case is Küster's (Langenbeck's *Archiv*, vol. xvii. 3 Heft. p. 385). About four and a half ounces of lamb's blood was transfused into the left radial artery of a man, aged twenty-six, who was moribund after intestinal hæmorrhage, in the course of typhoid fever, with very high temperature. The operation appeared to produce slight improvement, but four hours after he died exhausted. In neither of these cases was there any *post mortem* examination.

The third case was in a female patient of Dr. Havemann, of Sülz, aged eighteen years. The hæmorrhage occurred in the second week of enteric fever, and she is said to have lost three pounds of blood. She was so collapsed two days afterwards that little hope of success was entertained. Transfusion of defibrinated human blood was done by means of a common pewter syringe holding about three ounces. Five or six ounces in all were injected into the left

radial artery at the wrist. There was no subsequent rigor, the collapse all vanished, and recovery was uninterrupted. [*Zur Charakteristik der Transfusion*, von A. Evers, Rostock. *Deutsche Klinik*, 1870, p. 72.]

There are other cases in which transfusion has been done simply for anæmia after typhoid fever, without any bleeding from the bowel having occurred. These are not included in this list. Only four, including the one detailed above, are known to Professor Mosler. Of these, two only had a favourable termination. Of the unfavourable ones, the names of the operators are guarantees for the mechanical details. The renewed hæmorrhage which proved fatal is an accident no skill can guard against. In Küster's case the patient was already too exhausted. But according to Landois' researches [*Centralblatt für die Medicinischen Wissenschaften*, 1875, no. 1], it would seem that lamb's blood is not so good as human—it may even be feared that it is positively injurious. After experiments with various kinds of blood Landois finds, besides pyrexia, characteristic symptoms, which generally begin very soon after the operation, after a few hours more vanish, and, if the quantity of blood be small, do little permanent harm, though there may be more serious and less transient sequels. Landois, by repeated experiments, satisfied himself that the blood-corpuscles of one animal are broken up in the body of another, and that the masses of stroma caused by their destruction may cause coagulation in the blood-vessels through which they circulate; and he believes that the phenomena produced are owing to the blocking of capillaries and small vessels, and depend on the extent to which this occurs, this blocking being due to the conglomeration of the 'foreign' blood-corpuscles and fibrinous stroma. Possibly the 'native' blood-corpuscle may assist in the blocking. One of Landois' results is of special interest as regards transfusion after intestinal hæmorrhage; he has observed that transfusion of heterogenous blood causes violent peristaltic action, in the whole of the intestinal tract, with vomiting and purging. The bladder, genitals, skin, and muscles are also affected. In the nervous system the disturbed circulation produces excitement, restlessness, irritation of important centres, and, at a later date, symptoms of depression, paralysis, and coma. He asserts also that the certain destruction of the corpuscles of other animals when their blood is introduced into human bodies, forbids us to believe that the functions of these corpuscles will be performed as before. The nutritive value of the materials he regards as insignificant; but, in tendencies to hæmorrhage, there may be positive danger of inducing this to a dangerous extent. We must, therefore, on physiological grounds, prefer human blood in cases of hæmorrhage from typhoid fever, as not only the best, but the only safe material. Both Havemann's and Mosler's successful cases were done with human blood. Mosler believes that transfusion into an artery is always to be preferred; and defibrinated blood, which Panum long ago showed to be quite as useful in anæmia as that containing fibrine, should be used. Even Billroth, who combats transfusion in the *Wiener Medicinische Wochenschrift*, nos. 1-4, 1875, declares for defibrinated blood; and perhaps the successful cases here recorded may modify his objections.

[It is to be noted that rigors sometimes occur after saline injections, as well as after transfusion. The simplicity of the instrument in Dr. Havemann's

cases is also noteworthy, as it often happens that complex apparatus cannot be obtained when most wanted.—*Rep.*]

W. BATHURST WOODMAN, M.D.

PIERRET AND TROISIER ON TWO CASES OF PROGRESSIVE MUSCULAR ATROPHY.—In the *Archives de Physiologie* for March and April, 1875, Messrs. Pierret and Troisier relate two cases, one of which occurred under the care of M. Vulpian, another under that of M. Charcot.

The first case (that under M. Vulpian) was that of a man, aged twenty-seven. There was nothing worthy of note in his family history. By occupation he was a coppersmith. He had been a fairly healthy man up to September, 1872. He then first noticed that he was growing weaker. This condition increased, and in the month of December of the same year he was compelled thereby entirely to desist from work. He entered the hospital of La Pitié in April, 1873. At this time the muscular atrophy was strongly marked. It principally invaded the muscles of the neck, shoulders, and back. The arms were also affected. The lower limbs appeared intact. Speech was slow; the tongue, however, moved freely. The sight and hearing were good. The remaining organs offered nothing worthy of notice. His condition gradually became more and more marked; his respiration became difficult; he could not swallow without difficulty. The food escaped, into the back of the nose and the air-passages. The movements of the tongue became less free. The osseous points about the shoulders and the ribs stood out clearly. Gradually the movements of the lower limbs became more feeble. The head was bent forward on the chest. Latterly he became subject to attacks of suffocation, and in the end he succumbed to an attack of bronchitis. This occurred on November 11, 1873, about fifteen months from the commencement of the illness.

At the necropsy, made twenty-four hours after death, the lungs were found congested, the heart normal. There was congestion of the pia mater, on the lateral aspect of the cerebral hemispheres. The vessels at the base were healthy. All the cranial nerves were normal in volume, with the exception of the spinal accessory and the hypoglossal. The spinal nerves were atrophied, and presented a less white aspect than the cranial nerves, more particularly on the right side; the hypoglossal nerves were also atrophied, and had a translucent appearance. Just below the point of the calamus scriptorius the pia mater was thickened, and presented two or three small clots. The medulla and the upper part of the spinal cord were more pigmented than normal. The grey matter of the cord was rose-tinted: this was particularly found to be the case on making a section between the third and fourth pairs of nerves on the right side; the white substance was normal. The muscular system was all, more or less, atrophied and altered in colour. Microscopically, the muscular tissue was found to contain a large quantity of connective tissue, containing adipose vesicles, the fibres themselves varying in dimension. The striation remained clear. The nerve-tubes also varied in size and in the amount of myeline. The spinal cord, after being hardened in chromic acid, was stained with carmine and cleared by means of alcohol and oil of cloves, being subsequently mounted in Canada balsam. In the cervical region it was found to have undergone atrophy of the nerve-cells in the anterior

horns, and a diminution in their number. This alteration, though equal on each side throughout most of the cervical portion, was found to proceed higher on the right side than on the left. This was the chief morbid appearance presented throughout the cord.

Case 2 was that of a woman, aged fifty-six. She had had an unhealthy life, having had various complaints and disorders, more particularly those met with in scrofulous subjects. She was a lace-worker. The first symptoms of the disorder under observation seem to have come on about the age of twenty-two. These became more marked, rendering her less and less able to carry on her occupation. Various remedies, such as iodide of potassium under the suspicion of syphilis, galvanism, and various other forms of electricity, were tried without avail. Finally she was compelled to give up work, and was admitted into the Salpêtrière, where she remained for many years, her symptoms slowly becoming more marked but without remission. She was at length placed in the infirmary under the care of M. Charcot at the age of fifty-six years. The muscles all over the body presented a condition of atrophy. About a month after admission she was seized with a dry cough, difficulty in swallowing, loss of voice, and irregular and painful breathing. Death was caused by dyspnoea and arrest of the movement of the diaphragm.

At the necropsy, the lungs were found to contain remains of caseous pneumonia scattered throughout them. The heart was small, and its muscular tissue yellowish. The muscles were nearly all, more or less, altered in colour and shrunken. Microscopically they were found to contain pigmentary granules. The fibres were much reduced in volume, and of a pale yellow colour. In some parts, there was a proliferation of the cells of the muscular tissue. The spinal cord was examined in the fresh condition about the middle of the cervical region; some of the cells presented a normal appearance, others were pigmented. In those cells which were most affected the nucleus and the nucleolus had disappeared. After hardening with chromic acid, the white matter and the posterior horns of the cervical region were found to be normal, but in the anterior horns the cells had undergone pigmentary degeneration, and in some places, more particularly about the level of the fourth cervical pair, they had disappeared altogether. This was more marked on the right side. In the locality where this disappearance had taken place, the anterior horn corresponding to it seemed to have undergone a true inflammation; the horn itself presented a fibrous appearance, and contained no cells except in the neighbourhood of the tractus intermedio-lateralis. In the dorsal region, the cells of the anterior horns were small and few in number. In the lumbar region, the cells of these organs only presented a slightly pigmented appearance. In the medulla oblongata there was only to be observed a small patch of sclerosis in the neighbourhood of the left pyramid.

These two cases, in a general view, only differ from each other in the different time occupied by the disease. The first was more rapid than the second; but this rapidity does not remove it from the typical cases of progressive muscular atrophy. In both cases there were the same insidious approach, the gradual invasion of separate groups of muscles, the absence of febrile symptoms. In both of them also the disappearance of the nerve-cells from the

anterior horns was a marked symptom. In the first case there was no pigmentation of the cells, but this should be looked upon as a symptom of less importance than the entire disappearance or the atrophy of the cells. It is undoubtedly a condition brought about by an impairment of the nutrition; such, for example, as may take place from the vascular derangements of old age. Indeed, the researches of one of the authors of this paper, at the Salpêtrière, would seem to determine that this pigmentation is a characteristic sign of senile alteration. [This view would seem to bear out that expressed by Herbert Major in the *West Riding Reports*. He says, speaking of the condition of senile atrophy: 'I believe the great change, and the one which is invariably present to a greater or less extent, is a granular condition of the nerve-cells.'—*Ref.*]

This pigmentation, therefore, is not a lesion peculiar to progressive muscular atrophy, while the disappearance of the nerve-cells is characteristic. The sclerosed condition of the anterior horns in case no. 2 is due to the slow retraction of the tissue on the spaces occupied by the cells which had disappeared. These changes must all be admitted as the results of subinflammatory processes, and they are ranked by some pathologists among the subacute myelites. Each of these cases was terminated by glosso-labio-laryngeal paralysis, death in both cases being too rapid for there to be any well-marked changes discovered in the medulla. There is very little doubt that this form of paralysis is in its turn complicated with muscular atrophy, particularly in the muscles of the tongue and of phonation.

SURGERY.

VERNEUIL ON PRECOCIOUS SECONDARY TRAUMATISMS.—In an article in the *Archives de Médecine* for December, 1874, Professor Verneuil designates, under the title of 'secondary precocious' traumatic neuralgias, more or less acute pains in the traumatic focus, its neighbourhood, and even at a great distance from it, taking on the neuralgic character and intermittent type, not susceptible of explanation by the ordinary causes of traumatic pain, resisting antiphlogistics and narcotics, and easily yielding to sulphate of quinine. These neuralgias are not uncommon, and M. Verneuil's study is not only interesting from the point of view of general pathology, but also on account of the patient, whose cure is retarded, and even endangered, by them, whilst they

can be quickly cured by sulphate of quinine. The secondary pain presents five varieties. 1. Local pain, limited to the seat of the traumatism. 2. Local pain with peripheric irradiation. 3. Local pain with peripheric indolence and distant manifestation. 4. Simultaneous peripheric and local pain. 5. Local indolence; distant pain only. In order to establish the existence of these varieties M. Verneuil reports a series of cases which is very complete, and in many ways very interesting. He has the happy power of enriching his text as he goes on with many very valuable hints borrowed from his surgical practice and from ingenious researches on different points of surgical pathology. In one part we meet with an account of the laborious ablation of an enormous parotid tumour; in another, a case of extirpation of an enormous tumour of the breast, whilst amongst the notes we find a short description of a special plan of dressing for extensive wounds of the face, neck, and breast.

Whatever may be the nature of the traumatic lesion, all the numerous patients whose cases are reported show an occasionally very intense neuralgia, with repeated attacks which have yielded to sulphate of quinine. In the second part of his paper, M. Verneuil makes a careful investigation of the phenomena accompanying secondary traumatic neuralgias. In the muscular system there are clonic spasms of contraction, want of power in the limbs, simulating partial paralysis. In the vascular system at the epoch of the neuralgic attack there occur local congestions and even hæmorrhages, as intermittent as the neuralgic attacks. Sometimes the wound assumes a diphtheritic appearance, and in some cases even the distant neuralgic attack is a precocious symptom of a local phlegmon or an attack of erysipelas. The general phenomena are not very marked as a rule. Precocious secondary traumatism is in itself apyretic; it may, however, be preceded, followed, or accompanied by fever, but this is a simple coincidence. The neuralgic attack is, however, in some cases followed by the appearance of herpetic vesicles on the lips or face. M. Verneuil has already called attention at the Société de Biologie, in May, 1873, to the appearance of herpes labialis as a critical symptom in traumatic lesions.

The pathogenesis of precocious secondary traumatic neuralgias, their etiology, diagnosis, and treatment, complete the study. The relations of these painful attacks to impaludism rheumatism and other general affections are shown with M. Verneuil's well-known care, in the investigation into the relations between traumatisms and diatheses. He has long since pointed out that a traumatism may bring on the reappearance of a diathesis which had not made itself manifest for a shorter or longer period; traumatisms show a true revival of diathesis. The study of precocious secondary traumatic neuralgias, according to M. Verneuil's method, will form the basis of a future chapter of surgical pathology forgotten up to this time—pain in traumatism.

MACEWEN ON PENETRATING WOUNDS OF THORAX AND ABDOMEN TREATED ANTISEPTICALLY.—Dr. William MacEwen (*Glasgow Medical Journal*, January, 1875) gives four cases, all treated in the same way; and all with equally good results.

Case 1. A boy, aged twelve, was stabbed in the back, and only after much and careful probing was a visceral wound found, and then in the lung-substance

a piece of the blade of a pocket-knife; this was after some difficulty extracted, and was the means of detecting the assailant by fitting his broken knife. The wound in this, as in the other cases, was thoroughly injected with carbolic lotion (one part in forty) and then dressed in the usual way with antiseptic gauze. The probing was in the first instance persevered with, in consequence of a peculiar catching at the throat during breathing. In three weeks the patient was perfectly well.

Case 2. A man, aged forty-six, was stabbed on the left side of the chest, the wound passing into the anterior mediastinum. The heart could be felt by the finger passed into the wound. The treatment was the same, sutures being passed and tightened as soon as bleeding ceased. He was enabled to return to work, well, in less than three weeks.

In remarking on these two cases Dr. MacEwen points out that the antiseptic treatment enables a careful examination of the wound to be made with the probe or finger in safety, while in the first case a probable source of fatality was removed. This he claims as an advance in the surgery of these cases instead of the ordinary plan of not touching them, and thus 'groping in the dark' in the after-treatment.

Case 3. A lad, aged seventeen, was stabbed in the abdomen; a knuckle of uninjured intestine being held between the lips of the wound. The wound was injected, sutures passed and tightened after the bleeding ceased, and lead and opium given internally. In ten days he was well enough to desire to get up, and the wound had healed; but he was kept quiet for three weeks.

Case 4. A man aged twenty-eight, with an abdominal wound of three inches, and another of one inch, the former evidently perforating the intestine. The same surgical treatment was adopted, along with morphia suppositories, the bowels being kept quiet for a fortnight. In a month he was well and strong.

[We have seen similar cases treated antiseptically in Edinburgh with equally good results, and think Dr. MacEwen is right in advocating careful examination with antiseptic precautions in preference to the usual treatment recommended in the surgical textbooks.—*Rep.*] J. KNOWSLEY THORNTON.

BOUISSON ON THE PROPER TIME FOR ASPIRATORY PUNCTURE IN THE TREATMENT OF STRANGULATED HERNIA.—Dr. Bouisson (in his *Thèse de Paris*, 1874, and *Bulletin de Thérapeutique*, April 30) passes in review the principal cases relating to this new method of treating strangulated herniæ. He reports eight in his own practice, which yielded seven cures. From the whole number of cases, amounting to thirty-five, he draws the following statistical results: Cases of cure by aspiration after taxis, twenty-seven; insufficient aspiration, keliotomy, cure, four; insufficient aspiration, death, four. These figures speak strongly in favour of this operation. It affords excellent results in inguinal hernia. The issue is less certain in crural hernia, notwithstanding that it has been successful in several cases; and it is desirable to try it in all practicable cases. Either Dieulafoy's or Potain's instrument may be used, provided that the needle be sufficiently fine.

The writer only distantly points out one contraindication—the doubt as to the integrity of the intestine, if the surgeon be called in too late; for the rest, the rules to which the employment of aspiration is submitted are the same as those of taxis, of which

it is the most direct and efficacious auxiliary ; therefore it should be performed as soon as a methodically performed taxis has proved the irreducibility of the hernia.

LABATTU ON ANTHRAX AND FURUNCULUS OF THE FACE.—After having in his *Thèse de Paris*, 1874, studied *de novo* the acute form of these inflammations when they are complicated with acute phlebitis spreading along the side of the head, Dr. J. Labattu discusses some interesting points in relation to them, and especially the question of treatment. The gravity of anthrax of the face, complicated with phlebitis, is due to the spreading of the latter on the side of the cranial sinuses, or to purulent infections. The rapid supervention of exophthalmos indicates with certainty the spreading and the possibility of this inflammation of cranial sinuses. Large and early incisions seem to be the best means of preventing and sometimes putting a stop to the phlebitis. No medical means appear to exercise sufficient control over this affection. Dr. Labattu reports several interesting cases in support of his theory ; amongst others, one in which he was the sufferer, and where multiplied incisions seem to have stopped incipient phlebitis.

SCHRAMM ON THE INFLUENCE OF AMYL-NITRITE IN MELANCHOLIA.—In the *Archiv für Psychiatrie* (Band v. Heft 2), Dr. Schramm gives his experience of this remedy. After quoting Browne and Brunton, who have experimented with it in this country, he gives his results as follows. A temporary favourable result was, with one exception, seen in all the cases (nine). This occurred at once after the inhalation, and was both subjective to the patient and objective to outsiders. The mental state, at first depressed and painful, became more lively, and the dulness gave way to affability. A few hours after the inhalation the former state, without exception, returned. The favourable effect of the treatment was most apparent after the first or second inhalation, and by repetition became weaker ; so that after two or three weeks' experience it quite failed, especially in its influence on the heart's movement and the course of the circulation, though after an interval it acted as at first. In two cases the remedy preserved its sedative power up to the third month, though even here it failed to thoroughly subdue the symptoms. Even here, it should be added that the two patients were accustomed to morphia, from which they had experienced much relief to their depression.

In most of the cases anæmia was present ; but this gives no necessary premises for the psychic operation of the drug, for once it failed (even at the

first inhalation) in a notably anæmic person, and in two instances it succeeded where plethora and other congestive symptoms were present.

Although it is proved that amyl-nitrite causes dilatation of the brain-vessels, we have yet no means for deciding whether the influence is the consequence of the dilatation of the vessels and the greater flow of blood, or whether there is a direct influence of the blood, changed in composition by the amyl-nitrite, on the nervous apparatus. The last two cases, where plethora showed itself, seem to speak for the latter hypothesis ; although even here a still greater widening of the vessels may have occurred and have led to recovery. Anyhow, Meynert's theory of the dependence of melancholia on anæmia of the brain is confuted.

The practical result is, that we can by amyl-nitrite relieve for a time the condition of melancholia and its attendant neuro-pathological symptoms. To the cure of melancholia, having regard to the as yet unknown brain-changes causing it, our experience is only of use when the disease is of short duration or has frequent periods of remission.

When the remedy does not quickly act, it is of no special use ; and, as a palliative, it is, because of the rapidity with which the system becomes accustomed to it, behind other narcotics. Let it be only used in mild cases of simple melancholia ; but it is not yet clear that such cases are more easily influenced when associated with an anæmic condition than when with plethora. T. C. SHAW, M.D.

KOROWIN ON STARCHY FOOD FOR INFANTS.—In the *Fahrbuch für Kinderheilkunde und Physische Erziehung* is a contribution by Dr. Korowin, on the assimilation of food consisting of starch in infants. The practical object of the experiments and observations in this communication is the determination of the value of various preparations of starch in the nutrition of infants and young children.

It appears that a secretion may be obtained from the mouth of a child as soon as it is born, though in minute quantity and with difficulty.

It is generally found to be acid unless the mouth of the child has been previously washed carefully, when it has a neutral or alkaline reaction. The effect in converting starch into sugar of the secretion of the salivary glands of the mouth and that of the pancreas was obtained by making infusions from the glandular tissue, and observing the changes produced upon solution of starch. It was ascertained that till the end of the third week the glandular secretion of the mouth exerts no influence of this kind, though the pancreas does, and always to a much greater degree than the former. R. J. LEE, M.D.

DA COSTA ON BROMIDE OF IRON IN CHOREA. Professor Da Costa, in a clinical lecture on this subject (*Medical and Surgical Reporter*), says, 'Having now used it for three or four years, my experience from the treatment of a large number of cases, giving abundant opportunity to witness its good effects, induces me to like it better than any other one article in the treatment of chorea. It should be given in increasing doses, never commencing with less than five grains for a child, and rapidly increasing the dose to twenty. It may be given in plain syrup and water in the form of a pill, or better, in an effervescing powder. It not only affects the chorea, but also impresses the nervous system as a sedative, quieting it, and giving the

patient rest. It is also a valuable agent in treating the incontinence of urine in children. It was in a case of this kind, complicating chorea, that I first observed its value; being surprised and pleased to see that, as the symptom which led to its administration improved, the chorea also diminished and soon disappeared. Since then I have used it almost continuously. Local chorea, or clonic muscular spasm, such as twitching the eyelids, etc., in hysterical women, are sometimes cured by this drug after the failure of other remedies. In answer to the question whether it is the bromine or the iron that benefits, I think it is the combination; that neither alone accomplishes the result; for it benefits cases that have previously taken iron without improvement; and as regards the other bromides, we certainly can not claim for them any especial value in chorea, as they frequently disappoint us. The remedy occasionally fails, as all remedies sometimes do in this obstinate affection, but it certainly is one of the most valuable agents we possess for the treatment of chorea.

CARSTENS ON DYSENTERY CURED WITHOUT OPIUM.—Dr. J. H. Carstens, in a paper in the *Detroit Review of Medicine and Pharmacy*, says, 'Dysentery being an "infectious febrile disease," due to a specific poisonous germ, and quinine being the best remedy to destroy and neutralise the specific poisons, it ought to be good for dysentery. Ulceration being a prominent result of dysentery, as quinine diminishes ulceration, this is the remedy. Hæmorrhage is a prominent symptom, and as ergot contracts the smaller blood-vessels and prevents hæmorrhage, that is the remedy. Severe spasms and tenesmus being most complained of by the patient, and ipecacuanha being most emphatically an antispasmodic, it is good for dysentery. The proportions of these remedies in each suppository should be regulated by the symptoms. 1. By means of suppositories we can cure dysentery; 2. This is the most rational and scientific mode of treating this disease; 3. Children object less to their use than to nauseous drugs administered by the mouth; 4. And that probably quinine, ergot, and ipecacuanha are the best remedies to use at present at our command.' The following is the formula used by Dr. Carstens in a child five years old:—*R.* Pulv. ipecacuanhæ, ʒss; Pulv. ergotæ, gr. xv; Quinæ sulph., gr. iv; Olei theobrom, q. s. For twelve small rectal suppositories. Introduce one every two hours.

OBSTETRICS AND GYNÆCOLOGY.

SIMON ON THE EVACUATION OF HÆMATOMETRA THROUGH THE BLADDER AFTER DILATATION OF THE URETHRA.—In no. 20 of the *Berliner Klinische Wochenschrift*, there is a brief communication from Professor Simon, of Heidelberg, in which he states that an article in no. 16 of the same journal for the current year from Dr. Spiegelberg, of Breslau, on 'Fis-

tures of the Neck of the Bladder,' had attracted his attention, because Spiegelberg mentions, without details, a case in which he had opened a hæmatometra through the bladder, after first dilating the urethra, and that no injury to the bladder resulted. Simon states that he has for a very long time advocated this method in his lectures, and at least a year ago (April 21, 1874), he proposed it at a large meeting of professors and practical surgeons at Heidelberg, as the best method where there are objections to an opening between the rectum and bladder. Professors Hecker, of Munich; Schulz, of Jena; and Olshausen, of Halle, were present when he explained his reasons for preferring this to the opening through the rectum advocated by Scanzoni and Baker Brown. Dr. Bidder, of Mannheim, also present, in an article in the same journal, of Nov. 16, 1874 (no. 46), on a 'Case of Hæmatometra of the Uterus,' writes as follows. 'You must also allow me to remind you that we cannot always succeed in restoring the natural way to the uterus by separating the vaginal walls, or through artificial restoration of the vagina, and in such cases we must not forget Professor Simon's proposal. In such cases Simon would dilate the urethra, easily done by proper specula, and then push through the posterior wall of the bladder into the uterus below the peritoneum, making a free opening there, through which the retained blood may escape easily and with comparative safety.'

Simon adds that he has given details of the operation in an article (already in the press) entitled 'On the Means of Rendering the Bladder Accessible, and on Sounding the Ureter in the Female.' It is to appear in Volkmann's *Sammlung Klinischer Vorträge*.

[It is not quite clear whether the author refers to congenital or to acquired collections of blood within the uterus. From the extract given from Bidder, it would rather seem that cases of imperforate hymen and atresia vaginæ, and cases of occlusion of the os uteri with obliteration of the vaginal canal from accident or disease, are both included, provided that the uterus becomes filled and distended with blood, and that the natural outlet is obliterated.—*Rep.*]

W. BATHURST WOODMAN, M.D.

VOELKEL ON A CASE OF COMPLETE INVERSION OF THE UTERUS.—Dr. A. Voelkel of Berleburg communicates to the *Berliner Klinische Wochenschrift*, March 15, 1875, a case of complete inversion of the uterus occurring fifty-two hours after delivery. It happened in a primipara, aged thirty-two. When she was first seen by Dr. Voelkel, she had been thirty-six hours in labour; the membranes had been ruptured ten hours. The child's head was found firmly impacted in the pelvis in the first position with a large *caput succedaneum*. Delivery was effected by the forceps after three hours' hard work. The uterus did not contract well after the expulsion of the child, and the placenta was forced out by Credé's method. Immediately upon the delivery of the after-birth severe flooding set in, which was, with difficulty, arrested by cold-water injections into the uterus, and the internal administration of ergot. The patient did very well up to the morning of the third day, when severe after-pains came on, coupled with an ardent desire to micturate. Warm fomentations were ordered to the abdomen. Towards evening the pains became stronger and more frequent, with a sensation as if something wanted to pass out of the vagina. Suddenly, at eight o'clock, with

a strong expulsive effort, a globular body was forced out of the vulva, instantly followed by a gush of blood, and in a moment the patient was dead. When seen by Dr. Voelkel, four hours afterwards, the tumour proved to be the uterus completely inverted lying outside the vagina. No necropsy was made. The patient had always flooded at her menstrual periods.

DERMATOLOGY.

WEIR ON ICHTHYOSIS OF THE TONGUE AND VULVA.—Dr. Robert F. Weir has contributed a paper upon this subject to the *New York Medical Journal* of March, 1875.

After alluding to what has been written upon ichthyosis or tylosis of the tongue by various English and French authors, Dr. Weir proceeds to mention ten cases, which have either come under his own observation or have been communicated to him by professional friends. Of these cases two occurred in women, and in one of these the vulva was the part affected. This observation is of so much importance that we quote the case without abbreviation.

'Case 3 possesses unusual interest, as it is thought to be the only case yet reported of the disease attacking the vulva. It occurred in a single woman, of gaunt, spare habit, aged sixty-one, who was admitted into St. Luke's Hospital during my service in 1869, with the history of intense pruritus vulvæ running back for many years. She stated that she had had the latter since the age of sixteen; that many things had been tried and failed; that to obtain relief she had used opiates, at first in moderate quantities, but now required ten or twelve grains of morphine daily to quiet her. So severe had been her sufferings that she underwent an operation for the removal by excision and galvano-cauterisation of the mucous membrane covering the labia minora, with but moderate temporary benefit.

'On examination, the vulva was found to be extremely sensitive; vaginismus was also encountered, but forced introduction of the speculum showed the parts beyond healthy, the uterus being the subject of senile atrophy. Starting from the fourchette, and running upward, nearly covering each of the labia minora, and merging insensibly into the normal mucous membrane, was a long irregular patch of a pearly-blue colour, covered by a tenacious secretion of the same colour, which could be partly wiped off, showing thin minute islands, some circular, some irregular in shape, through which the reddened subjacent tissue was seen. The adjacent labia majora were also slightly involved. These opaque patches, or rather

patch (for it was all one) were appreciably thickened and very sensitive to the touch. The follicles of the vulva were in many places enlarged and prominent. A variety of local applications were tried without avail, and she left the hospital, to return in 1870, within eighteen months, with well-marked epithelioma of the vulva, which part was afterward removed *en masse* by Dr. Gurdon Buck.

'While it is acknowledged that the diagnosis of ichthyosis is made retrospectively, yet its characters are now so plain that I feel justified in recording it here.

'At the time of the first operation, which was performed at the clinic of the College of Physicians and Surgeons of this city, Dr. Thomas observed a thick, cheesy, cream-coloured covering of the labia minora which could not be entirely removed by wiping or scraping. The odour was offensive. The vulva was not swollen, though studded over by prominent follicles. Dr. Thomas pronounced it follicular vulvitis, but considered it unique, and was not astonished to learn of its subsequent development into epithelioma. The early history of the case is to be found in the *American Journal of Obstetrics* for May, 1869.'

In his general opinions with regard to the relative frequency of the disease in men, the various forms of irritation which may give rise to it, the difficulty of treating it successfully, and the tendency which it shows to become cancerous, Dr. Weir agrees in the main with those who have previously written on the subject.

W. FAIRLIE CLARKE.

GUIBOUT ON THE TREATMENT OF PSORIASIS. Under the influence of M. Broussais's ideas, Rayer employed blood-letting, leeches, and diet for this affection, and every kind of pommade and ointment have been recommended for its treatment. Petroleum oil and essence of turpentine have only succeeded in complicating matters by an inflammation of the skin, which necessitates treatment, M. Lutz, the apothecary at the St. Louis Hospital, had recommended the following lotion:

Bisulphuret of sodium and antimony . . .	30 grammes.
Water	1 litre.

This treatment, however, brought on vomitings, and an enormous redness of the skin of the whole body, as the only local result. The treatment which has been found to answer best at the Saint Louis Hospital consisted of frictions with pure juniper tar. These frictions must be carefully made twice a day, not only until the squamæ and the elevations have disappeared, but even until every trace of discolouration has disappeared. The duration of the treatment varies from two months to a year and more. At the same time alkaline baths, containing from 800 to 1000 grammes of bicarbonate of soda to each bath, must be used. When the patches are thick, it is advantageous to cause the bath to be preceded by a douche vapour bath, so as to make penetration easier. All skins will not support frictions of juniper tar, and pain and swelling will supervene; the frictions must then be suspended, and vapour baths, emollients and poultices only should be used. When the inflammatory condition has subsided, the use of the juniper tar must be resumed in one of the following formulæ:

Oil of sweet almonds	100 grammes.
Juniper tar	20 to 40 "

Glycerinum amyli	100 grammes.
Juniper tar	15 to 30 "

The best internal treatment is arsenic, which M. Guibout gives either in solution or in pills, giving the preference to arseniate of soda; for pills he prescribes:

Arseniate of soda	1 milligramme.
Extract of gentian	10 centigrammes.

This is sufficient for one pill, of which from six to twelve daily should be taken. The solution he prescribes is:

Arseniate of soda	10 centigrammes.
Distilled water	500 "

About half an ounce of this solution is equal to two of the pills. When M. Guibout prescribes arsenic he always recommends that it should be taken in the course of meals, and that the dose of twelve milligrammes per diem should not be exceeded.

REVIEWS.

On the Medicinal Treatment of the Unborn Child.

By J. THORBURN, M.D. Manchester, 1875.

In this small treatise, which the author aptly calls 'suggestions,' he discusses very temperately the effects of therapeutics on the intra-uterine life of the child, so far as they are known, instancing the well-known effects of mercurial treatment of the mother in syphilis, and of the chlorate of potash, as advocated by the late Sir James Simpson, in cases of intra-uterine death, which that writer thought to be dependent upon defective oxygenation of the blood. He considers also the physiological and the therapeutical effects of strychnine and chloral upon the fœtus. In those cases where an hereditary constitutional delicacy exists in the mother, and sickly, puny, strumous children are begotten, he considers that medication, in the form of steel and cod-liver oil, may have marked effect and benefit. One case is given in point, where a mother, who had previously had two fair delicate children, and was under treatment during gestation with her third for severe uterine hæmorrhages, iron being much used, gave birth to a fine, dark-complexioned, black-haired child; a later child, before whose birth no such treatment was adopted, was fair and died of morbus coxarius. Although firmly convinced in his own mind of the efficacy of large doses of iron during child-carrying, still he feels his cases are not numerous enough to carry conviction perhaps to a sceptic. The subject Dr. Thorburn regards as one well worthy of further investigation, and feels convinced it will open up a wide field of most useful information; and he suggests mercurial disease as one in which experiments might be made.

W. C. GRIGG, M.D.

A Treatise on Cutaneous Medicine. By H. S. PURDON, M.D. Belfast, 1875.

This consists chiefly of lectures delivered at the Belfast General Hospital, and will doubtless prove useful to those for whom it is more immediately designed.

NEW INVENTION.

NEW INSTRUMENTS FOR CLOSING THE VAGINA AND BREASTS.

M. Borin of Lyons, in order to obviate the inconveniences arising from the use of pessaries, has invented a new kind of instrument (fig. 1), to which

FIG 1.

he has given the name of *fermoir vulvo-vaginal*. This instrument is very easy to use, and patients soon become accustomed to wear it. They are able, after having applied it, to pursue their ordinary occupations, whilst pessaries necessitate inaction. M. Borin also laid another instrument of the same kind before the Paris Academy of Sciences, which he calls *fermoir des seins* (see fig. 2). This instrument

FIG 2.

may also be used to cure incontinence of urine. The urine escapes in consequence of the weakness of the vesical sphincter and the too great contraction of the bladder. By enclosing the end of the prepuce in the forks of the instrument, the flow outwards is prevented. The urine accumulates between the prepuce and the gland and eventually bring on contractions, which awake the patient. This instrument may also be employed in blennorrhagic affections, when it is desired to retain a topical or any other liquid in the canal.

'THESE BE BRAVE WORDS.'—The *Gazette de Pharmacie* is good enough to inform us that M. Haydach has analysed orthoamidotoluene-sulphonic acid and diacorthoamido-paratoluene-sulphonic acid; and also affirms that the action of pewter and hydrochloric acid on nitrobromacetanilide produces hydrochloride of ethenylbromophenylenediamite.

MISCELLANY.

DR. LYON PLAYFAIR has withdrawn his bill for restricting experiments on animals, on account of the appointment of a Royal Commission on the subject, the names of the members of which have not yet been published.

LORD DERBY, in presiding at the annual meeting of the Hospital for Consumption and Diseases of the Chest at Brompton, congratulated the governors on the improved position of the institution.

THE PRESERVATION OF EGGS.—M. Saree, a Professor at Neufchatel, has, says the *Revue Scientifique*, found out a plan for keeping eggs. Whilst they are fresh he coats them with paraffin, and they are said to keep without any trace of change for two years.

THE LOSS OF THE 'SCHILLER.'—Amongst the list of deaths by the wreck of the *Schiller*, the name of Susan Dimock, M.D., will be observed with regret. This lady, who was well known as a physician in Boston, also held for some time the post of resident physician in the New England Hospital for Women and Children.

A TRULY MATERNAL GOVERNMENT.—The Council of State for Switzerland, under date of December 1, 1874, has issued a decree prohibiting the use of injurious substances in the manufacture of sweetmeats; a very proper, though a very minute precaution. Happy indeed must be that country whose statesmen can busy themselves with the composition of hardbake and bulls'-eyes. We recommend this example of the *dulce* and the *utile* to the consideration of Prince Bismarck, whose thoughts are lately supposed to have run more on needle-guns and cartridges than is good for himself or for the peace of Europe.

THE MEDICAL PROFESSION IN SPAIN.—The status of the profession in Spain has lately been the subject of legislation with a view to its elevation and improvement. By a decree dated April 2 last, whenever a professorial chair is vacant, three months' notice will be given, so that candidates may have time to prepare themselves. During that interval they must have submitted all their testimonials, writings and titles, and a document showing what mode of teaching has hitherto been adopted by each candidate, and what will be his plan in the future. The members of the electing jury are named by the minister. Two of them must be taken from the acting professors of the Faculty or School of Medicine; the five others are chosen from amongst the university or scientific bodies, to which the chair is affiliated. There are three examinations: 1. A verbal examination, in which the candidate is interrogated on ten questions. 2. A lecture of one hour's duration on a subject indiscriminately chosen; after which, each candidate may discuss the subject with his competitor for half an hour, the latter being allowed half an hour to reply. The candidates are, as far as possible, arranged in series of threes, but if a series should comprise but one candidate, the president must take up the discussion. 3. A lecture or verbal conference, of which the object is evidently to show the fitness of the postulant for the professorial chair. These lectures, of course, vary according as they are in connection with a chair of clinical medicine, pathology, or anatomy, and are practical or theoretical according to the chair to be filled. The judges are not allowed to take part in the voting unless they have been present at all the examinations. Candidates cannot be declared eligible until they have obtained a majority of votes, and they are classed according to merit. The documents are afterwards to be sent to the Board of Public Instruction, submitted to the Council of State, and finally to the Prime Minister. The novelty in these decrees consists in the foundation of the competitive examination with its various trials of knowledge, and in the composition of the jury, as nothing of the kind has hitherto been proposed in other countries.

THE London Temperance Hospital has now been nineteen months in existence, and at the annual meeting of its supporters it was reported that the treatment of disease without resort to alcohol had been prosecuted with fidelity and success. It is proposed to erect a new building on a plot of freehold ground in the Hampstead Road.

MIDWIVES IN RUSSIA.—M. Matuciev, a distinguished obstetrician of Kiew, has just established a kind of dispensary school for obstetrics, attached to the University Faculty of Medicine of the city. Pupil midwives who are legally admitted into this school will be deputed to give consultations and to attend poor women in their confinements at their own homes.

'EARTH TO EARTH.'—The declaration of opinion by the eminent men whose names are appended to the appended document should do much to set at rest the groundless fear of being buried during a state of suspended animation, which is but too prevalent amongst all classes of unscientific society. 'The following question, arising out of an apprehension admitted to exist, lest a curtailment of the interval now allowed between death and burial might lead to the accident of interment before life were extinct, has been proposed to us by Mr. Seymour Haden. "As hospital physicians and surgeons of extended experience, has it ever occurred to you to see a case of so-called suspended animation or trance, which in your opinion could be mistaken for death; and do you think, the present state of our knowledge and resources considered, that the occurrence of such a case, or of such a mistake, can be regarded as possible?" In reply to this question, we desire to say that no case of the kind it suggests ever presented itself to any of us, and to express our confident belief that the dread of the possible occurrence of such a case is without support in the medical experience of this country; and, further, that the signs of death are as certain after a few hours' suspension of the vital functions as they can be after many days. It would, we feel, be a matter of regret, and an indication of a low state of public intelligence, if the groundless fears to which our attention has been directed by Mr. Seymour Haden, should hinder for a moment the adoption of an improvement in our social system, the importance of which cannot be overrated.—George Burrows, M.D., President of the Royal College of Physicians; Wm. Fergusson, William W. Gull, M.D., William Jenner, M.D., James Paget, Thomas Watson, M.D.'

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

WEDNESDAY, JUNE 9, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

HUGHLINGS JACKSON ON NERVOUS DISSOLUTION, AS ILLUSTRATED BY EPILEPTIC MANIA.

Dr. Hughlings Jackson accepts the hypothesis of nervous evolution as stated by Spencer, and the hypothesis of reflex cerebral action of Laycock. Dr. Carpenter is, next to Laycock, the most able exponent of the latter doctrine, for which, however, he uses the term 'unconscious cerebration.' Dr. Hughlings Jackson uses the term 'dissolution' as the opposite of 'evolution.' Cases of disease of the nervous system, he considers, are strongly in favour of the verity of the two hypotheses mentioned. In the following paper the doctrine of dissolution is illustrated by cases of epileptic mania. The dissolution here is, Dr. Hughlings Jackson thinks, that the highest nervous processes are temporarily exhausted by an excessive, that is, an epileptic nervous discharge. It is just what, according to him, happens to a subordinate series of nervous processes when there is hemiplegia after a severe convulsion; then the corpus striatum is the part temporarily exhausted. The highest nervous processes are the anatomical substrata of consciousness. The principles here stated apply to cases of insanity, ordinarily so-called, as well as to the acute temporary insanity after epileptic paroxysms. In the former cases there is 'defect of consciousness,' and comparatively slight increase of mental automatisms.

It must be explicitly mentioned that the division into two elements, negative and positive, corresponds practically to a similar division made by Laycock about thirty years ago, and to one subsequently made by Monro. The increased automatic action on suspension of consciousness is, to use the words of Anstie and Thompson Dickson, due to 'loss of control.'

The following is from the abstract of the *Transactions of the Hunterian Society*, 1874-5.

In a case under the care of Dr. Woodman, a lad had paralysis of the tongue on the left side, paralysis of the left side of the palate, and aphonia from paralysis of the vocal cord. Dr. Hughlings Jackson has described cases of this kind with necropsies in the *London Hospital Reports*, vol. iv. 1868. He believes that the palsy of the palate and that of the vocal cords are certain warrant for the diagnosis of disease of the eighth nerve within the cranium, no doubt of the spinal accessory division of it which gives motor power to the pneumogastric. He does not believe that there is paralysis of the palate in uncomplicated disease of the portio dura nerve, as many physicians suppose.

After mentioning in his paper several modes of connection of mental conditions with epilepsy, Dr.

Hughlings Jackson said that he should consider only temporary mental disorders immediately following epileptic paroxysms. The parts of the paper read were chiefly made up of reports of cases. In this abstract of what was prepared for reading, the several principles which the cases were intended to illustrate were stated.

The condition of mind after such paroxysms is duplex. There is (1) negatively, the passive symptom of loss of consciousness; as well as (2) positively, the active symptom, mental disorder. The loss of consciousness is the most important symptom. There are, after paroxysms of different degree, all degrees from very transient, slight confusion of thought (defect of consciousness), to deepest coma; degrees corresponding to the quantity of the highest nervous centres suddenly put *hors de combat*. With regard to the positive, or active element, Dr. Hughlings Jackson did not limit himself to speaking of epileptic mania; he pointed out that the abnormal conditions after paroxysms varied in degree from a slight departure from normal actions to seemingly objectless fury. Otherwise regarded, they varied in degree from actions which were often in themselves trumpery and mere caricatures of innocent normal actions to coarse and violent actions; as, for example, purposely smashing of furniture, and unprovoked murderous assaults. It was therefore, he thought, necessary to have a term of more inclusive meaning than epileptic mania. All the actions, whatever their kind or degree, had the common character of being automatic and unconscious. Hence he used the general expression, 'mental automatism.' The term was useful for what it implied; the actions being automatic and unconscious, the 'agents' were irresponsible. Dr. Hughlings Jackson insisted that the slightest cases (*i.e.*, cases in which the actions are but slight caricatures of normal actions) are the most important. They are so in two ways. As experiments on the organ of the mind, they are more easily analysed, and thus they are of greater scientific value. Then, practically, they are important because from the consideration of the automatic actions in these cases, we can prove that elaborate and highly compound actions may be done unconsciously by epileptics after their seizures. Thus, we could more easily convince the laity of the possible irresponsibility of some particular epileptic lunatic, whose mental automatism had resulted in murder under circumstances at first glance suggesting design. Dr. Hughlings Jackson insisted, that both for scientific purposes and for the practical purpose just mentioned, our first task is to note, not so much the enormity, nor the violence, or speaking generally, the 'importance' of the mental automatism, as the complexity of the actions gone through; and again, the absurdity or insanity of the actions. He related the case of a man whose mental automatism was that he mixed cocoa in a dirty gallipot intended for cat's food, with a mustard spoon. This, although in itself a trumpery action, was a far more elaborately compounded action done unconsciously, than the simple headlong fury of many epileptic maniacs. It is just as much so as buttoning the waistcoat is a more highly compound manual action than striking a heavy blow with the fist. The cocoa-mixer went to a cupboard to get a spoon, as he might have gone to another room for a poker. The whole action was determined by a conversation held just before the attack. The slighter the discharge, and consequently the shallower the dissolution after-

wards, the higher in kind would be the mental automatism, that is, the actions possible would be more special, more highly compounded, and more easily guided by external circumstances. This obviously has a practical bearing, for it amounts to saying that actions, which from their elaborately compound nature would look conscious and voluntary, may be automatic doings occurring after a fit too slight to attract attention. On the other hand, the more deeply the brain is affected, the less special the actions, the less highly compounded, and less guided are they by external impressions. Thus maniacal fury is action of a more general although of a more violent kind; it is less complex although more important to bystanders, and less guided, although perhaps, more easily excited by external circumstances.

For purposes of illustration, several degrees may be arbitrarily assumed. 1. If the dissolution be very slight, the patient's mental automatism represents more or less what he was about to do, what he had been talking of, etc. 2. If it be deeper, it refers to some fixed habit, his occupation for example. 3. If it were deeper still, the lower strata of the man's disposition would crop up. 4. If it were still deeper, all mental processes would be affected, and the automatism would be no longer mental but physical, there would be coma.

A CASE OF CONGENITAL ANAL OCCLUSION OF AN UNUSUAL KIND.

By the late SUSAN DIMOCK, M.D.,
Resident Physician to the N. E. Hospital for Women and Children.

WITH AN OBITUARY OF THE AUTHOR,

By MARY PUTNAM-JACOBI, M.D.,
New York.

Nora N—, a mulatto child aged eleven years, was brought to me in summer for examination, with a view to an operation for incontinence of fæces. From the rather imperfect history given by the aunt of the little patient, it appeared that at birth the anus was imperforate, with, however, a fistulous opening in the perineum. Within the first week after birth, she was operated upon at the Massachusetts General Hospital by Dr. S. Cabot, with whose kind permission I insert the record of the case. While there, a diagnosis was made of congenital constriction of anus, the passage being pervious, admitting a full-sized probe. A small sponge-tent was introduced and retained in place by adhesive strips. Next day a no. 12 bougie was introduced. The opening was then considered large enough and the patient was discharged. She was re-admitted to the hospital a short time after, on account of the opening being insufficient for the demands of nature, and an operation was now deemed necessary. Upon further examination the case was decided to be one of congenital occlusion of the anus. The place where the true anus should be was marked by a depression and discolouration of the skin, but no opening existed there. One inch in front was the fistulous opening enlarged by Dr. Cabot, through which the fæces were discharged. A large silver probe was introduced into the false anus, and carried back as far as the centre of the depression in the direction of the true anus. With the probe for a guide a + incision was made through the skin. The mucous membrane exposed by the incision was then united to the edge of the wound by means of three sutures. A small roll of

cloth, well oiled, was introduced into the anus and left for a short time. Fæces continued to pass through both openings, when the patient was discharged.

The passage of fæces has always been involuntary, and the action of the bowels very irregular, there being sometimes no movement for a week, and at other times as many as twenty-four discharges in a day, while, whether constipated or otherwise, there is no voluntary control over the passage.

Upon examination, I found two openings into the rectum, one (the artificial opening) where the anus is normally found, large enough to admit a goose-quill, the other opening through the perineum about three-quarters of an inch in front of the first, and large enough to admit the fourth finger. The child being very nervous, very sensitive, poorly nourished, and slightly feverish (the temperature ranged from 99° to 100° Fahr. during several evenings when it was observed), all operation was deferred, and nourishing diet and out-of-door play recommended during the summer.

In September the patient entered the New England Hospital for Women and Children, and upon the 13th was etherised for thorough examination and such operation as should show itself advisable. I had hoped that the contraction of the artificial anus might be owing to the sphincter, and might be overcome under the influence of ether, in which case a closure of the congenital fistulous opening would remedy the evil, but I found that the anus remained impervious to the finger, a tense cicatricial ring preventing the least dilatation, while water injected flowed constantly from both openings, showing the entire absence of any sphincter action.

Under these circumstances, the best thing seemed to be the division of the bridge between the two apertures, and I hoped that the one large opening thus formed might become small through cicatrization of the cut surfaces, and that even perhaps later a tolerable sphincter might develop itself through use, as is often the case. I therefore divided the bridge of the perinaeum without much bleeding, the tissue cutting like cicatrix, and the cut surfaces, which were half an inch in diameter, retracting immediately to a line. The opening thus formed was large enough to admit with ease four fingers, but to my surprise and great pleasure began to contract visibly and take on the folded appearance of a normal anus, so that after the lapse of ten minutes a quart of water being injected was retained perfectly, and only ejected with the use of a Sims' speculum. The after history of the case confirmed the most favourable anticipations; the wounded surfaces healed rapidly, there was no fever again, and not the least involuntary defecation. During the first week the bowels were moved by enemata, but afterwards naturally, and by September 21 the child was discharged well.

The question naturally arises as to the exact nature of the malformation. It seems to me that we can exclude here the usual atresia of the rectum caused by deficient development of the anal end, which, as embryonic investigations show, starts from the skin and stretches upward toward the rectum. For in such case the sphincter, which shares to some extent in the deficient development, could not have attained so perfect an action in so short a time. Neither can the anterior opening have been of the fistulous nature which is usual in many cases of aproctia, for even after opening the true anus the fæces continue

to discharge involuntarily through the fistula, which is of course without sphincter. But in our case the anterior opening, the artificial anus, and the divided surfaces, all contracted regularly and alike into one round aperture with sphincter action everywhere. Are we not, then, justified in considering this case one of embryonic ulceration and adhesion of the nates near the anal opening, an adhesion complete posteriorly, but leaving anteriorly a canal between the bridge thus formed and the perinæum, which canal passed backward into the anus? With this view of the case, the mechanism by which the sphincter was kept powerless for so many years is easily explained. Draw together, as illustration, the commissures of the mouth, and the action of the orbicularis oris will be so far prevented that at least no liquid can be retained in the mouth. The adherence of the skin at the margin of the anus drew together the sphincter laterally, and rendered its circular action impossible. When this strain was taken off by the division of the bridge, the sphincter naturally assumed its normal action.

The above article was entrusted to Dr. Mary Putnam-Jacobi, of New York, for publication, by Dr. Susan Dimock, just before her departure for Europe in the ill-fated *Schiller*. Dr. M. Putnam-Jacobi also furnishes the following obituary to the *New York Medical Record*.

'Dr. Dimock graduated with honours at Zurich after the prescribed four years' term of study. Her thesis was written on the cases of puerperal fever she had had an opportunity of observing in the wards of the hospital. She has been practising medicine in Boston a little over two years, but in this short time has already won for herself a deserved reputation among some of the best surgeons in the city. As resident physician at the New England Hospital, she has already performed many important surgical operations. A case of vesico-vaginal fistula was published in your columns some months ago. Last fall, while on a visit to Boston, Dr. Dimock showed me the photographs of another hospital patient, from whose neck she had removed a large sarcomatous tumour. The operation had been performed in the presence of the students of the hospital and of Dr. Cabot, consulting surgeon. After reading the record of the case, I mentioned a precisely similar operation that I had seen performed by Richet in the Clinique at Paris, and the lecture, in which he described the great difficulties of removing a tumour deeply imbedded in so dangerous a locality. The professor had seemed not a little proud of his own success in coping with these difficulties, and had taken care that a numerous auditorium should witness his triumph. At this Dr. Dimock laughed, and said, "I was asked why I had issued no invitations, but I had forgotten all about them." She added, "Indeed I have too little personal ambition to care who sees, when I am once assured my work is well done." The remark was characteristic of the modesty and simplicity that distinguished the young surgeon. She was as fresh and girlish as if such qualities had never been pronounced by competent authorities to be incompatible with medical attainments. She had, indeed, a certain flower-like beauty, a softness and elegance of appearance and manner, such as is abundantly lacking in the women most eager to denounce surgical accomplishments as outrageously unfeminine. I have wondered whether she did not resemble Angelica Kaufman. Underneath this soft-

ness, however, lay a decision of purpose, a Puritan austerity of character, that made itself felt, though unseen. "She ruled her hospital like a little Napoleon," said a lady who had been there under her care. The ideal steadfastness, which is only possible in characters of this kind, was shown to me at my first interview with her, when she came—a girl scarcely out of her teens—to Paris, on her way to Zurich. We urged her to spend a few days in the capital, for the sake of the recreation to which American students usually consider themselves entitled before they settle down to their studies. Miss Dimock alone refused, for the reason, which she gave with the utmost frankness, that she had been obliged to borrow money in order to prosecute her studies, and should not feel justified in spending a cent of it for amusement or sight-seeing. She put forward all amusements into the future, until she should have won her university degree, and should have fulfilled a pledge of hospital service in Boston. Towards this horrible voyage of April, 1875, converged the pleasurable anticipations of nearly seven years. Among all the bright lives that have been engulfed in this dreadful shipwreck, none is more valuable than hers. Perhaps no woman's life of equal social value has met this tragic fate, since the body of Margaret Fuller was washed ashore on the western coast of the Atlantic.'

THE DISCUSSION ON FERMENTATION IN THE FRENCH ACADEMY.

The discussion on fermentation in the French Academy of Medicine is worthy of a passing notice, in view of the recent debate at the Pathological Society. We may best seize upon the salient points of the discussion, by concentrating our attention upon one of the brilliant speeches delivered by M. Pasteur, the distinguished author of the germ-theory of fermentation, and by noticing the objections urged against his arguments by his critics. It is admitted on all sides that germs cannot penetrate under ordinary circumstances through the shell of a common hen's egg, and this renders it very probable that experiments on eggs will lead to important results in determining the part played by organisms in the production of fermentation and putrefaction. M. Gayon has been for some time conducting experiments on eggs in M. Pasteur's laboratory, and under his superintendence; and the latter thought that the results obtained greatly favoured his own views. M. Pasteur asserted that, in every putrid egg examined by M. Gayon, organisms were found in large numbers. On the other hand, M. Colin denies the constant association of organisms with putridity in the eggs. In eggs which were examined by them together in M. Pasteur's laboratory, M. Gayon pointed out myriads of organisms which he regarded as bacteria, but M. Colin asserted that the particles he saw were not organisms, but mere specks of albuminoid matter exhibiting Brownian movements. He also affirmed that M. Gayon can only find the constant association of putridity with organisms by a too rigid definition of a rotten egg. M. Gayon, he says, will not call an egg rotten until the smell is so offensive as to show that it is in an advanced state of putrefaction. Hence the constant association of organisms and of putrefaction in this narrow sense, even if proved, does not show that the former are the cause of the latter. Both may be the effects of a prior change in the egg, a change which is independent of organisms,

and which ought to be taken into account, whether it be called putrefaction or not.

If organisms be found in putrid eggs, the next question is, how did they originate? The panspermists (of whom MM. Pasteur and Gayon may be taken as the representatives) say that they have been derived from germs which have penetrated from without; while the heterogenists maintain that they have been evolved from within.

M. Gayon thinks that germs may gain access into the interior of the egg in two ways; 1. By passing up the oviduct and reaching the egg before the shell is formed; 2. By passing through the shell under special circumstances. The arguments upon which he relies to show that germs penetrate in the first way are, that organisms have actually been observed in the lower end of the oviduct, and that spermatozoa must pass up in order to gain access to the egg. On the other hand, the unreliable nature of these arguments was pointed out by M. Colin. With regard to the second mode, M. Gayon says that, although germs cannot pass through the shell under ordinary circumstances, yet, by altering the pressure from the exterior to the interior, he has succeeded in making bacteria pass through in large numbers. He placed an egg in a vessel full of water, and put it under the exhausted receiver of an air-pump. The result was that gas became disengaged at various points in the shell; and on re-establishing the atmospheric pressure, water, carrying with it numerous bacteria, when they were present, penetrated through the pores of the shell. M. Colin replied that the conditions of the experiment were such as to form cracks in the shell for the admittance of both water and bacteria.

The next question with regard to the putrefaction of eggs which was hotly contested was, whether all eggs become putrid after a shorter or longer time. If putrefaction of eggs be an exceptional event, then it is more likely to depend upon the accidental introduction of germs from without; while if it is a constant and never-failing occurrence, it must depend upon general causes, and will most probably be of the nature of a chemical change independently of organisms. It is not surprising, therefore, to find the panspermists declare that only a small proportion of eggs putrefy, and the heterogenists that all eggs become putrid. M. Pasteur says that in a large number of eggs kept by M. Gayon for a long time putrefaction was an exceptional event. M. Gayon, according to M. Colin, found that from 33 to 75 per cent. of the eggs became putrid; and this shows that the event is not so exceptional as M. Pasteur asserted; and even this number would be largely increased but for M. Gayon's restricted definition of a putrid egg. But if to the eggs which had putrefied were added those which had become mouldy, those which were altered by the alcoholic and acid fermentations, those in which crystals of tyrosine had developed, and those which were mummified, and in which the embryo was macerated, the percentage of the eggs which had undergone changes closely allied to putrefaction was so largely increased, that very few sound eggs were left. Even M. Colin admitted that a few eggs were still left which had not undergone a change; and M. Pasteur triumphantly declared that he could exhibit eggs which were kept upwards of three years, and which were now perfectly unaltered. His opponent, however, maintained that these have been preserved from putrefaction only because they were kept at an uniform temperature of 77° Fahr.,

and that all of them would have putrefied had they been kept at a temperature of 104° Fahr. He also said that, if eggs be placed under the hen so that their embryos begin to develop and then withdrawn, so that the embryo dies, all of them will putrefy. Nay, even if they be shaken so that the white and yellow are mixed, every one without exception will putrefy. These proceedings do not alter the shell, and therefore it cannot be supposed that germs have penetrated; and yet all the eggs so treated will undergo putrefaction; and this shows that the change in question depends upon general causes and not upon the presence of organisms.

Such, then, are the main arguments and replies of the advocates and opponents of the germ-theory respecting the putrefaction of eggs, and we do not see that any definite result has been obtained, or that victory can be claimed by either of the combatants. The assertions and counter-assertions respecting the presence of vibrios in ammoniacal urine were similar in principle to those respecting the putrefaction of eggs, and are equally barren of definite results, and they need not, therefore, detain us.

Probably the most interesting part of the discussion was elicited by a question put by M. Bouillaud to M. Pasteur, the reply to which led the latter to give a graphic and eloquent description of the successive changes and fermentations which occur when a quantity of grapes are placed in a vat and exposed until the whole of the organic matter is returned to the atmosphere in the form of various gases, and the inorganic to the soil in the shape of various salts. M. Pasteur's general conclusion is, that there are two kinds of organic ferments: 1. Organisms which live and multiply in the absence of air, and take their oxygen from organic solutions, such as that of sugar; 2. Organisms which fix free oxygen upon the organic matter and burn it as surely though more slowly, as it is burnt by fire. He admits that there is a third class of ferments, such as *diastase*, which oxidise animal matters directly, without the intervention of organisms. Of these three ferments, however, the first is, according to M. Pasteur, the only true ferment. 'La fermentation est liée à la vie sans air.' M. Pasteur's critics were not slow to notice that this formula is incompatible either with known facts, or with the theory of fermentation which regards microscopic organisms as the cause of the chemical change. After noticing the researches of MM. Lechartier and Bellamy on the formation of alcohol and carbonic acid in fruits without the intervention of microscopic organisms, M. Poggiale said that M. Pasteur's definition of fermentation would comprehend processes set up by the elementary cells of the higher plants and animals, as well as those caused by certain unicellular organisms. Instead of denying this, M. Pasteur accepted the position, and claimed the facts brought to light by the researches of MM. Lechartier and Bellamy as a striking proof of his theory; only his theory, in order to include the new facts, would now require to be enlarged and extended. In short, he has now virtually abandoned the *germ*-theory, and has advanced what may be called a *vital*-theory of fermentation. According to this new theory, whenever we have life carried on in the absence of free or dissolved oxygen, we have fermentation, and whenever we have fermentation, there is life in the absence of air. Hence every mutation of tissues which takes place in the absence of free oxygen is essentially a fermentation.

M. Pasteur now passed on to apply this theory to the elucidation of the nutritive changes which occur in the higher organisms. He first related a very interesting observation made on yeast-cells, which are true ferments living in the absence of air. But if these cells be entirely deprived of either free or dissolved oxygen, they cease to multiply actively, become granular, and many die, everything showing a lowered state of nutrition. But if a small quantity of oxygen be allowed to gain access to the cells, even such a small quantity as would be dissolved by pouring the fermenting liquid from one vessel into another, the activity of the cells becomes greatly increased, they multiply more rapidly, lose their granular aspect, and act much more energetically as ferments, and this activity continues for a long time without any fresh supply of oxygen. This observation shows that, although free oxygen is not a necessary element to the nutrition of the yeast-cells, yet it does give a certain impulsion to their vital activity—in other words, stimulates the irritability of the cells. M. Pasteur thinks that essentially the same thing occurs in the tissues of the higher animals. Cell-life is constantly carried on without either free or dissolved oxygen, and hence results true fermentation; while in the short interval between two inspirations, the cells have access to free oxygen, which acts as a stimulus to their nutrition. Animal heat, therefore, owns two main sources; that produced by the combustion of free oxygen, and that resulting from the decomposition of fermentable matters. Such, then, is M. Pasteur's new theory of fermentation, and his application of it to physiology. But, although he regards the process set up by living units in the absence of air as the only true fermentation, yet he admits that microscopic organisms, such as bacteria which live on the surface of organic solutions, and to whose nutrition free oxygen is essential, are ferments; and if they be, surely the process set up by them is essentially a fermentation. If, then, the process set up by living units, which require for their nutrition the presence of free oxygen, be a fermentation, as well as that caused by those which live in the absence of air, life itself is, as one of M. Pasteur's critics pointed out, only an universal fermentation. But M. Pasteur also admits that chemical agents which oxidise organic matters directly, such as diastase, are ferments; and the process set up by these also must be a fermentation. By implication, therefore, he allows that fermentation is a general process, including various varieties, which may be grouped under three principal kinds. In short, the words 'ferments' and 'fermentation' are used both in a generic and in a specific sense, and frequently even the same speaker does not consistently employ them in any one sense. If distinct names were given to all the processes which may be embraced under fermentation in its generic sense, and a definite sense given to those names, it would be seen how largely the debate in the French Academy, and the recent debate on the germ-theory at the Pathological Society, turned upon the ambiguous use of words.

JAMES ROSS, M.D.

DECOMPOSITION OF TALLOW.—According to the *Revue Scientifique* of May 22, M. Marticorena, a manufacturer of San Sebastian, has observed that tallow is easily decomposed by salt water. Having bought some tallow which had been for some time immersed in sea water, he had it washed and pressed, and thus obtained stearic and oleic acids.

ANATOMY AND PHYSIOLOGY.

CALORI ON SOME BURSAE MUCOSÆ CORRESPONDING TO THE TRACHEA, LARYNX, AND CERTAIN ADJACENT PARTS.—Professor Luigi Calori describes in the *Memorie dell' Accademia delle Scienze dell' Istituto di Bologna* (series iii. vol. v. 1874) certain synovial sheaths which he has found within the thorax.

One form of bursa is described as lying between the aortic arch and the lower extremity of the trachea; and the author terms it *aortico-tracheal*. It is situated behind that portion of the arch of the aorta from which the three principal arterial trunks arise. It is rather large, reaching about as high as the corresponding portion of the arch of the aorta, and being as wide as the lower end of the trachea. It is so firmly united to the aortic arch that it cannot be separated; it is less adherent to the trachea, from which it is easily stripped off; and is enveloped in abundant loose connective tissue. In front of this bursa Dr. Calori has sometimes found a second—an arrangement analogous to the prepatellar bursa. In some rare instances, above the aortico-tracheal bursa, towards the left side, is another small bursa corresponding to the left common carotid artery. Dr. Calori observes that, when the pericardium is prolonged behind the aortic arch, especially towards the left, the aortico-tracheal bursa mucosa is smaller. The bursa was met with in thirteen out of forty bodies. Dr. Calori regards it as facilitating the movement of the aortic arch on the trachea.

The second bursa mucosa is situated between the trachea and the isthmus of the thyroid body, and is met with a little more frequently than the aortico-tracheal bursa. It is found immediately below the isthmus of the thyroid body, and insinuates itself somewhat between that isthmus and the trachea, and sometimes ascends nearly to the upper margin of the isthmus. It is covered anteriorly by loose connective tissue. Its union with the corresponding tracheal rings and with the posterior aspect of the isthmus is close. It varies in size; but its transverse diameter is generally a little below, and its vertical a little above one-third of an inch. It is usually single; but in one case, in which the isthmus was incomplete, it was double; the two bursæ lay side by side, separated in the middle line by a septum. Dr. Calori purposes to call this bursa the *thyro-tracheal*. Its evident function is to diminish the friction between the trachea and the thyroid isthmus.

The third bursa lies between the crico-thyroid muscle and the thyroid gland, and is also in contact with the upper rings of the trachea. It may be called *crico-thyroid-thyroid*. It is found on both sides, and does not belong to the isthmus, but to the lateral lobes of the gland. It is very thin where it covers the external surface of the crico-thyroid muscle; but becomes somewhat thicker where it covers the cricoid ring, the upper ring of the trachea, and the corresponding portion of the internal surface of the lateral lobe of the thyroid gland. Superiorly and internally it is in relation with a branch of the superior thyroid artery, from which the crico-thyroid artery proceeds. It serves to remove the slight difficulty which the supraposition of the thyroid gland would place in the way of the free action of the crico-thyroid muscle.

In some cases the bursæ are represented merely by loose and rather soft connective tissue. They present the ordinary structure of bursæ mucosæ or synovial sheaths.

The paper is illustrated by five lithographic figures.

A. HENRY, M.D.

BOCK AND HOFFMANN ON DIABETES.—C. Bock and F. A. Hoffmann (Berlin, Oliveri, 1874, 8vo, pp. 70) communicate the results of their experiments on the normal quantity of sugar in blood of rabbits. Well nourished animals, simply tied down, always showed in their blood taken from the heart or from an artery, from 0.07 to 0.11 per cent. of sugar, which was estimated by Fehling's solution. Only when artificial respiration was kept up by pressure on the abdomen (on the liver) did the quantity rise in the cardiac blood to 0.2 per cent. By an ingenious experiment, the authors show that the sugar found arises from the liver and from the lymph of the intestinal canal. From other experiments, it is very probable that glycosuria depends upon increased activity of the liver. After puncture of the fourth ventricle, the quantity of sugar in the blood rose abnormally high during the first hour (to 0.29 per cent.). If in the second hour, where already sugar was distinctly found in the urine, the liver was excluded, in six out of eight experiments the diminution of sugar was quite apparent; and the increase of sugar after the puncture is not to be ascribed to diminished destruction of sugar in the organism, but to a greater supply in the blood, probably arising from the liver.

LEWIN ON THE PRESENCE OF BILE-PIGMENTS IN THE URINE.—L. Lewin (*Centralblatt für die Medicinische Wissenschaften*, no. 6, 1875), remarks that Gmelin's reaction sometimes fails when instituted in the ordinary way. In a case of icteric urine, the author could not get satisfactory results, either by Huppert's method, or by the ordinary Gmelin's reaction, though by other signs it was very probable that the urine contained a large amount of bile-pigment. The urine was allowed to stand in ice for twenty-four hours, when a deposit, intensely reddish brown in colour, separated, which proved to consist of uric acid salts. On applying Gmelin's test to a solution obtained by gently warming the sediment, the characteristic reaction was at once obtained. The filtrate did not give the reaction. The bile-pigment was in this case united either mechanically or chemically to the urate. The author, therefore, recommends the precipitation of the uric acid salts by the action of cold, and then the application of Gmelin's test to the dissolved sediment.

HOPPE-SEYLER ON A SIMPLE PREPARATION OF URINARY PIGMENT FROM HÆMOGLOBIN.—Hoppe-Seyler (*Berichte der deutschen Chemischen Gesellschaft*) formerly observed that on heating hæmatin in alcoholic solution with tin and hydrochloric acid *i.e.* by reduction, a splendid colouring matter is formed. This colouring matter is identical with hydrobilirubin (Maly) and urobilin (Jaffe). Hæmoglobin itself similarly treated yields the same colouring matter, and it is shown that urobilin is a changed decomposition-product of hæmoglobin, and that bilirubin and biliuridin are intermediate stages in this transformation. The quantity of urobilin excreted within a certain time is the measure of the destruction of red blood-corpuscles.

WM. STIRLING, D.Sc., M.B.

PATHOLOGY.

DÉJÉRINE ON THE CONDITION OF THE SPINAL CORD IN A CASE OF TALIPES EQUINUS.—In the *Archives de Physiologie* for March and April, M. Déjérine describes the microscopical appearances found in the spinal cord of a well marked case of talipes equinus. After staining and clearing the sections in the ordinary manner, the following lesions of the grey matter of the vessels and of the neuroglia were noticed. About the lumbar enlargement, the right side, the same as that on which the deformity existed, the exterior portion of the anterior horn of grey matter was found to take the colour of the carmine more deeply than the rest. The nerve-cells, with the exception of one or two that had lost their processes, and were much atrophied, had disappeared from this portion of the horn. The vessels here, in comparison with those on the left side, were much increased in number, and their walls thickened. In the rest of the horn the structure was normal. These alterations were most marked at the middle of the lumbar enlargement; from that point, both upwards and downwards, they gradually disappeared, the dorsal region not being affected. The posterior horn of the grey matter was normal.

In the same portion of the cord, the white substance had undergone sclerosis of the right antero-lateral column. The lateral column also presented a band of cortical sclerosis about 0.6 millimètre (0.024 inch) in thickness. This condition of the white matter occupied the whole of the lumbar region, disappearing, like the lesion of the grey matter, above and below. The nerve-roots springing from this part were found to contain many tubes wanting in myeline; others had their myeline, but were much reduced in volume.

An examination was also made of those muscles which were affected in this case, the anterior muscles of the leg and the peronei. These were found to have undergone simple atrophy of the primitive bundles, the striation being preserved. There was also an increased production of connective tissue.

The points which the observer of this case thinks most important are the existence of the band of cortical sclerosis, and the marked limitation of the lesion in both the grey and the white matter.

W. KESTEVEN, JUN.

VON BUHL ON A CASE OF TWIN MONSTROSITY.—A female twin monstrosity was exhibited by Professor von Buhl, of Munich, at his pathological-anatomical demonstration on Feb. 6, 1875 (*Erstliches Intelligenzblatt*, no. 9, 1875). It had two heads and two bodies. There was union of the parts from the sternum to the umbilicus; the two breast-bones were fused into one, to which the ribs on both sides were attached. There was an umbilical hernia about 2.35 inches in circumference; hence proceeded one umbilical cord, to one placenta, which contained two arteries and two veins, which divided immediately on entry into the foetus. Each had an œsophagus and a stomach, which were fused into one duodenum, from which proceeded one jejunum, which in the region of the ileum formed itself into a wide sac, probably corresponding to the entry to the ductus omphalo-entericus; from this sac proceeded two ilea and colons, one for each individual. Meconium was

only found in one. The two livers were fused together posteriorly. The most important abnormality was the heart. It was evidently two moulded into one. It contained two ventricles, each of which had taken on the functions of a left and a right ventricle; with one auricle, corresponding originally to four auricles. By means of small valvular arrangements it was divided into two, which directed the blood into the corresponding ventricles. There was no septum ventriculorum; from each ventricle there arose one aorta and pulmonary artery. A small ductus Botalli was present on only one side. All the other organs were double. W. C. GRIGG, M.D.

MEDICINE.

KORNMÜLLER ON MELANÆMIA.—The Vienna *Medicinisch-Chirurgisches Centralblatt* for May 14, 1875, gives an account of three cases of pigmentation of the skin after intermittent fever, occurring in the practice of Dr. W. Kornmüller, of Karfreit. He remarks that such cases rarely occur in the Austrian Empire, even in the most malarious districts. The effects of malaria, or the results of exposure to marsh miasms, vary greatly with the particular district in which they occur, with the time of year and the constitutions and hygienic conditions of the patients. Particular epidemics also have their own special characteristics. In one epidemic the majority of cases are slight, easily curable, and of simple type. In another, most of the cases are of a severe kind, and always induce constitutional cachexia. In some epidemics we meet with an unusual number of malignant cases of malarial fever. Imperfect as is our knowledge of the etiology of these diseases, there is much that admits of rational explanation. For example, the malarial fever-district of Isonzothal, surrounded by a gigantic Alpine wall of mountains, is never properly ventilated; whilst the adjacent vast malarious region on the north coast of the Adriatic is thoroughly swept, so to speak, by storms from the south-east and north-east. There Italian colleagues say that pernicious forms are rare, but the malignancy of the malaria in the author's district is shown by three cases of melanæmia occurring in the spring of 1869 in his own practice.

Case I.—A previously robust and healthy young married woman, of the peasant class, came to him in June, 1869, to beg some ointment for the purpose of removing the horrible smutty and swarthy coloration of her skin. Having previously known her, he was greatly surprised at the change. It was the first case of melanæmia he had seen. Her skin was of a dark slaty grey, and on this ground-colour were numerous, thickly strewn, large and small spots and stripes of varying form, of brownish-black pigment; these were most abundant in the natural flexures of the skin, rendering it almost totally black in these situations, most conspicuously so at the wrists and ankles. The mucous membranes were of a light ash-grey; both liver and spleen were enormously enlarged, but the urine was free from albumen. The patient had suffered six weeks previously from a very severe intermittent fever of quotidian type. After three weeks use of domestic remedies the paroxysms ceased, but she still had occasional shiverings, great weakness and pallor. Fourteen days before Dr. Kornmüller saw her, she first noticed the pigmentation, which grew worse day by day. She

was now extremely weak, unable to stand, much emaciated, feverish, and without appetite; pulse 90. From noon to 10 P.M. her temperature rose from 99.4° to 102° Fahr.

Dissatisfied at not getting promise of immediate restoration to health, she once more resorted to quackery. After four weeks of this, she again sought qualified advice. The pigmentation and cachexia were intensified. Six weeks of iron, quinine, and liberal diet stopped all the febrile processes; her strength returned; there was no further destruction of blood-discs; and she once more enjoyed life, and did her work; sensibly renouncing her hopes of recovering the former brilliancy of her complexion.

The second case was in a yeoman, aged forty, from Pelfery, over the Italian border, and occurred in the same month. His skin was of the same dark colour, and he had enormous spleen and liver, after a short attack of severe intermittent of quotidian type. His urine was free from albumen. Iron, quinine, and good diet restored him to health and strength, but the colour remained unaffected.

The third case, a lad of a village on the Austro-Italian frontier, sickened at the beginning of May with a pernicious fever, which seems, from the imperfect history to have been of remittent type. Four weeks afterwards, cachexia set in, with oedema of joints. After some time he became weaker and weaker, his legs began to swell, and the skin to become pigmented. Day by day he grew darker. His liver and spleen were enormously enlarged; he had slight catarrhal bronchitis, and his urine contained much albumen. Iron, quinine, and good diet restored him to health, but his skin remained dark as before.

Dr. Kornmüller believes that iron is a specific for malarial anæmia, as quinine, in large doses, is for the malarious poison; but he thinks we are powerless to restore the skin to its pristine colour; for although we know the cause to be the breaking up, in large quantities, of red blood-discs, and the deposition of their hæmatin as pigment, we know no means which will produce absorption of this pigment.

[Has the constant current, say four or five cells, and tepid bathing, ever been tried?—*Rep.*]

W. BATHURST WOODMAN, M.D.

MILFORD ON CHOLERA TREATED WITH SUBCUTANEOUS INJECTION OF MORPHIA.—Dr. F. Milford relates the following two cases in the *New South Wales Medical Gazette* for March.

Case 1.—About 3 A.M. on the morning of November 23, 1874, I was called to Paddington, to see a lady whom I had been in the habit of attending for several years before. She had gone to bed about eleven o'clock, after partaking of a light supper, and about twelve o'clock complained of pain in the stomach. This symptom was soon followed by severe vomiting and purging. When I arrived, severe pain in the stomach, rice-water stools, coldness of the extremities, and periodic attacks of vomiting coming on at intervals of about ten minutes, were the most conspicuous symptoms. Upon ascertaining the exact nature of the case, I gave about half a drachm of laudanum and a tablespoonful of brandy mixed with half a wineglassful of water to my patient, who, immediately after swallowing it, rejected it by vomiting. I then gave, through the subcutaneous syringe, thirty minims of a solution of

morphia, which contained one grain of the muriate. The effect was immediate; the diarrhoea and vomiting directly ceased, and the patient, in about half an hour's time, fell off into a quiet and gentle slumber. 11 A.M. I saw her again, when I found that she had slept during the interval between this and my previous visit. There being still a slight inclination to vomiting and purging, I gave her one-third of a grain of muriate of morphia in aqueous solution subcutaneously. 8 P.M. On seeing her again at this time she stated that she felt quite well; that the purging and vomiting had quite ceased; that the epigastric pain had left her; but that she felt slightly hot and uncomfortable. From this time forth she progressed favourably, and although somewhat feverish, the utmost precautions having been taken by good nursing and diet, she rapidly recovered, and was, in the space of a fortnight, able to take a drive into town.

Case 2.—On Saturday, January 23, 1875, I was called, at 6 A.M., to see Mr. H., aged twenty-four. I found him in a cold sweat, pulse scarcely perceptible at the extremities, complaining of pain in the epigastrium, and constantly vomiting. He also stated that liquid motions were frequently running away from him. He was evidently in the collapsing stage of cholera. I returned home, obtained my subcutaneous injection syringe, and injected one grain of morphia in aqueous solution under the skin over the epigastrium. This was followed by most beneficial results; the diarrhoea ceased at once; the vomiting also became less; and in about half an hour afterwards, heat having returned in the extremities, the patient fell off into a quiet doze which lasted about two hours. About 1 P.M. I found the extremities warm, the pulse 100, skin dry and hot; vomiting continuing, but not so incessant; diarrhoea entirely ceased. I administered one-third of a grain of morphia again subcutaneously.

January 24. I saw him again twice to-day, and directed that a mixture containing nitrate of bismuth and morphia, should be given every four hours, as the vomiting still continued; light and nutritious diet, mutton broth, milk, arrowroot, etc.

January 27. He was much better to-day; the vomiting and purging had both ceased; the temperature was 98°. He had a gentle perspiration all over the skin; tongue clean; pulse 68°.

The administration of medicines either by the mouth or *per rectum* was entirely prevented by the nature of the complaint, and I was compelled to fall back upon the hypodermic injection of morphia; and now so satisfied am I with its use (having lost some cases of cholera in Sydney before where it was not used) that I shall exhibit it *cateris paribus* in every case threatening life for the future, unless I see some good cause why the remedy given in this form should be discontinued.

DE LA ROCHE ON PHTHISIS AND CLIMATE.—In a pamphlet issued from Pau (1875), Dr. Cazenave de la Roche combats some of the conclusions of Dr. C. Theodore Williams in his recent work on Phthisis. He first asserts that the application of figures in the practice of medicine is a method subject to serious mistakes, and which ought to be rejected as unphilosophical. It is not that they are elastic only; they do not take into account the individuality of the patient classed under any heading. While Dr. Williams says, 'the duration of the disease was calculated as well as the influence of the age,

sex, family disposition, and origin,' Dr. de la Roche incisively remarks, 'The form he does not mention.' Then he proceeds, 'Let us take two phthisical patients, one torpid, the other erethetic; and suppose we give the alkaline waters of Ems to the former, the sulphurous waters of Eaux Bonnes to the other, what will happen? A disastrous effect in both cases. Through its alkalinity the Ems water will diminish the plasticity and tonicity, already greatly reduced, of the blood of the torpid patient, whereas Eaux Bonnes, through its exciting properties, will exaggerate beyond measure the pyretic condition of the erethetic one; the consequence being in both cases the acceleration of the tuberculous progress. Must we then conclude that the waters of Ems and Eaux Bonnes are contraindicated and fatal in the treatment of tuberculosis? Certainly not. Who can prove, he asks, that the tuberculous patients mentioned by Dr. Williams as having been so seriously injured by their stay at Pau, Rome, and Madeira, did not belong to the category of the torpid patients; whereas the phthisic, whose condition was made worse under stimulating climates, were not erethetic tuberculous?' De la Roche attaches much importance to the adoption of certain places and climates to the form of the tuberculous affection in every case.

J. MILNER FOTHERGILL, M.D.

CORRAL ON THE TREATMENT OF TYPHOID FEVER BY QUININE.—The *Genio Medico-quirurgico* for March 15, 1875, contains the records of several cases of typhoid fever successfully treated by sulphate of quinine. In one case the patient was a woman, aged forty, who, one month after her husband's death, presented herself all the symptoms of the same disease. The usual treatment not having given satisfactory results, Dr. Corral administered sulphate of quinine in small doses for several days. This was followed by a great improvement in the general symptoms. The pulse was 98°, and the temperature nearly normal. Quinine was again employed, and its use was followed by a relapse which presented all the characters of intermittent fever. The same treatment was employed against the access, and the patient, after having had three new paroxysms of intermittent fever, entered rapidly on convalescence.

M. Corral has often employed quinine in cases of nervous and adynamic forms of typhoid fever. According to his experience, this alkaloid modifies the temperature and febrile state, and gives the disease the intermittent type.

TORRES ON INTESTINAL OBSTRUCTION SUCCESSFULLY TREATED BY GASEOUS ENEMATA.—Dr. Bernardino Torres, of Alcazar de San Juan, publishes the following case in the *Siglo Medico* for April 4, 1875.

Francisco Gonzales, aged eighteen, shoemaker, had typhoid fever, and was subject to frequent attacks of indigestion. On February 19, after much indulgence in a common aliment called *la cuaresma*, he was suddenly seized with a sharp pain over the abdomen and was unable to work. He went to bed and the symptoms increased. Paroxysms of abdominal pain were immediately followed by vomiting, which continued for three days and nights without ceasing, and in spite of soothing applications, narcotic enemata, and mixtures. On February 23, the patient was much worse, and vomited some yellow faecal matter; the abdomen was

ympanic and distended, but no tumour was discoverable; the extremities were cold, and the pulse scarcely perceptible. The patient, however, was a little relieved by a tepid bath, and the application of an enema with belladonna. On February 25, the face was sunken and pallid. The bowels were not open in spite of an energetic drastic treatment. A gaseous enema of bicarbonate of soda eight grammes, and tartaric acid four grammes, was prescribed. The general state was slightly improved the following day, and the vomiting decreased, but the bowels were not moved. The same enema was given three times a day during a week. The abdomen was smaller and the pain more supportable, but vomiting of faecal matter still continued. On March 4 the patient was again much worse. Another gaseous enema was prescribed, bicarbonate of soda thirty grammes and tartaric acid fifteen grammes. Its administration was followed by a sudden cry, retching and exhaustion, after which it was at once expelled, and a large quantity of faecal matter passed. The same enema was again given four hours later, and produced copious fluid stools. On the following day the vomiting and pain had ceased, and the abdomen was much smaller. On the 10th, the patient was quite out of danger.

DISEASES OF CHILDREN.

SINKLER ON THE PALSIES OF CHILDREN.—Dr. Sinkler (*American Journal of Medical Sciences* April, 1875) gives an analysis of a hundred and forty cases of the various forms of paralysis met with in childhood. Of these eighty-six were instances of so-called essential paralysis, twenty-three of cerebral hemiplegia, while the remainder included cases of several less important varieties.

With regard to the eighty-six cases of essential paralysis, Dr. Sinkler's observations show the following results. 1. They were almost equally divided between the two sexes, forty-two occurring in boys, and forty-four in girls. 2. Age exercises an important influence. In seventy of the eighty-six cases the attack occurred between the age of six months and three years, and in no instance under six months; while in forty-one it occurred between the first and second years, and in twenty between the second and third; 3. The season of the year plays an important part in the development of the disease. The time of year in which the affection commenced was noted in fifty-seven cases, and in all but ten of them the attack was found to have taken place between the months of May and September, *i.e.*, during the hot weather. 4. The attack may come on suddenly or gradually, without any previous symptoms, or it may follow a well-marked feverish attack, with vomiting, or convulsions, or symptoms of cerebral or spinal injury, or some acute disease. 5. Statistics of the

different limbs affected show, amongst other points, that Niemeyer's statement that this form of palsy is never strictly unilateral is erroneous. 6. In no case was there any paralysis of the bladder or rectum. 7. In all cases the sensibility of the affected muscles to faradisation was impaired or destroyed. 8. In nearly all the cases the children were otherwise healthy. 9. Prognosis was found to be favourable, in proportion to the earliness of the stage of the disease in which it first came under treatment. 10. Treatment consisted in leeching and counter-irritation to the spine at the first onset, with iodide of potassium; in the later stages strychnia, with shampooing and the slowly interrupted galvanic current. It was ascertained by experiment that, while galvanism raised the temperature of a palsied limb only $1\frac{1}{2}^{\circ}$, manipulation elevated it from 8° to 10° . Of the twenty-three cases of cerebral hemiplegia, ten were in boys and thirteen in girls. In eleven the left side was affected, in twelve the right. The age varied from three months to eight years. The patients generally were in feeble health. In two cases the affection was congenital; in three apparently due to injury by forceps during delivery; in two it was referred to embolism, and in four to convulsions; but in the majority of cases the cause was obscure, although in many instances assumed to be cerebral h morrhage. SURGERY.

CLEMENS ON TRANSPLANTATION OF SKIN.—In the *Berliner Klinische Wochenschrift*, no. 18, 1875, Dr. Clemens, of Rudolstadt, gives the results of some observations made on a case in which it was necessary, by reason of the extent of raw surface, to transplant about 120 pieces of skin. The subject of this case was a young woman aged twenty years, who had been scalded over nearly three-fourths of the surface of the body. The damage on the skin of the trunk seems not to have passed beyond the second degree of scald, but in the legs the epidermis had been quite destroyed, and extensive ulcers formed, from which there was a profuse and continuous discharge of pus. To these raw surfaces pieces of skin were transplanted, at first with no good results, but subsequently, on the application of a strong solution of nitrate of silver to swollen and unhealthy granulations, with complete success. Dr. Clemens found that the grafts placed on flabby granulations grew slightly, if at all; whilst those placed on granulations presenting a healthier appearance grew rapidly, stimulated cicatrization in surrounding parts of the ulcers, and speedily gave rise to the formation of a layer of normal epidermis. It was interesting, Dr. Clemens writes, to observe the behaviour of skin-grafts placed so closely together that their margins were in contact, and the granulations quite covered over. This method was practised over the tibiae, where the suppuration threatened to lay bare the bone at several spots. The skin-grafts,

thus placed in contact, united very soon and protected the bone. Where a graft had been placed on a lower level than its neighbours, the evenness of the epidermis soon became restored, the small depression being filled up. In many of the grafts there was excessive growth of epidermis from the surface, and the centres of the growing piece of transplanted skin were covered by deposits of a soft sebaceous material, not unlike that found on the surface of the fœtus. In instances of this kind, the deposit of sebaceous material bore an inverse relation to the growth of epithelium at the margin of the graft. This case afforded opportunities for observing the influence exerted on the skin-grafts by the prolonged contact of water, as it was thought necessary to keep the trunk and lower limbs of this patient in a bath for several days and nights. It was then found that grafts applied but three or four days previously, soon died; whilst those that had been growing on the ulcers for seven or eight days before the use of the bath became arrested in growth, though they still maintained their vitality, and threw out on their surfaces masses of soft and white material, in which, on microscopical examination, epithelial cells were to be found. The grafts in this case were taken from many volunteers of both sexes, and mainly from the arm. For cutting away the piece of skin, Dr. Clemens prefers a dry knife to one moistened with water or smeared with oil. The graft taken with a dry knife can, it is stated, be more readily dealt with, and more rapidly takes root and grows. The smaller the portion of skin removed, the sooner will it adhere and the more quickly will it grow.

W. JOHNSON SMITH.

WEIR ON MANUAL EXPLORATION OF THE RECTUM.—We have, on several occasions, referred to the plan, first practised by Professor Simon of Heidelberg, of exploring the interior of the rectum by means of the whole hand introduced through the anus. Simon's example has been followed on the continent to some extent, but it is in the United States that the proposal seems to have been most favourably received, and notices of the operation in the American papers have been of late somewhat frequent.

The *New York Medical Record* (March 20) contains an instructive paper by Dr. Robert F. Weir, in which he calls particular attention to the risks of the operation. The caution does not appear to be unnecessary, for some of the American surgeons seem almost to have surpassed the originator of the operation in boldness. Thus we are told that one New York surgeon passed his hand and arm into the rectum and descending colon to the extent of sixteen inches; he was then able to touch the inferior border of the liver, and his fingers, when projected forwards, could be felt through the abdominal wall four inches above the umbilicus; and that another surgeon, before performing lumbar colotomy, explored the rectum in this manner to a distance of twelve inches, 'his forearm was too large to go further,' as though the limit of exploration was the possible dilatability of the anus. In his first accounts of the operation, published in Langenbeck's *Archiv für Klinische Chirurgie*, and of which a summary appeared in the *LONDON MEDICAL RECORD* of February 12 and August 20, 1873, Professor Simon states that it is not safe to introduce the greatest circumference of the hand, i.e., the knuckles, to a greater depth than seventeen to nineteen centi-

mètres (seven to seven and a half inches), on account of the great narrowing of the calibre of the bowel, which commonly occurs about this situation. With this dictum, which was based on careful measurements of many recta, and on numerous experiments on the dead subject, Dr. Weir quite agrees, and he mentions two recent American cases, in which rapidly fatal collapse followed the operation, and in which laceration of the rectum and of the peritoneum was found to have occurred. In one of these cases the hand was introduced to the extent of twelve inches, and in the other to eleven inches, measured to the tips of the fingers. The operation is most useful as a means of ascertaining the nature and position of strictures of the bowel, and it is just in these cases that most caution is necessary; for when the obstruction is situated high up, and has existed for some time, the rectum not only becomes contracted, but its coats become weaker and less dilatable than in health, and but little force is required to produce serious mischief. This was no doubt the cause of the serious results just referred to.

J. W. LANGMORE, M.D.

BRICKELL ON RUPTURED PERINÆUM.—Dr. Brickell, Professor of Obstetrics and Diseases of Women in the Charity Hospital Medical College, New Orleans (*American Journal of Medical Sciences*, April, 1875), considers all the usual operations for the restoration of the perinæum 'unsurgical' and unsatisfactory. He says that interrupted sutures exert too much antero-posterior traction and cause 'corrugation of the denuded surfaces,' and consequent reduction of their areas; hence the wedge-shaped perinæum is not restored, but merely an abrupt wall partially closing the gap between the neck of the bladder and the anus. In many cases, too, the soft vaginal tissue is partly cut through in the first few hours, and thus only a portion of that included in the sutures at the time of operation unites finally. The same results occur to some extent with clamps or quills, with the additional evil of more or less sloughing from the pressure. Dr. Brickell has contrived steel 'perineal stays,' which he figures. The stays are made of steel and nickel plated, the internal end being in the form of a cap and movable. The deep sutures having been passed as usual, the stay, which is forked at each end, is placed between the denuded surfaces, the movable fork being pressed against the deep or vaginal part of the suture, while the external ends of the suture are tied over the opposite fork; thus the denuded surfaces are kept in position by indirect lateral pressure: one or more stays may be used as required and a few auxiliary sutures if necessary. The stays are removed on the fourth, fifth, or sixth day. The suture being cut, the long external part of the stay is drawn out and the small cap is left free in the vagina; it is well to steady the internal end with a pair of curved forceps while withdrawing the other part. He appends four cases. He has not found any trouble from fistulæ in the track of the stay, and recommends catgut in preference to silver wire for sutures. In a postscript he gives a fifth case in which he used nothing but catgut with the stays, the result being excellent.

[This seems likely to be a most valuable contribution to the surgery of the perinæum. All who have tried the ordinary operations will have met with some disappointments, and here we seem to have a rational hope of pretty constant success.—*Rep.*]

J. KNOWSLEY THORNTON.

STIMSON ON A CASE OF MOLLUSCUM SIMPLEX : OPERATION.—During the past year a very important case has been operated on by Dr. Daniel M. Stimson, of New York, and reported in the *New York Medical Journal* for March, 1875. The patient, a young man, aged eighteen, had on the right side of his neck a tumour, which constituted a great deformity. The growth began in early life, and consisted, for the most part, of a double fold of much thickened and hypertrophied skin; it sprang from a line running from a point near the occipital protuberance behind, downward, and forward, to a point on the lower jaw, nearly below the angle of the mouth, and hung down so far as to cover the lapel of his coat. The ear had grown to double its natural size, was very much thickened, and the top of it turned over on itself. The meatus auditorius externus was drawn down by the weight of the ear, very nearly, if not quite, an inch. The growth contained evidently many large blood-vessels and firm nodules, pressure on which caused unconscious spasmodic contractions of the muscles raising the shoulder. The lower jaw and clavicle on that side had never been developed to correspond with the other side of the body, and there was marked drooping of the shoulder. A few years ago, nearly all the celebrated surgeons in Europe were consulted, and advised against operation; only one of them, Billroth, thinking that it might be done, but refusing to undertake it. Dr. Willard Parker was of the opinion, in the spring of 1874, that the growth could be removed with safety, and the result proved the correctness of the decision. The tumour was removed at two sittings, the first on May 28, and the second on October 1. The first operation lasted two hours and a half, and consisted of the removal of the anterior portion of the tumour, by a long and tedious dissection, which exposed the pes anserinus, and also the sheath of the carotid artery, for the space of an inch and a half, and involved the removal of a part of the parotid gland. A considerable amount of blood was lost, but the patient rallied well from the operation, and the wound healed kindly. The second operation lasted about as long as the first, consisted of the removal of the remainder of the tumour, and was not attended by any special difficulty. The hæmorrhage was severe, but the means ordinarily in use sufficed to control it. Microscopical examination proved the growth to be a molluscum simplex. The improvement in the patient's appearance, after its removal, was most marked.

M. J. DEBY, in making an examination of the contents of the stomach of some mussels (*Mytilus edulis*) bought in the market at Brussels, found thirty-seven species of diatomaceæ, comprising the *Hyalodiscus stelliger*, which had never yet before been found except in Florida.

MATERIA MEDICA AND THERAPEUTICS.

CALDWELL ON DAMIANA.—In the *Virginia Medical Monthly* for May, Dr. J. J. Caldwell of Baltimore describes a new medicinal agent. It is a plant which grows on the western borders of Mexico. The writer is unable to give its technical name and its classification; this much, however, is known about it. The plant does not flourish in the mountains, nor yet very far from the sea. Amidst the gorgeous vegetation of Mexico, the dark green leaves, the small white blossoms of the damiana, and the fragrance of the gum which exudes upon the stem, attract the attention of the traveller. After the annual rains, when vegetation bursts into life, this plant is readily found. In July, when it ought to be reaped, it is most easily gathered. It appears that it is used as an aphrodisiac, and one case is given of an old man, Anclos, who took his damiana tea until he was more than a century old. 'There are a great many such in this country. I do not mean to say or to intimate that damiana does it all, but only this fact, that very many of these old stagers do sire children, as old Anclos did, up to the last, some of them having two or three dozen legitimate, without counting outsiders.' The root possesses the same properties as the leaf. There are two classes of damiana. The best bears a white blossom, and has a small leaf; the other has a yellow blossom and a large leaf, and is found in much larger quantities, but is inferior in every way. Cases are given illustrating its efficacy; one, a man of seventy, was, by its use, restored from the impotence of senectude to the virile powers of earlier life. Sexual anorexia from ill health and mental trouble is equally relieved by the remedy. Impotence of alcoholic origin, or from disease of the genito-urinary organs, also yield to it. The tincture and the fluid extract are the best forms. Dr. Caldwell concludes as follows. 'This remedy seems to have a specific effect upon all the organs of the pelvis, giving increased tone and activity to all of the secretions in that vicinity.'

[In speaking of this communication the *Medical and Surgical Reporter* of Philadelphia, for May 15, advises caution in the matter of credence, and is instituting inquiries among its Mexican correspondents.—*Rep.*]

MINICH ON THE HYPODERMIC INJECTION OF ERGOTIN IN PURPURA HÆMORRHAGICA.—In the *Philadelphia Medical Times*, May 8, Dr. Andrew K. Minich gives an account of a very serious case of purpura hæmorrhagica treated successfully by the subcutaneous injection of ergotin. The condition of the child was very grave, and blood was issuing everywhere, when a grain of ergotin was injected under the skin of the arm. Sponging with infusion of oak-bark was also ordered. Four hours afterwards the profuse vomiting of blood had entirely ceased; but blood still issued from the nose. Another grain of ergotin was then injected. Next morning the bleeding had entirely ceased. He gave another injection. The small spots upon the skin then disappeared. Some fluid-extract of ergot with sulphuric acid and opium was then administered by the mouth. The patient made an uninterrupted recovery. Dr. Minich then proceeds to consider the pathology of purpura hæmorrhagica as read by the

light of this case. He dismisses the hypotheses that the disease rests upon some change in the blood, or that it is due to a condition of fatty degeneration of the capillaries, and gives it as his opinion that the real pathology is vaso-motor paralysis; and that the ergot acts upon the capillaries by causing them to contract, and does good by inducing vaso-motor spasm.

J. MILNER FOTHERGILL, M.D.

GARRIGOU ON THE PYRENEAN WATERS.—Dr. Garrigou (*Journal de Thérapeutique*, May 10, 1875) has, by special modes of analysis, obtained interesting results in many of the waters of the Pyrenees, namely, Aulus, Ax, Barèges, Saint Bois, Eaux Bonnes, Cadeac, Capvern, Cauterets, Eaux Chaudes, Gamardi, Luchon, Ravi, Saint Sauveur, Salies de Bearn, Tremesaygues.

Thus, without mentioning potass, soda, or phosphorus, which occur everywhere, he has demonstrated the presence of lithia, of alumina, of iron, and of manganese in all the waters mentioned above, without exception. Strontium exists at Aulus, Saint Bois, Capvern, and at Tremesaygues.

Copper and arsenic have been found everywhere, (they were not sought for at Salies de Bearn); but it is doubtful whether there is arsenic at Eaux Chaudes. Antimony accompanied the arsenic at Aulus, Barèges, Capvern, and even at Cauterets. Cobalt, the presence of which is doubtful in the sources of Aulus and of Eaux Bonnes, exists certainly in those of Saint Bois, Capvern, Gamardi, and Luchon. There is probably tellurium in the sources of Aulus, and of Capvern, but this is not quite certain. Lead has been found at Aulus, Capvern, Eaux Chaudes, Gamardi, Luchon, and Saint Sauveur. Bismuth has been found only at Luchon. Cesium and rubidium are wanting at Aulus and Ravi, but have been found at Ax, Luchon, Tremesaygues, and the last separately at Eaux Bonnes. Iodine, which is absent at Ravi, occurs at Saint Bois, Luchon, and Salies de Bearn. Bromine has only been discovered at the last of these places. Fluorine exists at Saint Bois, and at Luchon. Finally, chromium is present in the source of Aulus. As for the organic matter, one portion of it behaves like crystalloid substances, and passes through the dialyser; the other part remains on the dialyser, and is like colloid matter. The first sort of it has been obtained at Aulus, Eaux Bonnes, Capvern, Luchon and Ravi. Dr. Garrigou ends by observing that although these rare substances have been detected only in the few springs which he has examined, it does not follow that they may not exist in the many waters which he has not analysed by his processes.

J. MACPHERSON, M.D.

MCBRIDE ON NITRITE OF AMYL IN EPILEPSY.—Dr. James H. McBride, of the Hospital for the Insane at Oshkosh, Wisconsin, publishes in the *Chicago Journal of Nervous and Mental Diseases*, April, 1875, some valuable observations on the action and use of nitrite of amyl in epilepsy. It is stated that epilepsy depends upon a condition of cerebral anæmia induced by spasmodic contraction of the arteries of the brain. The action of amyl is directly antagonistic to this. It causes distension of the cerebral blood-vessels and congestion of the brain. The action of the drug was very prettily demonstrated in some experiments which were made by McBride and Kempster. A portion of the skull of a live full-grown rabbit was removed, so as to expose a considerable surface of the cerebral mem-

brane. After the effects of the anæsthetic used during the operation had passed away, the nitrite of amyl was administered, and its action on the brain observed through the aperture in the cranium, with the aid of a strong lens. In a few moments the vessels of the pia mater became engorged with blood, so that vessels could be seen distinctly which were before invisible to the naked eye; the brain became dark and congested, and so swollen as to protrude through the artificial opening. At the same time the external vessels of the ear were distended with blood. The inhalation being stopped, all these symptoms soon disappeared, and returned as soon as the amyl was administered again. A second experiment of like character yielded precisely the same results.

McBride details several instances in which the nitrite of amyl has been employed under his observation for the treatment of epilepsy. The results were remarkably favourable. The effect of the remedy was immediate, and its efficacy in warding off imminent attacks was particularly striking. The good effect does not appear to have remained, however, after discontinuance of the remedy. The mode of administration consists in dropping ten to fifteen drops upon a piece of cotton, and the vapour is then inhaled.

Particularly favourable results are promised in those cases where the aura is very decidedly marked. A caution is given against employing the nitrite of amyl in certain spurious forms of epilepsy, convulsions which are dependent upon congestions of the brain, where the drug might have a decidedly pernicious effect, through simply aggravating the existing disturbance.

PSYCHOLOGY.

HUNT ON THE RELATIONS OF THE GENERAL PRACTITIONER TO INSANITY.—In the *New York Medical Record* of April 10, Dr. Ezra Hunt insists upon the importance of some knowledge of insanity on the part of ordinary practitioners. Until of late the consideration of insanity has been quite left out of the curriculum of medical study, and yet, whether he will or not, the early treatment of insanity falls upon the average medical practitioner, and not upon institutional experts. A few days, and sometimes weeks, are necessary to determine the degree of insanity, or the need of transfer, or the case itself is gradual in its development. Some delay often must occur in arranging change, unless the attack is of the exceptional character of raving mania. Yet so important are these days, that they often mark the limit between acute and chronic cases, and determine the ultimate curability of the patient. From the last reports of the two asylums of Philadelphia, of that of New Jersey, and of that of the Commissioners of Lunacy for Massachusetts, it appears that a large proportion of those cases which recover do so within one year after admission, and these are largely of

not more than three months' duration. It is well known that the chances of recovery for cases which have lasted over eighteen months are exceedingly limited. The Massachusetts report for 1874 says: 'If the proper treatment can be applied in the first attack or stage, it is estimated by some that, taking all cases as they arise, from seventy to eighty per cent. can be cured, and others estimate the rate still higher; but if not treated at all, or attempted unsuccessfully, till the disease passes into a chronic state, it is found, as a general rule, that not more than ten per cent. recover. The recoveries are confined chiefly to fresh admissions, or to the acute stage of the disease. Many of the causes of derangement are within the reach of public and personal lay appreciation. Very many cases consist in a yielding of the will, associated with some physical invalidity, which if controlled in time would not get the mastery. There is more room for skilful tact in such cases outside of asylums than in them, and a grander field for prevention than for cure. The private and institutional physician must join closer in this work. The medical student must study more the nerve department of all disease. The whole profession must realise how wonderfully of late years new and valuable remedies have been found available in morbid conditions. Hopefully and heroically the art of prevention must be joined to that of cure, and we should learn to realise the portentous moment of those first early formative days of all physico-mental disease, on our dealing with which so much depends—the prolongation of the malady, its limitation in a few months, its speedy cure, or its irremediable permanency.'

DERMATOLOGY.

BESNIER ON IMPERMEABLE CAOUTCHOUC DRESSINGS.—Dr. Besnier, of St. Louis hospital, publishes a good account of this method of treatment in the *Bulletin Général de Thérapeutique* (Jan. 30, 1875). The application was devised by M. Colson of Beauvais, and had been used by him with great success for several years before he published his paper 'De l'Emploi de la Toile de Caoutchouc vulcanisé dans les Maladies dartreuses' (*Gazette des Hôpitaux de Paris*, Feb. 25, 1869). After he had recommended it to Prof. Hardy in 1866, the latter distinguished dermatologist introduced it into St. Louis, where it is also used by MM. Lailler, Rendu, and Besnier, with great success.* The last of these physicians bases his present report on two years' continuous observation.

The material used is not of great importance. It must be completely water-tight, and thick enough to maintain an equable temperature. Vulcanised India-rubber cloth fulfils these indications best, but wax-cloth, gold-beater's skin, or gutta-percha sheeting may all be used. [The cold-cream paper lately recommended by Dr. Duckworth (*Archives of Dermatology*,

U.S., Jan. 1875) acts no doubt in the same way]. It must be laid *directly* upon the affected surface and kept in contact, but without pressing on it, by a suitable bandage, care being taken to prevent the access of air or the exit of secretions. An ordinary roller is a better application for the fingers and feet than India-rubber gloves and shoes, and the same for the limbs, neck and trunk. Or a sleeve may be made for the arm, a glove for the hand, and confined at the shoulder and elbow or at the wrist by an India-rubber band or a tape. A cap must be made for the head, with a bandage to keep its edges tight, a bag for the scrotum, and a mask for the face. After taking it off it should be carefully wiped, washed in cold water, and dried, before applying it again; the diseased surface should be cleansed by irrigation and powdered, anointed, or left free to the air, according as its condition may demand. This applies to the majority of cases, where M. Besnier finds it enough to apply the caoutchouc during the night, and let the patient go about his business in the day. In severe cases, like general eczema, it is desirable to keep it applied continuously, changing it night and morning.

Without pretending to decide whether the benefit of this treatment depends on protection from contact with air and other irritants, on uniform temperature, or on the effect of the secretions and the exudations of the skin, the author lays little stress on any chemical effect of the sulphur or caoutchouc, and compares the action of the remedy to that of a poultice (or water-dressing). It is therefore generally applicable to inflammatory affections and also to those characterised by itching. Like all treatment it sometimes fails; but this is rare, and only once or twice (in cases of psoriasis) has any harm appeared to result from its use. The only inconvenience is the somewhat unpleasant smell (which soon disappears) and the cold feeling when it is first applied.

The diseases for which M. Besnier particularly recommends this remedy are eczema, impetigo, ecthyma, lichen, and all kinds of prurigo. Since, however, impetigo is generally regarded as a mere variety of eczema; since ecthyma apart from boils and scabies, lichen apart from papular eczema and syphilis, and prurigo apart from pediculi, are exceedingly rare, we may say that practically the use of the India-rubber dressing is applicable to cases of eczema in the wide sense of the term, to less specialised cases of dermatitis, and also to any disease in which pruritus is a chief symptom. On the other hand it is found to be useless, or possibly even hurtful, in cases of psoriasis, particularly when extensive, of erysipelas of all kinds, of cutaneous syphilis, and of lupus ('scrofulides malignes'). The most striking instances of cure have been observed in eczema rubrum and eczema rimosum, the local eczema of various trades, impetigo of the face and scalp in children, and lichen agrius; it is less fitted for the eczema of vari cose legs, though sometimes beneficial in softening indolent varicose ulcers, with the aid of rest, elevation and time. In some severe cases of pemphigus, though not affecting the disease, it notably relieved the distressing irritation.

P. H. PYE-SMITH, M.D.

BUCQUOY ON HERPES ZOSTER.—M. Bucquoy (*La France Médicale*, April, 1875) discusses the relation between the eruptions of herpes zoster, or zona, and its accompanying neuralgia; whether they depend upon morbid changes in the nerve or centre from

* Professor Hebra, having seen the treatment on a visit to St. Louis in 1867, has practised it in Vienna. See *Archiv für Dermatologie und Syphilis* for 1869.

which the part affected is supplied ; and whether the cutaneous affection is the cause of the neuralgia, or the neuralgia the primary affection, and the eruption the secondary result. It has been shown by M. Charcot and others that phlegmonous changes or zona have supervened upon lesions of nerve-trunks or their centres ; and M. Hybord has collected a number of cases in which *post mortem* examination proved that the eruption followed some inflammatory lesion of nerves, spinal ganglia, posterior columns of the cord or the Gasserian ganglion. These facts show that changes in the nervous system have an undoubted influence upon the trophic condition of the part supplied by the affected nerve, and the affection of the eye which accompanies herpes frontalis is consistent with the results known to follow injury or disease of the fifth pair and Gasserian ganglion. The conclusion that every case of zona is necessarily accompanied by injury or inflammation of the nerve which supplies the affected territory is not, however, to be accepted without certain reservations. The connection between the eruption of herpes zoster and nerve-pain may be regarded as satisfactorily established. Yet, having regard to those slight cases of zona, in which the nerve-pain is so trifling and transient an element, M. Bucquoy cannot venture to affirm absolutely either that in simple neuralgia there is actual change in the painful nerve itself, or that the neuralgia which accompanies zona certainly indicates something more than hyperæsthesia, such as active hyperæmia or inflammation of the nerve.

W. B. CHEADLE, M.D.

OPHTHALMOLOGY AND OTOLOGY.

TAYLOR ON SYPHILITIC AFFECTIONS OF THE LACRYMAL APPARATUS.—The *American Journal of Medical Sciences* (April, 1875) has an article by Dr. Taylor, of New York, upon the syphilitic affections of the lacrymal organs. In addition to the different diseases of this nature already recorded, the paper contains an account of two cases in which the caruncles appeared to have become the seat of a gummy infiltration, a disease not previously recorded. Primary syphilitic inflammation of the lacrymal gland has been reported but once only, by Chalons of Luxembourg (*Preuss. Vereins-Zeitung*, 1859) ; and it may be stated, with much positiveness, that the syphilitic affections of the canaliculi, sac, and nasal duct are never primary in their origin, but are due to disease of their surrounding structures. The special disease to which Dr. Taylor wishes to draw attention occurred, in the first instance, in a man, aged twenty-nine, who became syphilitic in 1865, with a chancre which was followed by a rash, buccal mucous patches, and rheumatoid pains. He was under treatment for a considerable time, but very irregularly, and remained in extremely bad health for two or three years. Whilst thus enfeebled he married, and his wife became affected, and their child was born diseased with coryza and an extensive eruption. In 1868, the husband noticed a small tumour at the inner angle of each eye, which rendered closure of the lids difficult and caused a flow of tears over the cheeks. On examination, the caruncles were found to be enlarged to four times their natural size, and pyramidal in shape ; their colour was deep red, without any ulceration, and when the lids were closed they pro-

jected about two lines from between them ; they were firm and elastic to the touch, and did not appear to discharge at all, though the lids were frequently gummed together in consequence of repeated attacks of ophthalmia. The disease was considered by Dr. Taylor to be gummatus infiltration of the caruncles ; the patient, however, put himself under the care of a surgeon, who, without inquiring into his previous history, told him the growths were cancerous, and removed them at once by a free excision of parts, which resulted in considerable deformity. Disappointed at such a result, he returned to Dr. Taylor's care, who treated him for secondary syphilis, with gradual improvement of his general health, until he ultimately lost all evidence of being syphilitic. The second case was that of a labouring man, aged thirty-four, with much the same history of syphilis. The affection appeared at the same time with other well-known secondary symptoms, and corresponded in all respects with that of the caruncles in the previous case. Anti-syphilitic treatment was at once adopted and steadily persisted in, and in the course of ten months the parts had regained their normal size and appearance ; but, unfortunately, the caruncles became completely atrophied, so that a rounded sulcus was formed at the inner angle of each eye, and he was ever after annoyed by epiphora.

The paper concludes by a reference to the cases of a girl, aged eighteen, and of a boy, aged ten, recorded by Von Graefe (*Archiv. vi.*), in which there was partial enlargement of the caruncles by fibrous growth.

MASSELON ON CONJUNCTIVAL GRAFTING.—From the clinical report of Dr. Masselon, in the *Annales d'Oculistique* (March, 1875), it appears that grafting of the skin and of the conjunctiva has been attended with encouraging success in the practice of M. Wecker and of other continental surgeons, in the treatment of ectropion and other deformities of the eyelids ; the grafts of skin have been taken from the arms of other patients, so that there has actually arisen a considerable traffic, each graft having a definite money value. It has been found, too, that portions of integument which have been removed during operations for entropion and the like, may be made available for the purpose. Although in general surgical practice skin-grafting has not realised the degree of success anticipated for it, in hands of ophthalmic surgeons, it has been found most useful ; and the high opinion of its value entertained by Dr. Masselon is fully endorsed by M. Illing, who has great experience of it in Vienna. In M. Wecker's clinique the operation has, however, undergone some modifications, as it has also in the hands of Professor Stellwag von Carion ; so that portions of skin of considerable size are now adapted to raw surfaces, and are kept in place by sutures ; and the method which has been termed mosaic-grafting is not employed till the former plan has been tried and has failed, or in those cases in which the shape of the wound prevents the application of a flap to a raw surface.

The transplantation of the conjunctiva of the rabbit has twice been carried out with success ; and it is impossible any longer to doubt that grafting of this kind will succeed, although the entire original graft appears to melt away. The cases in which Dr. Masselon recommends it are those of partial symblepharon ; it was in such as these that Dr. Wolfe first tried it with success ; in cases also where

it is desired to form a smooth *cul-de-sac* in which the artificial eye may be worn, and in many instances where the conjunctiva has become contracted in consequence of prolonged disease, such as granulations, etc. The operation has been performed with success lately by several surgeons in Paris, by Otto Becker, and especially by Illing in Vienna. The tissue made use of has not always been the conjunctiva of a rabbit, but the mucous membrane of the human lips has been used; and, on one occasion, even the mucous membrane of the vagina was transplanted with success. Otto Becker advises that the graft should be taken from the conjunctiva of an eye which has been lost and has become wasted; but it is a remarkable fact that, when the mucous membrane of the rabbit has been used, the membrane in time appears to become completely absorbed, and to be replaced by a tissue which closely resembles that of the human eye; and, if further experience show this to be the case, it will be quite as advantageous to make use of it, seeing that it can be so readily procured.

HIRSCHBERG ON GONORRHEAL OPHTHALMIA.—In a paper on this subject which appears in the *Berliner Klinische Wochenschrift* (March 15, 1875), Professor Hirschberg has given a concise history of this most terrible form of ophthalmia, from which it appears that until the beginning of this century no description of the disease is to be met with; and the writings of those who first described it differ widely in the accounts of its mode of origin and of the treatment to be employed. Later writers have been more agreed as to its disastrous effects, and in consequence have given more precise directions for its treatment; and it is remarkable that several of our most eminent surgeons agree in asserting that the best results have been obtained in those cases in which mercury has been freely given. In his classical paper on diphtheritic ophthalmia (*Archiv*, vol. i. 1854), Von Gräfe has drawn a distinction between the cases which admit of cure by the energetic use of nitrate of silver, and others which call for much general treatment, and which seem to be greatly benefited by the employment of mercury, and it was while acting as Von Gräfe's assistant that Hirschberg had the opportunity of observing the same good effect of mercury in cases of purulent ophthalmia which were supposed to be due to inoculation by gonorrhœal matter. There is no doubt that this form of ophthalmia is as comparatively rare in other countries as it is in our own; and this is due, Dr. Hirschberg thinks, to the fact that it is difficult to set it up by slight inoculation, except in eyes which are unhealthy, and which present granular conditions of the conjunctiva; and that, as there is a tendency to rub eyes which are affected in this way, a patient with an urethral discharge is consequently more likely to contract ophthalmia of this kind.

The greater part of Hirschberg's paper is devoted to an account of the most minute details of a case of this kind, that of a lad who had for some time suffered from granular lids, and who had the misfortune, while under treatment, to acquire an acute gonorrhœa. The symptoms were typical, and were very severe. The left eye was first attacked, and in spite of every care the right became affected a few days subsequently. The patient was completely isolated, and two nurses gave him their undivided attention. Mercury was used by inunction, and

taken internally in the form of calomel. The eyes were carefully washed, and all discharges were syringed out every quarter of an hour; meanwhile iced applications were employed; when the chemosis was extreme the aperture of the eyelids was enlarged by an incision at the outer canthus in each eye, and in the later stages nitrate of silver in the form of the mitigated solid stick was used occasionally. During the progress of the case the cornea in each eye became ulcerated at the margins, and was treated by atropine; commencing suppuration in the centre of the right cornea was at once met by an incision into the anterior chamber, and the use of a compressive bandage.

In the result, which in spite of the severity of these symptoms may be considered most encouraging, very useful vision was restored to each eye at the expense of very limited opacity of each cornea.

MISCELLANY.

THE Royal College of Physicians have unanimously awarded the Baly medal to M. Claude Bernard.

THE death of M. Schrotter, the permanent Secretary of the Vienna Academy of Sciences, and the discoverer of red phosphorus, is announced.

MR. CHARLES DARWIN has been appointed foreign honorary member of the Imperial Academy of Science, Vienna.

PALMAM QUI MERUIT FERAT.—Professor Drake, the eminent Berlin sculptor, has just finished a colossal statue, nine feet high, of Alexander von Humboldt, ordered by the City of Philadelphia.

NEW IRON MINES.—Some new and very rich mines of iron have been discovered in the neighbourhood of Bodo, in Norway. The ore, which neither contains sulphur nor phosphorus, yields from 54 to 67 per cent. of iron.

THE Emperor of Brazil has sent a collection of Indian skeletons and craniums to Professor Virchow, of Berlin. A very friendly letter from His Majesty accompanies the present, signifying the greatest interest in anthropological researches.

A MISTAKE IN DIAGNOSIS.—Two prominent physicians of Kingston, Ulster Co., New York, have been indicted by the grand jury of that city for mistaking a case of small-pox for chicken-pox, thus causing the spread of the former disease.

COMFORT FOR INVALIDS.—The *Bulletin Français* publishes a description of the plan recommended by Dr. Maurin to keep sick rooms cool. It consists in opening the windows wide and covering the openings with cloths steeped in water. It is well known how largely water, in passing from the liquid to the gaseous state absorbs caloric. This absorption lowers the temperature of the room from five to six degrees in a few minutes, and the humidity diffused in the air causes the heat to be more readily supported. By this system, patients even in the hottest time of the summer, find themselves in a perfectly fresh atmosphere.

CLAY TO CLAY.—Mr. Wilcox has communicated to the Philadelphia Academy of Natural Sciences the description of a singular method of inhumation formerly practised by the Indians of North Carolina. A large number of graves have been found in which the bodies had evidently been laid on their backs and covered with a layer of plastic clay about an inch thick. A heap of wood was then piled up and set on fire, the body was consumed, the clay became baked and retained the impression of the body. After this operation was completed, the mould was covered with earth.

HYDROPHOBIA.—The military commission on hydrophobia, composed of military veterans either in active service or on half-pay, have written, through their president, M. Decroix, to the Institute of the Paris Academy of Medicine, and of the Central Society of Veterinary Surgery, to offer their services in experimentally testing all remedies for hydrophobia submitted to those bodies. A delegate from each or all of these bodies is invited to be present at the experiments. The remedies are administered to undoubtedly mad dogs, and not to dogs which have been bitten and are only suspected to be mad, amongst which, there are four chances to one that they are not actually mad. At the present time the commission is making experiments on a remedy which is held to be so potent a specific against hydrophobia in Tonquin, that Monseigneur Gauthier, bishop of that country, has felt it to be his duty to send some to France.

TOBACCO: ITS USE AND ABUSE.—Dr. Bertherand, in his recently published book on *The Use of Tobacco*, gives the following sensible advice to smokers. Never smoke more than three or four pipes or cigars daily, and, if possible, limit yourself to two. It is not advisable to smoke either when fasting or immediately before or after a meal. In whatever way you smoke, the direct contact of the tobacco with the mucous membrane of the mouth should be avoided, and more especially with the teeth, which are thus excited to grinding against each other. Cigars should be smoked in an amber, ivory, or enamelled porcelain tube. To relight and smoke pieces of cigar is, in connection with the prevalent system of blackened and saturated pipes, the most certain way of incurring disagreeable consequences from nicotine. It is advisable for all smokers to rinse out the mouth after smoking when practicable. For the same reason, all pipes and tubes in which tobacco is consumed should be frequently washed out, either with ether, or water mixed with alcohol or vinegar. Of all forms of tobacco, Dr. Bertherand recommends the cigarette, and is entirely opposed to the use of tobacco in childhood and early youth.

INSECT-EATING PLANTS.—The *Medico-Pharmaceutical Abstract and Review* contains the following accounts of experiments made by Mrs. Mary Treat, New Jersey, on the nature of insect-eating plants. 'When an insect is entrapped a slimy secretion begins to ooze from the inside of the leaf, and in a day or two envelopes the insect's body. After a period of several days the insect disappears, with the exception, perhaps, of some hard parts, which are ejected, and the leaf reopens, if it is healthy, to receive another victim. Such being the *modus operandi* in general terms, Mrs. Treat proceeded to make more careful observations. She found that the leaves and plants differed greatly in their power of assimilation. Some leaves were unable to digest even a single fly, while others disposed of three successively, but never could manage a fourth. When a leaf has done its duty in contributing nutriment to the parent stem, it dies, and is replaced by another or others. The leaves were not restricted to an uniform diet. Mrs. Treat tested them with beetles, spiders (of the daddy-long-legs variety), etc., and even sat for some two hours with her little finger in one of the leaves. This last experiment was unsatisfactory, as for some reason her nerves refused, much to her regret, to let her remain a prisoner long enough to be even partially digested. The leaf had, however, begun to exude its digestive fluid, as if

it would have been quite pleased with a human victim had it been big enough. Beetles and other hard-winged insects were digested by some of the stronger leaves, the operation requiring in some cases as much as two weeks. The strongest plant in the collection caught in all forty insects between May and October, and digested most of them, but this was accomplished by successive sets or relays of leaves. Insects removed after two or three hours of confinement sometimes recovered, but if they were left long enough to become covered with the slimy secretion they always died, although in some cases the secretion was carefully washed off.'

INFORMATION FOR GIN-DRINKERS.—Dr. Richardson, in his Cantor 'Lectures on Alcohol, its action and uses,' gives the following elaborate account of the processes employed to make gin suit the palates of consumers. 'Gin,' he says, 'has to be made cordial, to be sweetened, to be rendered creamy and smooth, to be flavoured, to be made biting to the palate, to be beaded, and what not else. To be made "cordial" it must be charged with oil of juniper, with essence of angelica, with oil of bitter almonds, with oil of coriander, and with oil of carraway. To sweeten it, it must be treated with oil of vitriol, oil of almonds, oil of juniper, spirits of wine and loaf sugar; to "force down" the same, it must be further treated with a solution of alum and carbonate of potassa. To be rendered creamy and smooth, it must be sweetened with sugar, and lightly charged with a small quantity of garlic, Canadian balsam, or Strasburg turpentine. To give it piquancy, it must have digested in it shreds of horse-radish. To be made biting to the palate, it must receive that touch of caustic potash of which I have spoken. As you see the habituated gin-drinker partaking of his favourite drink you observe, often, that he enjoys it the more if it be what he calls "pearly" or "beaded." He holds up the precious liquid in his glass, and as he sees the oily fluid as beads roll down the sides, leaving each a creamy train behind it, he rejoices in his treasure. It is *crème de la crème* of gin. Those wicked pearly drops are, to his flushed eyes, the proofs of the purity and excellence of what he would probably tell you was, without mistake, the genuine article. The genuineness consists in the fact that our enthusiastic friend's gin has been beaded by the addition of the following artistic mixture. An ounce of oil of sweet almonds has been added to an ounce of oil of vitriol. These have been rubbed together in a mortar with two ounces of loaf sugar until a paste has been formed. The paste has next been dissolved in spirit of wine until a thin liquid has been produced; and this, added to one hundred gallons of gin, has given the fine pearly bead that is so much admired.'

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 6d.: free by post, 19s. 6d. Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each. VULPIAN'S EXPERIMENTAL PATHOLOGICAL STUDIES ON THE PHYSIOLOGICAL ACTION OF TOXIC AND MEDICINAL SUBSTANCES.

(Continued from page 303.)

M. Vulpian's third lecture treats of jaborandi, and contains the botanical description of the plant, according to M. Baillon (See LONDON MEDICAL RECORD, vol. ii. p. 317), with references to the researches of MM. Gubler, Rabuteau, Robin, Féréol, Carville, Galippe, Sydney Ringer, Gould, Tweedy and Martindale, published in the LONDON MEDICAL RECORD, vol. ii. pp. 317, 794, 804, vol. iii. pp. 66, 132, 162.

M. Vulpian sums up the properties of jaborandi in the following terms. The sudorific and sialagogue qualities of jaborandi are incomparably more decided than those of all the therapeutic agents hitherto employed in medicine. It may even be affirmed that, before the introduction of this plant into the materia medica, no sialagogue or sudorific acting by the circulation was really known. In French practice tisanes only, which acted by introducing a certain quantity of water into the animal economy, were known. The stock of salivants was rather more extensive; for instance, pyrethri radix. But the effect produced by this root is not the result of a direct action on the secretory glands; pyrethri radix, by reason of its irritant properties, acts directly on the mucous membrane of the mouth, and then by reflex action on the salivary glands. But no sialagogue having the powerful action of jaborandi through the medium of the circulatory system has hitherto been known. With regard to the therapeutic indications of jaborandi, M. Vulpian points out that it produces excellent results in cases of acute exacerbation of chronic bronchitis. He also states that he has seen in young men of twenty a case of undoubted pleurisy disappear in two days. These facts demonstrate that jaborandi is henceforth destined to take a high place in therapeutics. It is certainly likely to play an important part in the treatment of uræmia and dropsies generally. It may also prove to be useful in rheumatism, though on this point there still remain doubts which will assuredly be cleared up by ulterior researches. In the actual state of medical knowledge, it cannot be admitted that the increased amount of perspiration obtained in rheumatic patients by therapeutic means has an incontestable curative action; on the contrary, the suppression of perspiration has been seen to produce good effects in this disease. M. Vulpian has, he says, indeed seen several cases in which the arrest of perspiration by means of atropine has considerably relieved the patient without producing the least aggravation of the symptoms of the disorder, and without prolonging its duration.

Jaborandi being destined to hold a considerable rank in therapeutics, it is useful to know in what dose it may become toxic. Many experiments have been made with this object. M. Robin has produced death in a guinea-pig after having injected 1·7 gramme (26 grains) of extract of jaborandi in dilution in 10 grammes of water. The injection of this liquid was made at several different times—about ten in the space of half an hour. This quantity will appear very considerable, if it be remembered that the extract injected contained the active principles of twenty grammes of jaborandi. M. E. Hardy experimented with the non-crystallised chlorhydrate of pilocarpine. Half a centimètre of a watery solution, not titrated, but very much diluted with this salt, introduced under the skin of a guinea-pig in M. Vulpian's laboratory, killed the animal at the end of an hour and a half. The experiments M. Vulpian performed on frogs gave little or no result. Finally, in numerous experiments made on jaborandi by M. Vulpian, he often injected an infusion of ten and even twelve grammes of jaborandi leaves without producing death. MM. Rochefontaine and Galippe have also frequently injected the same doses of infusion of the bark, stems, or leaves of jaborandi in dogs, and death only occurred once. In the experiment which ended by the death of the animal, ninety grammes of water, having had ten grammes of leaves coarsely powdered into it, were used. The injections were made on three occasions at intervals of two or three minutes. Some minutes after the first injection the animal began to salivate abundantly; its eyes were full of lacrymal fluid. A little later on vomitings ensued, succeeded by diarrhoea. San- guinolent mucus came out of the nostrils. The pulse was small, unequal (100 per minute). The pupils, at first enlarged, reverted to their normal condition. The animal trembled, and appeared very weak; it died during the night. The mucous membrane, the stomach, and intestines were found to be intensely congested, as were also the encephalon and its membranes. There were ecchymosed points in the lungs, especially above the pleura. To sum up, the degree of toxicity of jaborandi still remains to be determined. As to the toxic power of the active principle of jaborandi, it can only be studied with something approaching precision when we shall have this principle perfectly isolated at our disposal, either in the alkaloid form or as a salt, and titrated solutions can be made from it. The physiological action of jaborandi is of various kinds.

Jaborandi acts very powerfully on the secretions, modifies the temperature and the circulation, and when applied to the eye brings on a very decided myosis. Taking first in order the hyperæmia brought on by jaborandi, the secretory action of the majority of the glands becomes increased. The salivary glands are often first attacked; then the lachrymal glands, then the glands of the skin and mucous membranes, then the liver, the pancreas, the mammary glands, and the kidneys. It is useful for the physiologist to be cognisant of these effects of jaborandi, for this substance is a very important agent in experiment and research. In fact, jaborandi furnishes the means of obtaining at pleasure the products of the secretions of various glands. If, for instance, it be desired to collect the pure sub-maxillary saliva of the dog, free from all mixture with the rest of the buccal saliva, it is only necessary to introduce a cannula into Wharton's duct, whence the liquid will flow under the influence of

jaborandi. But this substance is particularly useful to obtain the parotid saliva, which, in the case of dogs, has only been able to be collected with great difficulty and in small quantities by all the plans hitherto employed. The means consists in introducing a cannula into Stenson's duct; by the help of jaborandi a truly considerable amount of parotid saliva is obtained. M. Vulpian has thus procured from a moderate-sized dog eight cubic centimètres of this saliva. Sublingual saliva may also be obtained by the same plan. Saliva secreted by the molar gland in the dog could doubtless even be obtained. The salivary liquids collected in this way have the particular characteristics which distinguish them when they are obtained under other conditions.

Jaborandi also gives us the power of collecting pancreatic juice at the various periods of digestion or in a fasting condition. When a dog is curarised and submitted to artificial respiration, the secretion of the pancreas is generally very inactive, and if a cannula be placed in Wirsung's duct, only very few drops of pancreatic fluid flow from it. But if the animal be submitted to the action of jaborandi, a comparatively large quantity of pancreatic juice may be collected into a vessel. This liquid is, without doubt, normal pancreatic juice; it is of a watery fluidity, colourless, clearly alkaline, and gives a very copious white precipitate when it is treated with nitric acid. In one of M. Vulpian's experiments, it became solidified in the form of a massive white block under the influence of that acid. It likewise exercises a slight saccharifying action on starch.

Henceforward, as has already been remarked, by this method pancreatic juice can be obtained during the various stages of digestion, and the data laid down by M. Lucien Corvisart with regard to the more or less powerful influence exercised by this liquid over albuminoid substances, according to the moment in which they are collected, can be easily verified. The same will hold good of the bile, which may be collected in abundance, and in an absolutely pure state, by means of a cannula introduced into the common bile-duct, in a curarised or non-curarised animal, into the crural vein of which a watery infusion of from two to three grammes of jaborandi is infused. Besides this advantage of being able to procure at will the secretion of various glands, there is still another, that of being able to study the elimination of toxic or medicinal substances through these glands. The interest attaching to this experimental process and to its probable results will be immediately perceived.

The next point under review is the study of the physiological mechanism of the action of jaborandi.

As the starting-point of this study, M. Vulpian takes the effects produced by jaborandi on the secretions, and chooses those secretions which are principally increased; that is to say, salivation and the sudorific secretion.

With regard to salivary hyperæmia, he studies in an exhaustive way the mechanism of the effects of jaborandi on the submaxillary gland, because the relations of the nervous system with this gland have been much investigated of late years, and that they are better known to us than those belonging to the other salivary glands. It is, besides, almost unnecessary to add that what is said of submaxillary sialorrhœa may be applied to the mechanism of the effects of jaborandi on the other salivary glands. When it is sought to discover by what means jaborandi may increase the secretion of the

submaxillary gland, we find ourselves face to face with two hypotheses. 1. Either the jaborandi acts directly on the cells belonging to the gland, by bringing on, likewise, vaso-dilatator reflex adjuvant phenomena; 2. or it acts on the secretory action of the gland in an indirect way by the medium of the nervous system. We will see which of these two hypotheses best corresponds with the facts.

The first hypothesis owes its origin to M. Gubler. According to it, the jaborandi eliminated by the salivary glands would excite, at the time of its passage, the cells belonging to those glands. This excitation would produce, as a connected phenomenon, an irritation of the peripheric extremities of the centripetal nerves which are distributed in the glandular tissue.

This last irritation, acting by a reflex path, would bring on dilatation of the glandular vessels, and consequently a more considerable afflux of blood. And the afflux of blood, furnishing more abundant materials to the secretory action of the tongue, would in its turn favour an excessive secretion of saliva.

M. Vulpian considers this theory to be scientifically conceived, and that considered by itself it is very satisfactory. Only, in order that it should be accepted, it must first be demonstrated that jaborandi is eliminated by the salivary glands. Now M. E. Hardy has made the analysis of the submaxillary saliva which M. Vulpian collected in one of his experiments on jaborandi, and has not found any trace of alkaloid in it. M. E. Hardy made an analysis for bile, and in this case the result was, if not negative, at least doubtful. Here we already meet with a presumption against M. Gubler's theory, and it seems probable that jaborandi does not produce salivation by acting directly on the cellular elements of the *cils-de-sac* of the salivary glands. However, before affirming anything of this kind, the experiments must be varied and repeated, so as not to retain any doubt as to the non-elimination of the principle of jaborandi by the salivary glands.

M. Heidenhain's experiments also furnish another argument against the theory in question. In order that the value of this argument may be thoroughly appreciated, it will be as well to give a rapid sketch of the plan of innervation of the submaxillary gland. This gland receives nerve-filaments coming from two different sources. 1. Certain of these filaments emanate from the medulla oblongata. These are the filaments coming from the chorda tympani, a branch of the facial nerve. The chorda tympani unites itself to a branch of the trigeminus, the lingual nerve, so as to form with it a single trunk, whence a nerve starts which in the dog follows a recurrent path, and returns to the submaxillary gland. This anatomical disposition might give reason to imagine that the glandular filament comes from the trigeminus and originates in the pons Varolii, but physiology and histology have clearly demonstrated that it is formed by the filaments of the chorda tympani, a branch of the facial nerve. The other nerve-filaments of the submaxillary gland come from the great sympathetic, and are furnished by the superior cervical ganglion; the majority of them are conducted to this ganglion by the cervical cord of this nerve-system.

It will now be easy to understand the processes in use amongst physiologists to excite the submaxillary gland. It is not very easy to get at the facial nerve in its intracranial course, above the point of origin of the chorda tympani. The chorda

tympaui may be easily got at by the external ear, and divided in the drum by perforating the tympanic membrane; but it is scarcely possible to excite it at that depth by means of an electric current. It is, on the contrary, easy to discover the lingual, at a point of its course situated above the origin of the recurrent filament, which distributes itself to the submaxillary gland; this filament can thus be either paralysed or excited by acting on the lingual at this point, and it is evident that the same effects should be obtained as a direct action on the gland, as if the section or the excitation of the chorda tympani itself were made before its union with the lingual nerve.

Excitation of the sympathetic nerve does not offer similar difficulties. The experiments are made on dogs; in these animals the cervical cord of the sympathetic is united to the pneumogastric, and the branch formed by them is called the vago-sympathetic nerve. Consequently, if, after having bisected the vago-sympathetic in the middle of the neck, its upper end, that is to say, the one nearest to the encephalic centre, be excited, the fibres of the sympathetic which go to the submaxillary gland after having traversed the superior cervical ganglion are inevitably excited. After having recapitulated these anatomical facts, M. Vulpian continues his subject by stating that Ludwig had seen that the excitation of the lingual nerve, practised above the filaments furnished by it to the submaxillary gland, produces a remarkable increase in the secretion of saliva. M. Claude Bernard has confirmed this observation, and has shown that the effect obtained was due to the excitation, not of the fibres of the lingual nerves, but of those of the chorda tympani.

Professor Schiff had also placed beyond doubt the influence of the chorda tympani over the submaxillary secretion. In a memoir published in 1851 on motor-paralysis of the tongue, he says, 'As I intend to show in detail in my work on the nerves of taste, by the excitation of the chorda tympani the acceleration of the salivary excretion is induced; by the destruction of this nerve, this acceleration is prevented.'

On the other hand, Czermak had shown that faradisation of the nervous filaments furnished to the submaxillary gland by the great sympathetic stops the secretion provoked by the excitation of the chorda tympani. However, this stoppage does not take place immediately on the electrification. MM. Eckhard and Adrian have, on the contrary, shown that during the first few moments there is an acceleration of the salivary flow. At that time there flow some drops of a thicker, more viscous, more opalescent saliva, than under the influence of the excitation of the lingual nerve united to the chorda tympani; and it is only after this short period of secretory augmentation that the submaxillary secretion stops.

(To be continued.)

HUGHLINGS JACKSON ON CASES OF NERVOUS DISEASE.

A report of some interesting cases, with remarks by Dr. Hughlings Jackson, appears in the *British Medical Journal* of June 12.

A man had much twisting about of his right arm of some months' duration. The movements were not choreal; they were not punctuated, but glided into one another—the simple expression 'twisting about' describes them best. The right leg was but slightly affected. Dr. Hughlings Jack-

son uses the term 'hemikinesis' for over-movements of one side of the body, as, for example, hemichorea, hemispasm, etc. He believes there is a 'discharging lesion' of the cerebral hemisphere in these cases; but why in one the nervous discharge is in an almost continuous stream, in others in a punctuated sequence, and in others abrupt and occasional, he does not pretend to know. Very many kinds of treatment were tried for this poor fellow, but the only thing which was followed by benefit was the subcutaneous injection of woorari. There could be no doubt of the benefit which followed this injection; for a time, too, the man's general health was better. Recently, the injection has been discontinued because he has severe headache after it. It is noteworthy that, since its use, the sensation of the left arm has greatly diminished; it was slightly but decidedly less than that of the left arm before the injections were used, but now it is very much less.

Several cases of optic neuritis with supposed intracranial tumour were shown. Dr. Hughlings Jackson insisted that extreme neuritis very often existed with good sight. The ophthalmoscope ought to be used whenever a patient had severe headache. He said that he believed that, were the ophthalmoscope used by routine, there would be less blindness. He thinks it probable that there is always a pre-matrotic stage of neuritis, and that, were large doses of the iodide of potassium given at that stage, the neuritis would often retrocede. As he invariably gives iodide of potassium in optic neuritis, he cannot make a confident statement. He showed a patient whose neuritis had disappeared under iodide of potassium. He thought that optic neuritis was, although not certain, the best evidence of gross or coarse disease within the cranium. It was, however, of no value in localisation.

In one case, from the fact of convulsion of the right side, Dr. Hughlings Jackson said there would be disease of the left cerebral hemisphere (a discharging lesion); next, from the fact that there was optic neuritis, the discharging lesion would be the result of irritation by coarse disease; and, in the case spoken of, this coarse disease was probably an abscess, as there was disease of the bone in the orbit. He insists on this diagnosis of stages. This diagnosis was in essentials recapitulated with regard to a patient of Dr. Hughlings Jackson's, whose body was to be examined *post mortem* by Dr. Sutton that afternoon. The lad had had convulsions (some with and some without loss of consciousness) beginning in the left hand; he had double optic neuritis and intense headache (Dr. Hughlings Jackson believed that the lad died of pain). So far there was clear warrant for the diagnosis of 'a discharging lesion' of the surface of the right cerebral hemisphere, and that that discharging lesion was the result of coarse disease. As to the particular nature of the coarse disease, there was a doubt. Dr. Hughlings Jackson thought that, as there was organic ear-disease, there would be a scrofulous tumour. He had several times seen scrofulous tumour at necropsies of patients who had died with organic ear-disease, 'instead,' so to speak, of cerebral abscess. In this lad there was found *post mortem* local roughening of the bone, subjacent adherence of membrane, and little tumours going from it into the convulsions. The area involved was over about half a square inch behind the lower third of the fissure of Rolando on the right side. There was considerable local softening, and also great cedema beyond the

parts actually softened. Dr. Sutton agreed with Dr. Hughlings Jackson in thinking it most probable that the local coarse disease was syphilitic. If so, it is the only necropsy on a case of congenital syphilitic disease of the nervous system that Dr. Hughlings Jackson has seen, which has revealed any coarse alteration. Such cases are valuable as bearing on Hitzig's and Ferrier's experiments, but unfortunately the disease in this case was too extensive for any precise localisation.

Several other patients also were subjects of that kind of convulsions which the lad had whose case has been just mentioned. These are such cases as are illustrated by the experiments of Hitzig and Ferrier. Dr. Hughlings Jackson's plan is to ask the patient to describe his fits himself; this he can do in great part, as in the convulsions spoken of (commonly called epileptiform convulsions), a good deal occurs before the patient loses consciousness. One patient gave a very vivid account of what Dr. Hughlings Jackson calls the 'march of the spasm.' This patient's fit began in his left index finger and thumb; it then passed *up* the arm, and affected the face, and next passed *down* the leg. It is the rule that fits which begin in the hand should begin in the index finger and thumb; when they begin in the foot, they usually begin in the great toe.

Speaking of these cases, and with reference to their difference from such cases as are commonly called epilepsy *par excellence*, Dr. Hughlings Jackson said that he thought the abrupt division into cases with and cases without loss of consciousness was not even justifiable on grounds of convenience. The absolute separation was, he thought, a 'survival' from a metaphysical stage of thought, when consciousness was thought to be an entity. The real distinction even empirically broke down in practice. The distinction was, he insisted, into cases where consciousness was lost first of all, very early or late in the paroxysm. If the 'discharging lesions' were in the very highest nervous processes there would be loss of consciousness first of all; if the 'discharging lesions' were seated in a subordinate series of nervous processes, consciousness was lost late or not at all. Wherever the discharging lesions were seated, consciousness would be lost if the discharge were strong enough.

With regard to several cases of graver cerebral disease, Dr. Hughlings Jackson insisted strongly on the fact that active mental symptoms (delirium) were not of much value in the diagnosis of primary cerebral disease, such as tumour or meningitis. Such symptoms, he said, occurred most often in non-nervous cases, pneumonia, erysipelas, etc. They may be called Very General Mental symptoms, for they occur under the most varied circumstances; prolonged fasting will produce them. Cerebral disease itself is but one of many conditions under which they arise. Then, on the other hand, the valuable symptoms of primary intracranial disease were, so to speak, non-nervous symptoms; vomiting, slow and irregular pulse, constipation, retracted belly, and, in acute cases, emaciation. He said it was a grave fault to take a nervous view of nervous diseases.

Another patient had paralysis of the third nerve. Dr. Hughlings Jackson showed by this case that double vision was not the cause of the giddiness in patients who have ocular palsies. The good eye being covered, and the lid raised on the side paralysed, the patient was told to walk. He

tried, but reeled on to a bed directly. The irregularity of gait results from the erroneous estimation of the position of objects by the faultily moving eyeball, or, rather, by the nervous centre for the movements of it.

A patient who had had attacks of Menière's disease, for a long time after a paroxysm, when his eyes were closed, reeled in his gait. Dr. Hughlings Jackson is a firm believer in the association of ear-disease and vertigo, reeling, and vomiting. Sometimes the reeling lasts for months after an attack. He has three cases of Menière's disease under his care now; in one of them, as there is a renal disease—a common condition for retinal and cerebral hæmorrhage—he thinks there is hæmorrhage into the labyrinth. There are, however, no hæmorrhages in the retina. In cases where the ear-disease is irremediable, Dr. Hughlings Jackson treats the effects; he gives digitalis, bromides, etc.

Another patient had simple atrophy of the optic nerves, along with locomotor ataxy. Simple atrophy of the optic nerves is an aid to diagnosis in doubtful cases of ataxy. It is a 'masculine' affection; rarely seen in women, in whom also locomotor ataxy is rare. Atrophy after neuritis is common enough in women. The case spoken of was in other respects rare; the ataxy was chiefly in the arms. Atrophy of the optic nerves is rarely seen in locomotor ataxy.

There was a patient who, besides being absolutely deaf, had bilateral muscular atrophy. Progressive muscular atrophy, as a rule, not only begins unilaterally, but it affects, first and most, those muscles whose chief use is unilateral; it begins in the hand. In this class of cases, Dr. Hughlings Jackson showed, certain muscles of locomotion are bilaterally affected, which are often used bilaterally or alternately; there was complete palsy of both serrati magni, so that his scapulae stood out like wings; of the erectores spinæ, so that the man's shoulders were held further back than the buttocks; and of other muscles. Dr. Hughlings Jackson has seen these palsies with palsies of cranial nerves of vocal cords, deafness absolute, and with palsy of both facial nerves without deafness. He has had no necropsy. He has never seen a case in an active stage. Several he has had under care for many months, the symptoms remaining unchanged.

LUBIMOFF ON THE DEVELOPMENT OF NEWLY FORMED VESSELS IN PROGRESSIVE GENERAL PARALYSIS.

Dr. Alexis Lubimoff, of Moscow (*Archives de Physiologie Normale et Pathologique*, no 6, 1874), says that, among the different pathological phenomena which are found in the brain in progressive general paralysis, it has been observed that in some cases the number of blood-vessels appeared to be considerably increased. This phenomenon has been considered as the result of a real vascular proliferation; and Professor Ludwig Meyer distinctly speaks of this proliferation as one of the phenomena of pathological anatomy that is observed in progressive general paralysis; but he withdraws this opinion in a subsequent article.

In the special investigations on the anatomico-pathological alterations in progressive general paralysis which Dr. Lubimoff made in the laboratory of

Professor Meynert at Vienna, and in that of Professor Virchow at Berlin, and of which the results have been published in two papers, some cases were observed in which the number of blood-vessels was sensibly augmented. However, not having sufficient reason for believing in the existence of newly formed vessels, he did not venture to make a positive assertion as to a true vascular proliferation, so that he had confined himself to pointing out the fact without seeking to interpret it.

However, if we reflect that, in consequence of cerebral hyperæmia in progressive general paralysis, the vessels of the brain are considerably injected by the blood-corpuscles, and for that reason become more distinctly visible in the field of the microscope, it seems that this apparent proliferation of the blood-vessels might be thus explained. On examining the brain of an individual who had died from progressive general paralysis, and who presented well-marked pathological changes in the brain, Dr. Lubimoff distinctly observed some histological peculiarities which had a certain relation to the question of the development of newly formed vessels in this disease, and which for that reason deserve to be noticed. The history of the disease and the results of the necropsy may be passed over, since we have only to consider the histology of the pathological changes.

In the frontal lobes, which presented the most manifest alterations, there were found among the lesions small areas of softening, invisible to the naked eye; but, on macerating the piece in a weak solution of chromic acid, these areas became evident, because the softened portions were distinguishable, on section, by their loss of consistence and their friability. Under the microscope, the sections made in the neighbourhood of the softened parts showed a considerable number of blood-vessels, as well as a great number of cells of interstitial tissue. These cells had a stellate form, and their processes, which gave off numerous ramifications, themselves presented some peculiarities. It had already been observed by the author that these cells are in direct connection with the blood-vessels, and that the process which traverses the sheath of the vessels and the perivascular space, in order to be inserted into the walls of the vessels, is much more developed than all the others. In the present case, on examining transverse sections of two convolutions in the neighbourhood of the softening, it was seen that, in advancing from the healthy parts to the softened spot, these cells became more and more numerous, and those processes which ended in the blood-vessels presented an increase of development which exceeded anything that had been hitherto seen. Most of the blood-vessels had thin walls, and presented numerous ramifications. On the constant existence of this proliferation of the cells of the interstitial tissue, which the author has found in every case of progressive general paralysis, added to other pathological phenomena, he has based his theory of the true nature of that pathological process which he regards as a chronic interstitial inflammation.

On remembering, on the one hand, the proliferation of the cells of the interstitial tissue in the early stage of this disease (when the nervous elements have not yet undergone any alteration), and the intimate relation of the cells of the interstitial tissue to the nerve-cells, the processes of the cells of the interstitial tissue imprisoning, as it were, on all sides the nervous elements as in the meshes of a network; and on considering, on the other hand, the imme-

diate connection of these same processes with the vascular system, with which they seem to be continuous in the substance of the cerebral parenchyma, the author is convinced that the cells of the interstitial tissue have some influence on the origin of certain pathological phenomena that are observed in relation with the intellectual functions in progressive general paralysis.

In short, as a consequence of the hyperæmia which occurs in the course of this disease, the endosmotic conditions are changed, the cells swell up, augment in volume, and then disturb the functions and nutrition of the nerve-cells. If the hyperæmia happen to disappear, the cells of the interstitial tissue diminish in volume, and the nutritive functions, those of the nerve-cells especially, recover themselves in consequence. And this is precisely what explains the alternate disturbance and recovery of the intellectual functions as observed in this disease. It is known that patients may at certain times recover the perfect use of their faculties to lose it again, and then again recover it, until, by their frequent repetition, these hyperæmiæ, the duration of which often goes on increasing, at length produce an essential alteration in the nerve-cells, and a continued and decisive disturbance of the intellectual functions.

J. LOCKHART CLARKE, M.D.

MEDICINE.

COLRAT ON GLYCOSURIA.—In the *Cincinnati Clinic* of May 15th is given a translation from the *Lyon Médical* of Dr. Colrat's remarks on glycosuria. He writes:—"When the blood from different parts of the circulatory system is examined, with the exception of that of the portal vein, it is found to contain a very nearly constant proportion of glucose, no matter what the nature of the alimentation at the time may be. In the portal vein on the contrary, the blood contains a quantity of sugar which varies according to the alimentation, and according as the animal is experimented upon while fasting or during digestion. The liver therefore seems to act as a special organ for retaining sugar.

"The experiments of Claude Bernard prove this remarkable function. "If we inject 10 grammes of ordinary glucose dissolved in 30 grammes of warm water, we see that the proportion of sugar in the blood becomes too strong, and this substance in excess passes off in the urine. But if, instead of injecting the solution into the jugular vein, we make the injection with the necessary precautions into the rectal branch of the portal vein, we ascertain that the sugar does not pass into the urine, even although the dose be increased. The liver therefore acts as a sort of barrier which retains the sugar and prevents it from appearing in a large proportion in the current of the circulation." (Claude Bernard, *Revue scientifique*, May 10, 1873.)

"The same demonstration may be arrived at by ligation of the portal vein. When this operation is made after Ore's method, the collateral circulation is established by the anastomoses which unite the hæmorrhoidal branches of the portal vein with the veins of the abdominal parietes, also anastomoses with the œsophageal and diaphragmatic veins, and in animals especially with the renal veins, in such a manner that the blood coming from the intestine no

longer passes through the liver, but is emptied by these anastomoses directly into the general circulation. If in a dog thus operated upon ten or twelve grammes of sugar are introduced into the alimentary canal, after the lapse of half an hour or three-quarters of an hour the presence of glucose in the urine may be demonstrated, whereas in the same conditions, but not having his portal vein obliterated, thirty, fifty, sixty or eighty grammes of sugar are necessary to produce saccharine urine. (See Cl. Bernard, *Revue scientifique*, 1873, no. 49).

'The experiment of ligature of the portal vein is realised, so to speak, in the human subject under certain circumstances, in pylephlebitis and in cirrhosis of the liver. In the latter case the obstruction takes place in the ramifications of the portal vein in the liver; it is certainly not complete, but it is well known to what an extent the anastomoses of the portal vein are developed, which anastomoses, receiving the blood coming from the intestine, and consequently charged with the products of digestion, pour it into the general circulation.

'Under these conditions, identical with those in which an animal is placed whose portal vein has been ligated, sugar ought to be found in the urine after the ingestion of saccharine substances.

'It has seemed to us interesting to make this research, and we have, in a certain sort, experimented on two patients afflicted with cirrhosis of the liver. The result has been completely confirmative. We proceeded as follows in the analysis of the urine. In order to procure normal urine, that is, urine passed while the patient was fasting, we took care to have the patient empty his bladder in the evening at nine o'clock, five hours after the last meal. This urine was thrown away. The patient remained absolutely without food during the whole of the night, and was careful to urinate during this time until morning into a receptacle appropriated to the purpose. The examination of this urine was always negative. In regard to the urine of digestion, it was procured during the three hours following a meal or the ingestion of saccharine substances. The urine was always treated in the same manner, that is, filtered through well washed charcoal until quite colourless, and then subjected to the various methods of examination in use (those of Barreswill, of Moore, of Böttger, Luton, etc.). At the same time we took the precaution to examine comparatively the urine of a healthy subject, placed under the same conditions as the patients, that is, subjected to the same alimentation, except that for the healthy subject the quantity of sugar was doubled or tripled. Thus, while patients received 100 or 200 grammes of grapes, he took 400 or 500. When the experiments were made with syrup, the quantity of syrup was always double for the subject who served for comparison; the urine of this latter was moreover treated in the same manner as that of the patients, and we were never able to discover the presence of sugar in it.'

After giving several cases, Dr. Colrat writes :

'It is clear that in these cases we did not have to deal with true diabetes. The sugar, indeed, appeared in the urine only when it was brought from the intestines in too great quantity (about three parts in the thousand) into the general circulation. These conditions are only found realised when the patient has absorbed a certain quantity of amylaceous or saccharine substances, which, absorbed by the venous system, are poured directly by enlarged anastomoses into the general circulation, without

passing through the liver. There is to be found, however, in the *Recueil d'Andral* a case of diabetes in which the autopsy revealed an obstruction of the portal vein by pylephlebitis.

'We think that in this case the inflammation of the portal vein ought to be attributed to the diabetes. At all events, it is evident that it was not the same with our patients, who presented no sign of diabetes (no polyuria, no polydipsia, etc.), and the autopsy demonstrated cirrhosis of the liver. It is not only as a confirmation of a physiological theory already proved experimentally that these observations seem of interest to us.

'Glycosuria, demonstrated to exist under the conditions which we have indicated, becomes a sign of partial or complete obstruction of the portal vein, either by pylephlebitis or by compression, or by cirrhosis.

'We had an opportunity, in an obscure case, to appreciate the value of this clinical sign. It was the case of a young man, twenty-eight years of age, admitted into our service for ascites. This patient had indulged in alcoholic excesses; the affection developed progressively, without abdominal pains, and had commenced with digestive troubles; everything seemed to favour the diagnosis of cirrhosis. Nevertheless we rejected the idea, because the patient had no sugar in his urine after the ingestion of amylaceous and saccharine substances even in large quantities.

'The necropsy revealed to us a tubercular peritonitis which we had admitted in spite of the absolute integrity of the lungs.

'To repeat, we see that in man in disease, as in animals experimented upon, the obstruction of the portal vein determines what Claude Bernard calls an alimentary diabetes, and we think that in certain doubtful cases, this symptom may furnish important indications for the diagnosis.'

SPENDER ON A FORM OF UROHEMATURIA.—In the *Medical Press and Circular* (June 2) Dr. Kent Spender writes as follows. 'When blood exists in the urine in the usual, and (so to speak) the normal way, no symptom is more self-evident; any student can see it and demonstrate it. Now and then, it is true, there are fallacies which require sagacity and experience to detect: thus, a small quantity of blood derived from the kidneys gives the well-known sooty deposit in the urine, and a dark jaundiced tint may not always be quite easy to discriminate. As a rule, however, blood appears in the urine as blood, bright and red, and unmistakable in its physical and chemical characters; while albumen can be found in direct proportion to the quantity of blood present. But it is well known to many practitioners, though not so generally known as it should be, that a perfectly pale, almost colourless urine, of ordinary specific gravity, may be the unsuspected vehicle of blood, which is oozing out of the system in a clandestine way, and robbing the body to a not less certain and damaging extent than if it displayed itself in all its martial colours. Nay, still more, this treacherous, colourless urine, exhibiting no danger-signals to either doctor or patient, may contain every element of destruction, and may represent wear and waste of a most fatal kind.

'Here is a typical case. A young man or young woman, suffering from what we, as a cloak for ignorance, call hysteria or spinal irritation (or, perhaps still more darkly, "functional derangement"),

has a pale lip, a blanched cheek, and a palpitating heart. Sometimes there is so much irritation about the bladder as to give rise to the suspicion of stone, and the urine passed is so pale that possibly we are astonished to find its sp. gr. very little (if any) below the normal standard. This last point ought to be quite sufficient to excite further inquiry. Now, if to this colourless and seemingly innocent urine strong hydrochloric acid be added, it rapidly assumes a port-wine tint, showing that we have an excess of combined urohæmatin, which is liberated by the acid. The case stands simply thus—that an immense destruction of blood-corpuscles may take place in the body, and their *débris* be so eliminated as to be invisible until the application of an acid sets it free. In some of these cases the excess of urohæmatin in the urine is so great that after it has been set free by an acid, and taken up with ether, the ether after standing solidifies into a red-currant, jelly-like mass, and may actually be cut with a knife.

‘Sometimes a great part of the urohæmatin exists in the urine in a free state, and then the urine is red in colour before any acid is added, although the addition of the acid makes it still darker. These cases are essentially different from hæmaturia. In hæmaturia the urine is muddy, not transparent, and contains blood-corpuscles. In the cases I am describing, whatever may be the precise tint of the urine, it is always clear, and contains no blood-corpuscles. Whenever we have before us a disease like chlorosis, questions should be asked about the urine; and nine times out of ten we shall be told that it is all right, perfectly clear, and quite free. We may even satisfy ourselves that it has no trace of either sugar or albumen; and yet what a danger lurks behind! Both doctor and patient may be lulled into the belief that there is nothing materially wrong, when a grave lesion is making rapid strides towards a fatal end.

‘It is to the clinical sagacity of Dr. George Harley that we owe a knowledge of this lesion, and a means of clinically recognising it.

‘During the last few years I have, when possible, examined the urine in all cases of extreme chlorosis, and seldom without finding the reaction described by Dr. George Harley in greater or less intensity. A point worth noticing is, that the urohæmatin is not always in the same state of oxidation, and, like indigo, its colour depends on the amount of oxygen it contains, so that it may be pale yellow at one time, red at another, and brown at a third. In consequence of this, different acids act upon the urine differently. In one case we may find that the addition of nitric, sulphuric, or hydrochloric acid gives rise to exactly the same results; whereas in another case hydrochloric acid may turn the urine red, while nitric acid only causes it to become yellow; and in a third case sulphuric acid may develop the colour of the urohæmatin better than either of the others.’

J. MILNER FOTHERGILL, M.D.

LINCOLN ON SPINAL PARALYSIS IN AN ADULT RESEMBLING THE SO-CALLED INFANTILE PARALYSIS.—Dr. D. F. Lincoln reports the following case in the *Boston Medical and Surgical Journal* for March 25. A tall, stout man, forty-nine years of age, and of previous good health, noticed one morning, without any previous symptoms, a feeling in his legs as if they had fallen asleep. The feeling came on again and again through the day, and he

began to be a little weak in the legs. In the afternoon, when trying to step upon the platform of a street-car, he failed, and had to be helped in. On arriving home, he was able (with assistance) to walk up-stairs to his bedroom, and went to bed, where he remained.

When seen by Dr. Lincoln, two days later, he felt well. There was no giddiness; the muscles of the face and eyeballs were under perfect control; the pupils were normal in size and contracted well; speech was natural, vision and hearing without defect. The bladder and rectum performed their functions normally. The senses of touch, pain, and temperature were normal in the hands, and nearly so in the feet. Reflex contractions could scarcely be obtained from the soles. There were no abnormal sensations. Pulse 80, temperature 98°. There was no albumen in the urine.

The muscles of the neck and limbs, except below the knees, were generally in a condition of semi-paralysis. He lay on his back, almost helpless; could not raise his head from the pillow without some help, and could not raise his knees from the bed by flexing the thighs. The grasp of his hand was very feeble indeed. There was no paralysis of any muscle. Below the knees he seemed to have more strength. The weakness was much more marked on the left than on the right.

The treatment consisted at first in *nux vomica* and cinchona, and subsequently tincture of iron with strychnia, and Horsford's acid phosphates of lime and magnesia. On the fifth day of the attack, treatment by the induced electric current was begun, when it was found that some, at least, of the muscles had lost part of their susceptibility to this stimulus. The loss went on increasing until the twenty-first day, when the galvanic current was substituted, a descending current being applied to the spine, and interrupted currents to the muscles, three times a week; the faradic current was also continued for a few weeks.

The hot-air bath to profuse perspiration was used just before the application of the currents, together with regulated gymnastic exercises. The paralysis of the muscles was gradually relieved under this treatment to a very considerable degree. The patient's improvement was very gradual, and it was six months before he was able to ride out. He finally was enabled to attend to his business pretty much as before the attack.

LUBELSKI ON BULIMIA.—At the last meeting of the Academy of Medicine, on June 1, Dr. Lubelski read an account of a curious case of bulimia observed in a young woman aged twenty-six, who had generally enjoyed good health. She had been married for two months, when she suddenly had a nervous attack, which was first attributed to pregnancy, the menses not having made their appearance for some time. At the same time a devouring hunger and an insatiable appetite made their appearance. The patient ate from fourteen to sixteen pounds of meat per diem. Nothing abnormal was found in the urine; no albumen nor sugar. She grew very stout, so that at the end of some months she was unable to walk, and weighed about 250 lbs. All known therapeutic means were tried, of which the most lowering had absolutely no effect. The only peculiarity observed was a quite abnormal tolerance for toxic substances.

M. Lubelski sought for a cause to which he could

refer this pathological condition; it was not the bulimia or excessive obesity observed in certain kinds of insanity; the patient was in full possession of her faculties, and had neither tænia nor any other intestinal worm. The convulsive nervous symptoms exhibited by her, especially when she had not taken food, gave rise to suspicions of neurosis; but of what nature? M. Lubelski has not been able to solve this question, nor to fix on a course of treatment, since up to the present time every plan which has been tried has been entirely useless.

CLARKE ON TWO CASES OF TRANSFUSION.—Dr. D. Clarke reports the following cases in the *Canada Lancet* for April 1.

The first was that of a woman thirty-three years of age, the subject of advanced phthisis. The operation was commenced by the direct method with Aveling's apparatus, but, as this was found not to answer, defibrinated blood to the extent of six ounces, containing a small quantity of spirits of ammonia, was injected. Although some alarming symptoms followed the operation, yet the patient survived, and two months later was still living, auscultation and percussion showing no change in the parts affected.

The second case was also a woman of middle age, who had been the subject of phthisis pulmonalis for about a year. Six ounces of blood were injected by the direct method by the aid of Aveling's improved two-bulb apparatus, a solution of salt being used in the vessel instead of ammonia. The patient survived the operation, but sufficient time had not elapsed at the date of reporting to enable any estimate to be made of the permanent result likely to be gained.

SURGERY.

MEUSEL ON RESECTION OF THE KNEE AFTER GUN-SHOT WOUND.—In this contribution (*Berliner Klinische Wochenschrift*, no. 20, 1875), Dr. Meusel, of Gotha, reports two successful cases of resection of the knee-joint after gun-shot wound. The subject of the first case, treated by Dr. Meusel himself, was a man aged twenty-five years, who had been struck in the region of the left knee-joint by a ball from a revolver, fired at a short distance. The projectile entered about one quarter of an inch below the lower margin of the patella, passed through the ligamentum patellæ, and then downwards into the upper epiphysis of the tibia. The canal formed in the bone had smooth walls, and at its extremity, near the posterior surface of the tibia, the ball could be felt with a probe, but was so firmly fixed that it could

not be dislodged by bullet-forceps. When the patient was first seen on the day of the accident by Dr. Meusel, the knee was of the normal size, and free from pain. On the supposition that the joint had not been opened, the limb was fixed in a gypsum bandage. On the sixth day the joint commenced to swell, and two days later became much larger, and very painful, the patient at the same time being very feverish. On compressing the upper part of the joint, thin pus could be forced from the external opening. On the ninth day the joint was excised. A transverse incision was made below the patella, and carried through the wound in the skin made by the ball. A portion of the lower end of the femur, four centimètres in thickness, was removed, and a thin section taken from the head of the tibia, exposing the ball, which, together with a small piece of clothing, was extracted by forceps. The patella was left. On examination of the joint during the operation, it was found that the capsule had been wounded by the projectile. The synovial membrane was red, and thickened, and the joint contained purulent fluid. The tibia had not been splintered. At the eighth week there was firm union between the femur and the tibia, and six months after the operation the patient was discharged as cured, the limb being shorter than its fellow by about five centimètres. The patella remained movable, and could be pulled upwards by the action of the quadriceps extensor muscle.

The second case was one in which Professor Nussbaum performed primary resection of the knee of a young lieutenant, wounded by a Chassepot ball, in the Franco-Prussian war. The ball had passed inwards, near the external condyle, had shattered the lower portion of the patella, and had finally made its exit at the inner surface of the joint. The operation was performed within a few hours after the injury had been received. A transverse incision was made across the front of the joint. The upper half of the patella was left. The patient made a good recovery, the limb being shortened by about six centimètres.

W. JOHNSON SMITH.

DUPLAY ON ARTHRITIS DEFORMANS.—From the reports of Dr. Duplay's practice in the Hospital St. Antoine, by Dr. Gillette, published in the *Journal des Connaissances Médico-Chirurgicales*, we learn that Dr. Duplay treats this affection externally by tincture of iodine, revulsives, etc.; internally by sulphurous waters. Dr. Gillette observes that as a general rule, when the peculiar nature of an affection is not detected, it is very difficult to define its therapeutic indications; and this is precisely what occurs with arthritis deformans since the modern researches of which it has been the object. The intra- and extra-articular lesions belonging to it are known, such as the velvety condition of the cartilages, the arborescent productions of the synovial membrane, eburnation and transformation into *têtes d'ivoire*, ossifications of the ligaments, muscles, points and stalactites, foreign bodies; but the etiological conditions are ill-defined; sometimes a traumatic precedent (sprain, intra-articular fracture, luxation) does not admit of any doubt; sometimes a diathesis, principally of the rheumatic kind is discovered; sometimes nothing at all. Quite lately, however, a variety of arthritis called trophic arthritis has been described, which is developed under the influence of a change in the nervous centres. M. Duplay is inclined to regard arthritis deformans as the result of a trophic

disturbance, of an aberration of the nutrition of the joint, so that, in his opinion, the term arthritis is not a proper one, for the inflammation is certainly the least marked element. The treatment of this ill-defined affection is mostly in accordance with the complications it brings in its train. Thus it is frequently accompanied by very abundant articular effusions, fungosities, etc. Recourse must then be had to revulsives, blisters, methodical compression of the joint, painting with tincture of iodine, etc. M. Duplay advises that too much stress should not be laid on the immovability which is found to be so useful in the treatment of the other varieties of arthritis. In fact, in dry arthritis, notwithstanding the great deformity which is the fundamental characteristic of the disease the movements of the joints are partly preserved, though with the well-known rubbings and cracklings. Also in condemning such an articulation to a too prolonged immovability, it is deprived of the only benefit left by the affection itself, in the preservation of some movements; since every healthy object submitted to immovability partly loses its functions, and in a higher degree when it is in a diseased condition. M. Duplay looks on the iodised preparations, and the iodide of potassium in particular, as being to a certain extent efficacious; but a powerful modifying agent, which, unfortunately, can only be employed by persons in easy circumstances, is the treatment by taking the sulphurous waters at Plombières or Nérès for several seasons. These waters suit chronic rheumatism, and sometimes render great services to patients suffering from arthritis deformans.

ROBINSON ON THE NASAL DOUCHE.—In a paper read before the New York Medical Library and Journal Association (*New York Medical Times*), Dr. Beverly Robinson alludes to the wide-spread idea which is supported by some of the best authorities as to the frequent danger of using this appliance. Physicians are loth to abandon it, however, Dr. Robinson thinks, 'as it is thought to be so thorough in its work of cleansing the nostrils and pharynx.'

The latter generally received opinion is, however, an error in Dr. Robinson's opinion, and he endeavours to demonstrate the truth of his assertion by an examination of the relations between the stream thrown by the douche and the anatomical structure of the nasal passages.

He shows that the stream must issue from the nasal orifice of exit before it has flooded the upper part of the nose, and when from some obstacle the flow is interrupted, this flooding could only take place for a few moments, when the pressure in the naso-pharyngeal space would be such that the soft palate would give way almost immediately.

The effect of this would be that some of the liquid would pass into the stomach, or in the confusion of breathing get into the larynx. He does not believe that either the vault of the pharynx, the superior and middle turbinated bones, or the superior meatus are cleansed at all by the nasal douche.

ROBINSON ON COMPRESSION OF THE FACIAL ARTERIES FOR THE ARREST OF EPISTAXIS.—Dr. Beverly Robinson relates, in the *New York Medical Record*, a case of severe and obstinate epistaxis which, after recurring at frequent intervals during nine days, was at length arrested by compression of the facial arteries. Cold, astringents, and plugging, were first tried with very temporary success. The

facial arteries were then compressed against the superior maxillary bones just outside the alae of the nose by means of two small pads sewn at the proper distance apart on to a piece of tape, the ends of which were passed over the ears and tied together firmly behind the head. This quite controlled the bleeding, but for the first two days it recurred when the pads were removed; after that it ceased altogether, and the patient made a good recovery. Dr. Robinson adds that the blood in this case appeared to come from the septum; this part of the nose, which is not unfrequently the source of hæmorrhage, is supplied mainly by the terminal branches of the facial artery. Although he does not think that all cases of epistaxis can be cured by this plan, still its value was very evident in this case, and he thinks it may be useful in others.

MATERIA MEDICA AND THERAPEUTICS.

OXAMENDI ON THE THERAPEUTIC ACTION OF THE OLEUM ALEURITIS TRILOBÆ.—Dr. Calixto Oxamendi gives the therapeutic history of a new agent which may be considered as a good substitute for castor-oil (*Anales de Medicina de la Habana*, 1874).

The 'Aleuritis triloba' is a large tree of the euphorbiaceous family which grows principally in India and in all the intertropical countries. It is commonly designed in India under the name of 'Candle-nut tree' or 'Candleberry.'

The oil produced from the nuts of this tree is used for different industrial purposes. The native of Ceylon calls it 'Kekune oil' and it is known in England under the names of 'Nut Oil' or 'Artist's Oil.'

Very little has been said about the therapeutic

properties of this plant; nothing can be found on the subject in the works treating of *materia medica*. A little notice is, however, given in *Griffith's Medical Botany*. This author says: 'The nuts of the *aleuritis triloba* are considered as aphrodisiac when used in small quantity and in a dry state; they have laxative properties when taken in larger quantity and in a fresh state.' In one of his *Annales de Thérapeutique*, M. Bouchardat says that the oil of *aleuritis triloba* has purgative properties in a dose of thirty grammes. Renato de Grosourdy expresses the same opinion in his work on medical botany, but he thinks the oil must be used in a dose of two ounces (sixty grammes) in order to move the bowels.

Following the indications of Bouchardat and Grosourdy, Dr. Oxamendi has employed the oil of *aleuritis triloba*, and his results are not quite conformable with those arrived at by his predecessors. Having once given this medicine to a healthy negro woman, he obtained an effect much stronger than he expected. By subsequent experiments, he arrived at the conclusion that this oil must be employed in much smaller doses, and that half an ounce is quite sufficient to move the bowels of an adult.

The oil of *aleuritis* may be used with advantage as a substitute for other aperients. It greatly resembles castor-oil in its effects on the bowels, and it is by no means disagreeable; it has a pleasant taste of hazel-nuts. It acts quickly (about three hours after its administration) and very gently, without giving pain and griping.

What is the physiological action of this aperient? Dr. Oxamendi thinks the laxative effects are not only due to the disturbance produced in the bowels by the oil itself, but also to a special resin which irritates the intestinal mucous membrane.

The walnuts of the *aleuritis triloba* are so oleaginous that they yield nearly half their weight of oil. This valuable agent may be also used in emulsion. The dose of the oil is two drachms for a child or half an ounce for an adult. The following mixture is recommended by Dr. Oxamendi:

R.	Olei nucis <i>aleuritis trilobæ</i>	. . .	℥ss
	Gummi arabici	. . .	℥iij
	Aq. communis	. . .	℥iij
	Sacchari albi	. . .	℥ss
M.			

Good results have been obtained by making frictions with the following liniment over the abdomen in cases of rebellious constipation or abdominal pains:

R.	Olei nucis <i>aleuritis trilobæ</i>	. . .	℥ss
	Tinct. cantharid.	. . .	℥iij
	Ammon. carbon., aa	. . .	
M.	Linimentum.		

VALENTI Y VIVO ON THE ANTAGONISM BETWEEN STRYCHNIA AND MONOBROMIDE OF CAMPHOR.—Dr. Valenti y Vivo has made a series of researches on the supposed antagonism between these two substances; and has arrived at the conclusion that monobromide of camphor may be considered as an antidote for strychnia. According to Dr. Valenti, the following conclusions are well established (*Siglo Medico*, April 18, 1875).

1. Twelve dogs, after taking a fatal dose of strychnia, were saved by the use of bromide of camphor. The experiments were practised in a satisfactory manner, with crucial tests.

2. The tetanic convulsions produced by strychnia may be reduced in force and frequency by the use of

bromide. The action of the antidote is rapid and sure.

3. The hyposthenic action of the bromide mitigates the reflex activity of the poison. The tonic convulsions are converted into clonic.

4. The physiological antagonism is comparatively limited. A strong dose of bromide of camphor is necessary to antagonise the effects of strychnia.

5. The bromide acts on the sympathetic nerve; this is demonstrated by the myosis and the cardiac paralysis which were observed after its administration.

6. After an overdose of bromide, the united effects of the poison and the antidote produce death by syncope; when death takes place during the strychnism and without the antidote, cardiac impulses are observed *post mortem*; when it takes place after and through the use of bromide, cardiac impulses are never observed.

7. The experiments show that it is preferable to introduce the bromide by gastric ingestion, and in small and repeated doses. The subcutaneous method, employed in some experiments, has not given satisfactory results.

Dr. Valenti points out the importance of this antagonism in practical medicine. He thinks bromide of camphor may be used with advantage in cases of poisoning by strychnia, in quantity varying from four to six grammes, given in small doses.

[Dr. Valenti's experiments, if correct, show us a new antidote which may prove useful in therapeutics. Considered from a physiological point of view, this antagonism presents a great analogy with the antagonism observed by Dr. Hughes Bennett between chloral and strychnia ('Report of the Committee of the British Medical Association'). It may be remembered that Dr. Bennett's conclusions were as follows. 'Chloral-hydrate mitigates the effects of a fatal dose of strychnia, by depressing the excess of reflex activity excited by that substance; while strychnia mitigates the effects of a fatal dose of chloral by rousing the action of the spinal cord; but it does not appear capable of removing the coma produced by the action of chloral-hydrate on the brain.'—*Rep.*] A. LUTAUD, M.D.

THERAPEUTIC FORMULÆ.—The following are taken from the *Philadelphia Medical Times* of May 15, 1875.

Rheumatism: R Trimethylamini, ℥iv ad ℥viiij; Syr. zingiberis, ℥j; Aq. menth. pip., ℥j.—M. Take at intervals of one to three hours until pain is relieved.

Administration of Croton-Chloral Hydrate.—R Croton-chloral, gr. xxx; Glycerinæ, ℥jss; Ext. glycyrrhiz., ℥j; Aq., et syr. simpl., aa ℥jss.—M. Tablespoonful *pro re nata*.

Pills of Croton-Chloral.—R Croton-chloral., Pulv. glycyrrhizæ, Confect. rosarum, aa gr. xv.—M. Divide in pilulas xx.

In Pityriasis.—R Ol. theobromæ, Ol. ricini, Ol. amygdalæ, aa ℥v; Hydrarg. sulphat. flav., gr. xv.—M.

Lotion in Erysipelas.—R Camphoræ, Acid. tannic., aa ℥j; Etheris, ℥j.—M. Bathe the parts adjoining the diseased skin every two or three hours, or oftener.

Diarrhœa Mixture.—R Olei ricini, ℥xxiv; Sp. chloroformi, ℥jss; Sol. morphinæ mur., ℥j; Pulv.

gum. acaciæ, ʒijss; Syrupi, ʒss; Aquæ, ad ʒiv.—M. A dessertspoonful every hour and a half until the bowels are quieted.

Purgative in Dyspepsia accompanied by Constipation.—℞ Mass. hydrarg., Ext. colocynth. comp., āā gr. xxx; Pulv. ipecac., gr. iij.—M. Divide in pilulas xij. Two of these are to be taken every second or third night, and followed by a Seidlitz powder the next morning.

Chloral Suppositories.—The production of a chloral suppository containing a sufficient proportion of this drug to cause sleep has heretofore been deemed impossible. M. H. Mayet, pharmacien, of Paris, has, however, devised the following formula, by which he manages to get forty-five grains of chloral in each suppository: ℞ Ol. theobromæ, gr. xxx; Cetacei, Pulv. chloral., āā gr. xlv. For one suppository. These suppositories are of good consistence, and may be easily put into use.

Injection for Cystitis.—℞ Sodii hyposulphit., ʒiv; Aq. destillat., lb. j, ʒiv.—M. This solution may be employed in five injections, in chronic catarrh of the bladder, when there is pain and the carbolic acid injection cannot be employed.

Local Anæsthetic.—℞ Pulv. camphoræ, ʒijss; Ætheris sulph., ʒv.—M. Rub into the skin for a few moments at the locality where it is desired to produce anæsthesia.

In Diphtheria.—℞ Pulv. cubebis, Aq. menth. pip., āā ʒv; Syr. aurantii flor., ʒvij; Aquæ, ad fʒiv.—M. One or more tablespoonfuls for an adult, every three or four hours.

Antigastralgie Drops.—℞ Tinct. nucis vomicæ, Tinct. castorei, āā ʒss.—M. Two drops during the paroxysm, in half a wineglass of infusion of chamomile.

Camphor-Ointment.—℞ Pulv. camphoræ, gr. xv; Glycerinæ, q. s.; Axungiæ, ʒj. Useful in erythema and in vesicular and squamous affections of the skin.

Gargle in Syphilitic Ulcerations.—℞ Hydrarg. chlor. corros., gr. ij; Glycerinæ, ʒiv; Aquæ, ad fʒvij.—M.

OBSTETRICS AND GYNÆCOLOGY

FRANKEL ON A NEW METHOD OF TREATING SPASTIC UTERINE CONTRACTION DURING THE SECOND AND THIRD STAGES OF LABOUR.—The following article, by Dr. E. Frankel, of Breslau, has been translated from the *Archiv für Gynäkologie*, Band vii., by Dr. W. H. Taylor, M.D., Professor of Obstetrics, Miami Medical College, Cincinnati.

Spastic contraction of the uterus, whether of the internal os, the lower segment, or of the entire organ (tetanus uteri), presents a serious obstacle to the performance of operations which are sometimes necessary for the completion of the parturient act.

Tetanus uteri, before the birth of the child, is especially frequent in cases of contracted pelvis, where the membranes have ruptured early, and where

long-continued expulsive efforts have failed to deliver the child. Frequently, in these cases, the anterior part of the head or the face presents, remaining movable above the brim. Version is indicated, provided the contraction of the pelvis is not too great; but the attempt at version fails because the tetanic contraction of the uterus around the child precludes the introduction of the hand of the operator or the turning of the child without the most imminent danger of the rupture of the uterus. Similar difficulties are encountered in neglected cases of transverse positions in contracted pelvis, or in normal pelves, where the abnormal position is not recognised early, or where the liquor amnii has been discharged long before the arrival of the obstetrician. In these cases, either the whole uterus firmly compresses the body of the child, or the lower segment of the uterus has rigidly contracted around a prolapsed part, e.g. a leg or an arm. Formerly, under such circumstances, the advice was given to dismember the prolapsed part, it being the supposed impediment to delivery; at the present time, not unfrequently prominent obstetricians advise, in cases of head presentation, with moderate contraction of the pelvis and tetanus uteri, that perforation and extraction with the cranioclast be resorted to, on account of the asserted impossibility of turning, and that, in transverse presentations, evisceration or decapitation be performed.

I will not deny the necessity of the latter operation in certain cases; but I must assert that, in about one thousand abnormal labours which, as assistant to the Breslau polyclinic, I have attended, in some of which there was considerable contraction of the pelvis, and under the most unfavourable circumstances, I have never resorted to this horrible operation. By the application of the method which I shall describe, I have succeeded in performing version where experienced and skilful colleagues have regarded it as impossible and embryulcia as unavoidable.

No less serious is spastic contraction of the uterus in the period of delivery of the after-birth. Usually, in these cases, we have to deal with partial contraction—stricture in its limited sense—which sometimes occurs at the internal os, sometimes involves the whole isthmus uteri. It originates, usually, in improper attempts to remove the placenta, either by too early and great traction on the cord, or by rough efforts at expression.

A third series of cases, by far less frequent, occurs, without any fault of the accoucheur, developing spontaneously; viz., where the placenta is partially adherent. In such cases, a portion of the placenta is expelled from the uterus, another portion adhering, the intermediate portion, acting as a foreign body, induces violent contraction of the isthmus uteri, and develops the condition known as incarceration of the placenta.

In all these cases hæmorrhage occurs, and often to a very alarming extent. I cannot agree with Hüter (*Compend. der Geburtsh. Operationen*, s. 308), that there is a difference in the severity of the hæmorrhage, according as it is associated with atony or spastic stricture in the after-birth period. I have found no such difference in practice, and theoretically do not regard it as probable, because I frequently find spastic stricture of the isthmus associated with atony of the body and fundus. It is true, that in such cases the external hæmorrhage may be limited, as a coagulum may easily impede

the flow of blood; but proportionally greater will be the internal metrorrhagia—a condition which manifests itself by the unusually high position of the uterus.

Spasm of the isthmus uteri occurs almost exclusively with mature births. Neither Hüter nor I have seen a case in a premature delivery. In premature births, especially between the twenty-sixth and thirty-second week, and where there is a macerated foetus, there is often excess of liquor amnii. Now, if this condition be associated with a malposition—*e.g.*, transverse—the membranes rupture long before the lower portion of the uterus is sufficiently dilated for the delivery of the child; the heretofore greatly distended uterus suddenly contracts, the small foetus is firmly compressed, and the introduction of the hand of the operator is rendered impossible. Finally, I mention the spastic constriction by the neck of the uterus of the after-coming head in breech cases, by which the extraction of the head is prolonged, and the danger to the child greatly increased.

What, now, are the means recommended by the text-books and adopted in practice, by which to combat these various conditions? They may be placed in two categories, according as an urgent demand for delivery—*e.g.*, violent hæmorrhage—exist or not. In the latter case the elder school resorted to the whole list of antispasmodics—*i.e.*, castoreum, asafetida, warmth in the form of baths, injections, and fomentations. (According to my experience, the two latter act as irritants, and increase rather than allay spasm.) The nauseants (ipecac. and tartar emetic) have been abandoned; also, with our views of puerperal fever, venesection to syncope. Anæmic persons exhibit a very diminished power of resistance to surgical fever, and in the acute anæmia of lying-in women the closure of the uterine sinuses is the least perfect. There remains, therefore, for these cases only the use of opium internally, by clyster, or morphia by subcutaneous injection; and chloroform. Opium and morphia are often valuable, but not always. Opium requires too long time (one or two hours) for its full effects, for us to rely on it in urgent cases, and we have seldom seen the effects of large subcutaneous doses of morphia in less than half an hour, and often longer, as Lebert, who introduced it into midwifery practice, admits.

Nothing but chloroform remains, and even deep chloroform narcosis does not relieve the spastic rigidity of uterine contraction, and, according to Spiegelberg and others, the irritability of the uterus is very slightly diminished. During the anæsthesia the pains are weaker, the intervals are longer, and the chief effect is that the expulsive action of the abdominal muscles ceases entirely. The preceding are the methods resorted to where there is no urgent demand for delivery; but where the delivery must be speedily effected—*e.g.*, where there is incarceration of the placenta in the lower segment of the uterus, with dangerous bleeding—no time is allowed for the action of antispasmodics, the various forms of heat or opium, to be established.

Chloroform is recommended by many—*e.g.*, Schroeder in his text-book; but we have shown above, and have learned from experience, that it is of little value in such cases. Others—Hüter, for instance—fear the effects of chloroform, for the reason, as they assert, that the use of chloroform in anæmic women is always attended with danger, and

further, that *post partum* hæmorrhage more readily supervenes after chloroform.

These fears are purely theoretical. Ask the military surgeon if, in cases of wounds of large vessels and profuse hæmorrhage, he hesitates for a moment to administer chloroform to secure quiet for the performance of the needed operation? It is yet to be proven that chloroform narcosis is more dangerous to anæmic women than anæmic men. In hundreds of cases, in which chloroform was used, I have never seen hæmorrhage during or after separation of the placenta, where, in other respects, the conditions of delivery were normal, and it is inexplicable how chloroform which, during the expulsive stage, does not arrest uterine contraction, should in the after-birth period produce atony of the uterus. Heretofore there has been no other resource, in urgent cases, than the gradual dilatation of the stricture with the fingers. This enfeebled the hand, and unfitted it for further operative procedure; and second—and chief objection—it is a prolonged and intense irritation of the most sensitive part of the puerperal uterus; and when, as in this case, the organ is in a condition of intense rigidity, is not without malign influence on the convalescence after delivery. Equally injurious are its effects upon the parametric connective tissue with its enormous development of blood-vessels. Para- and perimetritis are the frequent consequence of this gradual manual dilatation of the constricted isthmus uteri. Consequently, this method is also objectionable.

It was, therefore, desirable to find a therapeutic combination which, while it secured the greatest relaxation of the uterus, excluded the danger of subsequent hæmorrhage, and that was so speedy and reliable that, in urgent cases, it could be used without such loss of time as to jeopardise either mother or child.

Until recently, I believed I had found this combination in the subcutaneous injection of morphia (fifteen milligrammes to three centigrammes) followed by chloroform anæsthesia. I was led to resort to this method by an article by A. Martin, upon 'Chloroform anæsthesia prolonged several hours by the subcutaneous injection of narcotics,' *Bayer. ärztl. Intelligenz-Blatt* xliv. 1863; and especially by Cl. Bernard's article in the *Bull. Génér. de Thérap.* 1869, p. 241, 'Upon the Physiological Effects of Morphia, and their Association with those of Chloroform.' Bernard shows that in dogs, who, it is well known, are with difficulty brought under the influence of chloroform, if five to fifteen centigrammes of muriate of morphia be injected subcutaneously, that, during the early stage of the effect of the morphia, small quantities of chloroform, which, under other circumstances would not produce narcosis, are sufficient to secure its full anæsthetic effect. The animal can be maintained in this condition for half a day; but if the inhalation be interrupted, sensibility returns.

I believed that from this proceeding a twofold advantage was derived for the woman in labour. 1. By the subcutaneous injection, the most speedy influence of the morphia against the uterine contractions was obtained, whilst the chloroform, in addition to a limited influence over the action of the uterus, arrested the action of the abdominal muscles, thereby facilitating any subsequent operation. 2. As in the administration of chloroform five to ten minutes after injection of morphia, a smaller quantity was required to induce complete anæsthesia, I hoped to lessen the danger which always attends

profound chloroform narcosis. These physiological inferences were in a great degree substantiated by clinical experience. I frequently had opportunity to observe where I could scarcely force the end of the finger through the isthmus uteri, that, after morphia injection and subsequent very slight chloroform narcosis, the sharp-edged rigid ring relaxed, and the whole hand could pass the constriction without difficulty. I have thus succeeded twice in performing version, long after the liquor amnii was discharged, where other operators had made futile attempts, and I have always succeeded in speedily overcoming the constriction of the neck in cases of incarcerated placenta, with profuse hæmorrhage, and have removed the placenta, adherent or not, and in no case did serious bleeding occur from subsequent relaxation of the uterus. On the contrary, chloroform narcosis, following injection of large doses of morphia, requires to be carefully watched, because of the great liability to asphyxia.

As I generally operated alone, this latter circumstance led me to seek for some agent whose combination with chloroform would be less dangerous, and more manageable by the physician without an assistant. Further, I had a case where there was a moderate degree of contraction of a simple flat pelvis: it was a first pregnancy—a face presentation. The os being fully dilated with chloroform anæsthesia, I performed version. In the attempted extraction, the lower segment of the uterus contracted so firmly around the head that the os appeared at the vulva when slight traction was made. The inspiratory efforts of the child demanded speedy delivery. I injected three centigrammes of muriate of morphia, and then gave a new dose of chloroform. Despite these means, more than five minutes elapsed before sufficient relaxation took place to allow the extraction of the child without danger of laceration of the lower portion of the uterus. The fœtus, in the meantime, was asphyxiated, and died soon after birth. This case was a new incentive for me to seek for a more speedy means of relaxing the uterus than the combination of chloroform and morphia.

I directed my attention to the preparations of belladonna, to which the older obstetricians ascribed great power in overcoming spasm, when locally applied; further, the good results obtained by Breslau in overcoming spastic uterine contraction by injection of atropine, are well known (*Wiener Med. Presse*, 1866, 3). This method fell into discredit because Spiegelberg reported a case which he had observed, where, after injection of $\frac{1}{40}$ gr. of atropia sulph., a very dangerous degree of atony of the uterus supervened (*Carstatt's Jahrb.* 1866). This, however, did not prove that atropine was not adapted to the purpose—merely, that in the particular case too large a dose had been injected, so that, not relaxation, but paralysis of the uterine muscular fibre occurred; for, through the researches of Bezold and Blöebaum, the action of this alkaloid upon organic muscular fibre has been determined—viz., that the irritability of the intestine, the uterus, bladder, and ureters is impaired by very small doses, and entirely destroyed by large, the result being the same whether the poison act through the blood or from local application. (*Untersuch. aus dem Physiol. Laboratorium in Würzburg*, 1867).

I believe, also, that the dose given by Spiegelberg was too large, the maximum quantity which I have given subcutaneously being one milligramme, and in the many cases in which I have used it, I have never

seen a dangerous atony nor hæmorrhage supervene, where in other respects the usual care was exercised in the placental and post-placental periods. I also sought to obtain the effect of large doses of atropine, by a combination of small doses of atropine and muriate of morphia. Such an attempt may appear to have been problematic, because of the generally assumed antagonism between atropine and morphine.

This antagonism prevails only to limited extent—e.g. in the effect of the two agents on the pupil and on the vascular system; and by a number of physiologists, all antagonism is denied. Harley's conclusions, from experiments with the two alkaloids separately and combined, upon dogs, horses, and men, are that no antagonism exists, and that the effects are more intense and prolonged when the two are used together, and that their effects are cumulative.

My own experience confirms the opinion that on the uterus their effects are cumulative. Very firm strictures relaxed in, at latest, not more than five minutes, and often immediately after subcutaneous injection. To remove the pressure of the abdominal muscles, I almost always allowed a few inspirations of chloroform, three to five minutes after the injection, and have been astonished at the ease with which narcosis supervened; what small quantities of chloroform were required; how quiet, and how easily managed by the operator without assistance; how regular the pulsations of the heart and the respiration were; and how seldom strangling and vomiting occurred. The asphyxia, which I have seen to an alarming degree when chloroform and morphine were used, has never been observed after the use of the combination of morphia and atropia.

The results, therefore, of physiological experiment and clinical observation are, that chloroform with atropine and morphine produce a certain, speedy and safe narcosis, the quantity of chloroform required being small; that chloroform and morphia produce anæsthesia more speedily than chloroform alone, but on account of the tendency to asphyxia it is dangerous and demands most careful watching; and finally, as a result of the foregoing observations and experience, I propound the following propositions:

1. In spastic contractions of the uterus, either partial or general, during either the second or third stage, the combined subcutaneous injection of muriate of morphia and sulphate of atropia, followed by chloroform narcosis, is the most speedy, safest, and least injurious means of relieving the constrictions and facilitating subsequent operation.

2. With appropriate doses (not over one milligramme of atropine), and otherwise proper management of the delivery of the placenta, there is no increased danger of atony of the uterus, and consequent hæmorrhage.

3. Chloroform narcosis is rendered easier and safer by preceding atropia (one milligramme) and morphine (fifteen milligrammes) injections.

PSYCHOLOGY.

BRIERRE DE BOISMONT ON THE TREATMENT OF MELANCHOLIA.—Dr. Briere de Boismont (*Journal of Psychological Medicine*, April, 1875) gives an able summary of the treatment proposed by him of this form of mental disorder.

A certain number of melancholic cases recover, once, twice, and thrice; some without having recourse to medical aid, and others by availing themselves of such assistance. Those who recover at home are especially those who preserve their sentiments of affection, do not feel any estrangement from their family, and do not manifest any dangerous tendency.

In most instances these patients, after several attempts which date from more or less distant periods, find their symptoms aggravated. The affections are perverted, and their relations and their homes inspire them with profound dislike. They are haunted by the most painful and terrifying insane ideas; they have hallucinations and illusions of the same kind; they have no desire for food, and they endeavour to destroy themselves. When they are taken in hand with these antecedents, some of them may still be cured. Most of them have long attacks; their faculties become altered more and more, and at last they become incurable.

At the commencement of the malady recourse may be had to travelling, or to some intellectual, artistic, or physical employment; and not unfrequently success is achieved by the employment of these means, which are equally useful in the period of convalescence.

A large proportion of these cases are suicidal. Out of 417 patients, 122 had made one or several attempts at self-destruction.

Dr. Boismont states that prolonged warm baths, with or without irrigations, lasting from one to two, three, four, or five hours, have proved beneficial when the malady was recent, with agitation, want of sleep, heat of skin, and refusal of food. If the patients be apathetic, unwilling to take any food, attempting suicide, passing their motions under them, then the half-warm bath, with cold affusions by sprinkling (*en arrosoir*), or in the form of the shower or the douche, is often beneficial.

Of the 108 patients who went out cured, the greater part received great benefit from the baths, the duration of which was in proportion to the effects produced. Dr. Boismont took notes of seventeen cases cured by this mode of treatment. One of them recovered his reason the third day, having had no previous attack. Nine others, similarly circumstanced, were convalescent at the end of a fortnight.

It is often indispensable to use purgatives, in addition to the baths; but the drugs must be disguised, because melancholic patients imagine that they are being poisoned. Tonics, chalybeates, and quinine, are also of great service.

A powerful auxiliary in the treatment is family life (*vie de famille*). Dr. Boismont considers that it is woman who takes the most important part in the

management of this system, in which the influence of the affections is a positive good. A man's character cannot bend itself to this kind of slavery.

Dr. Boismont insists upon the importance of the demeanour of the physician in combating the delusions of melancholia. A suitable observation, or a ready reply, is very efficacious, at an opportune moment, in arresting the attention and changes the course of the ideas. Some interesting anecdotes are related in illustration of this point.

The writer also touches upon a form of treatment somewhat unusual in this country. Speaking of the benefit derived by convalescent patients by the departure from the asylum, he mentions the case of a music-master, who, after an attack of melancholia, became more tranquil, though still retaining some extravagant notions. This patient returned to his home and gave his music lessons during the day, but returned to the asylum to dine and sleep. When the acute stage is passed and the malady remains stationary, when there are no evil tendencies, and the patient wishes to return to his own home and revisit his relatives, his wish ought to be granted.

Visits of relations, which are justly regarded as dangerous in the acute stage of the disease, when it is still at its height, may, on the other hand, produce a marked improvement when the patients wish for them, and even in some cases when they occur unexpectedly.

Dr. Boismont treats cases of refusal of food by making a disagreeable impression on the patient.

If the refusal of food be obstinate, and founded on an insane notion or hallucination, if the breath be fetid, if there be no febrile disturbance, then forcible alimentation is indispensable. The instrument most generally employed is the œsophageal tube, either simple or modified, of MM. Baillarger and Blanche. The silver mouthpiece of M. Billod is also useful. Dr. Boismont's method of disgusting the patient with the process of feeding is as follows.

A straight jacket is put on the patient, and he is fixed in an arm-chair, from which he cannot move, called a 'fauteuil de force,' or he is laid on the bed. A tube armed with an iron rod, slightly curved at the lower end, is then introduced into one of the nasal fossæ, and is passed as far as the back of the mouth, when the rod is withdrawn.

Dr. Boismont does not endeavour to pass the tube into the œsophagus, because that is not the object in view. An assistant closes the mouth with his hand or a napkin several times folded, another assistant applies his fingers on the nostril which is free, and the broth, tapioca, chocolate, etc., is poured in with the aid of a funnel, the end of which is introduced into the tube. An injecting syringe may also be used, the end of which is placed in the tube.

Forcible alimentation is almost always unsuccessful in the febrile state.

The refusal of food may sometimes depend upon separation from the domestic circle. In two cases, in which this cause was clearly proved to exist, Dr. Boismont sent away the patients to their homes, and this course was attended with success.

A happy thought may occasionally be sufficient to overcome this obstinate refusal of food. One melancholic, who had refused food for six days, at the sight of more numerous dishes and food more delicately prepared than usual, smiled, took what was offered to him, and ate with a good appetite. The crisis was over, and did not re-appear.

For suicidal tendencies, which are so rapidly

carried into execution by the French, Dr. Boismont employs a straight jacket and cuffs in extreme cases. Some important remarks are made on the utility of moral treatment, a knowledge of the different expressions of the face being especially insisted on.

Finally, Dr. Boismont recommends that we should always speak to the patients according to the excellent advice of Daquin, in the language of reason, even when they do not appear to understand it.

NEW INVENTION.

THE SPIROSCOPE.

M. Woillez lately read a paper at the meeting of the Academy of Sciences, in which he referred to some experiments made by him in 1854 on the study of the auscultation, anatomy, and physiology of the lung. For this purpose, he at that time invented an apparatus which he did not perfect until now.

The instrument as figured consists of the following pieces :

a. Tube on which the lung is fixed in the middle of the apparatus.

b. A movable spatula intended to approximate the lung to the walls of the glass cylinder for auscultation.

c. Cock to facilitate the working of the bellows placed inside the instrument.

d. A cylindrical bellows intended to produce a vacuum in the cylinder.

e. Stand for the apparatus.

f. Traverse to hermetically close the lid.

M. Woillez stated that the researches from a pathological point of view are as yet incomplete. One question notably has remained untouched, which is that of auscultation performed at the level of the lung immersed in the spiroscope as it is in the pleura in cases of liquid effusion, or in pneumo-hydrothorax, of which the conditions may be artificially produced.

From the anatomical point of view, the spiroscope produces perfect insufflation of the lung, which can receive five litres of air and subsequently be dried. Instead of air, coagulating substances which retain the impress of the air-cavities, or liquids which act chemically so as to facilitate microscopic studies, may be injected. The injection of the pulmonary vessels by aspiration by means of the spiroscope has not hitherto given satisfactory results.

Physiology as well as anatomy may be benefited by the use of this apparatus. It demonstrates that aspiration is the most perfect means of obtaining easy penetration of air into the lungs, which explains how half a litre of air can suffice for both lungs in ordinary respiration, as physiologists have established. The necessity for the permanent extension of the lung, even in the most energetic expirations, is clearly proved by the action of the spiroscope, which also permits demonstration of the number of respiratory movements necessary to entirely renew the air contained in the lungs. M. Woillez also referred to the best treatment to be applied to persons drowned or asphyxiated ; a question which might be better resolved than it has been up to the present time, by utilising the principle on which the spiroscope is based. The facility with which the external air penetrates into the lungs when, instead of insufflating them, these organs are first dilated, as is the practise with the spiroscope, seems in fact to prove that the best means of re-establishing respiration in asphyxiated persons would be external aspiration performed on the thoracic wall to produce their dilatation, and on the abdomen to produce the same effect on the diaphragm.

CORRESPONDENCE.

ON NERVOUS DISSOLUTION.

(To the Editor of the LONDON MEDICAL RECORD.)

SIR,—A paragraph on paralysis of the palate and vocal cord from disease of the eighth nerve has, I find, strayed into the account you give of my remarks on Nervous Dissolution. It might, indeed, have been in place as an illustration had there followed a reference to lack of inhibition of the heart as a consequence of paralysis of the pneumogastric. An error of more importance is the substitution of the word 'purposely' for 'purposeless' in the last paragraph but one. Loss of inhibition is but another name for what, after Anstie and Thompson Dickson, I call 'loss of control.' I now write to send a quotation from one of Rutherford's Lectures (*Lancet*, April 29, 1871) which expresses the same idea. After speaking generally of inhibitory nerves and centres, Rutherford says, 'I have just alluded to the inhibition of thought. This is an important point, and worthy of your deepest consideration. When we control our thoughts, words, and deeds we voluntarily exercise an inhibitory power ; probably we call into play certain inhibitory centres in the brain. These centres can, by exercise, attain to great importance. In some individuals they seem to be much more powerful than in others ; and one of the earliest signs in many cases of insanity is a diminution in the inhibitory power of these

centres. The mind is rendered thereby less able to control the nerve-processes concerned in thought and muscular movement.

The last volume of the West Riding Asylum Reports contains a masterly article by Lauder Brunton on Inhibition.

The Principle of Dissolution taken with the Principle of Loss of Control seems to me to be of value in the scientific investigation of mental diseases.

J. HUGHLINGS JACKSON.

MISCELLANY.

THE number of Professor Huxley's students in Edinburgh University now amounts to upwards of 350.

DR. ROBERT J. LEE has been elected by the board of the London Temperance Hospital one of the visiting medical officers of that institution.

LADIES FOR LADIES.—Madame Brès, who last week read a thesis before the Paris Faculty of Medicine and obtained a Doctor's degree, is reported to have been appointed physician to the Sultan's harem at Constantinople.

PRACTICAL BOTANY.—The Paris *Figaro* relates an amusing story of a late medical examination. A student had failed in everything. Botany alone remained. The good-natured professor took up a specimen of the plant tobacco, and asked what it was. The student looked at it with puzzled gaze, but knew it not. 'Something you take many times a day,' said the professor gently. 'I have it,' shouted the student, 'it's absinthe.'

LOYALE A MORT.—Out of sixty-four medical graduates of Michigan University who were lately examined, twelve were ladies, some of whom passed with honours. In one instance, says a contemporary, a husband and wife, who had been studying together, were separated by the fatal verdict of the judges; the wife was accepted, the husband was rejected in spite of the fact that he was the graduate of a Methodist college, a bachelor of laws, a master of arts, and had studied for some years in the universities of Europe. Like a loyal wife, nevertheless, the woman preferred to share her husband's misfortune, and went away with him, not wishing to receive an honour which he could not share.

WHOLESALE AND FOR EXPORTATION.—An article in the *Melbourne Medical Record* for Feb. 27, states that in Victoria, with a population of 700,000 inhabitants, there are 700 medical men, or one to every thousand people. The writer proceeds in a somewhat amusing way to show how this redundancy of medical men, or, according to his quotation from Voltaire, 'things on two legs putting drugs they know but little about into the bodies they know nothing of,' leads to an extraordinary exiguity of fees. He even speaks of the Vice-Chancellor of the Melbourne University as having given advice to a club patient for the very modest fee of sixpence.

THE Prussian order *pour le mérite* for science and art has been conferred by Royal decree upon three eminent foreigners, namely, the great physiologist Theodore Schwann, of Liege, Dr. George Bancroft, the historian, who was for many years American Minister at Berlin, and Professor Stokes, of Dublin. German members of this order can be appointed only when a vacancy arises, the number being strictly limited to thirty. Theologians are expressly declared ineligible to this distinction. Alexander von Humboldt was the first chancellor of the order, the second was the legist Savigny, the third the classical philologist and historian Boeck, succeeded by the historian Leopold von Ranke. The first vice-chancellor was the painter Cornelius, and on his death Professor Dove was appointed to the dignity. Field Marshal von Moltke is a member both of the military and of the civil order *pour le mérite*.

AN epidemic of measles introduced at Levuka, it is believed, by her Majesty's ship *Dido*, when that ship returned from Sydney with the King and his two sons last January, has assumed alarming proportions.

A CHARITABLE WISH.—Dr. Grabham, in a lately published pamphlet on the 'Origin, Varieties and Terminations of Idiocy,' relates that one of his lady correspondents, the mother of a patient, writes to him that 'Her late husband used to say that there was no such place as hell, but she hopes now he has found out his mistake.'

ICE IN THE HOUSE.—The use of ice in small quantities frequently repeated is very general in many diseases, but it is generally found to be a difficulty to keep it from melting, especially in small blocks. Dr. Schwarz recommends, to obtain this result, that the ice should be put in a vessel covered with a plate, which vessel should be placed on a feather-bed and covered with a feather-pillow or cushion, feathers being very bad conductors of heat. Dr. Schwarz states that by this plan he has been able to keep six pounds of ice for eight days when the thermometer marked summer heat.

THE MILD GORILLA.—The Marquis de Compiègne, one of the most enterprising French explorers of the Ogoone, in a letter to the *Explorateur*, confirms the statement of the late Winwood Reade as to the mild nature of the gorilla. Both travellers describe this animal as even of a timorous nature, flying from man to a much greater extent than he is shunned by the human race in those regions. The marquis was never able to get near enough to these animals to kill one, although he once saw two of them; they were perched on the top of a tree, and disappeared with amazing rapidity when they caught sight of the white man. He relates that one of his hunters found himself one day literally face to face with three gorillas; his gun missed fire, when man and animals ran away as fast as they could in opposite directions, the one as terrified as the other. M. de Compiègne confidently states that the gorilla is in no sense an intermediate link between man and animals, but a simple ape; a gigantic ape, it is true, of colossal strength and size; but in no way differing in its ways and habits from the other large anthropoid apes, as for instance, the chimpanzee.

ERRATUM.

The paragraph, line 37, p. 349, of the LONDON MEDICAL RECORD, in the article 'Dr. Hughlings Jackson on Nervous Dissolution as illustrated by Epileptic Mania,' commencing 'In a case,' and ending 'as many physicians suppose,' was inserted in error and belongs to a paper on another subject.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.: free by post, 19s. 6d. Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each. Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, JUNE 23, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

VULPIAN'S EXPERIMENTAL PATHOLOGICAL STUDIES ON THE PHYSIOLOGICAL ACTION OF TOXIC AND MEDICINAL SUBSTANCES.

(Continued from page 367.)

M. Keuchel, in some experiments made under the direction of M. Bidder, has discovered an interesting fact worthy of recapitulation. It is, that the sulphate of atropia abolishes the action exercised by the chorda tympani on the submaxillary gland; so that on a curarised dog, submitted to artificial respiration and also poisoned by a slight dose of sulphate of atropia, faradisation of the lingual nerve, united to the chorda tympani, does not bring on the slightest flow of saliva from Wharton's duct.

M. Heidenhain has established the existence of another remarkable peculiarity in repeating this experiment. It is that the faradisation of the chorda tympani, which no longer provokes the slightest submaxillary sialorrhoea, exercises the same action over the vessels of the gland as in the normal condition. The vessels of that gland become dilated; the circulation in them becomes more active; in a word, all the circulatory modifications which faradisation of the chorda tympani produces in the submaxillary gland, as M. Claude Bernard has discovered, show themselves as in a dog not poisoned by atropine. Finally, M. Heidenhain has made still another important remark. After having recognised that the chorda tympani has no longer any action on the secretion of the salivary gland in a curarised and atropinised dog, he submitted the upper extremity of the cervical cord of the great sympathetic to faradisation, and he has seen that the excitation of this cord further determines the flow of saliva, as in an animal simply curarised. It may be concluded, in agreement with M. Heidenhain, that if the atropia destroys the action, which in the normal state the chorda tympani exercises over the submaxillary gland, it is by modifying in a certain way the peripheric extremities of the glandular fibre of this branch of nerve, but not by annulling in a more or less permanent manner the secreting faculty of the cells which line the interior of the *culs-de-sac* of the submaxillary gland. Otherwise, faradisation of the sympathetic filaments which go to the gland should no longer, in an atropinised animal, produce any increase of the salivary secretion. It will, on the contrary, be understood, that the mode of termination of the nervous filaments springing from the sympathetic may be different from that of the fibres which take their rise in the chorda tympani, and that consequently atropia exercises a different action on the terminal extremities of these two sorts of fibres. These conclusions of M. Heidenhain are the starting-point, the basis, of the argu-

ment which opposes itself to the admission that the sialagogue influence of jaborandi is due to an action of that substance on the cells of the submaxillary gland. One or two centigrammes of sulphate of atropia are injected into the subcutaneous cellular tissue, in a dog curarised and submitted to artificial respiration. When the effects of the atropinisation are visible, that is to say, when the pupils are extremely dilated, thirty or forty grammes of water, in which two or three grammes of pulverised jaborandi leaves have been infused, are injected into one of the crural veins. A cannula destined for the flow of the submaxillary saliva is first fixed in Wharton's duct, and, as MM. Carville and Rochefontaine have shown, there is not the issue of a single drop of saliva by the cannula.

However, as already said, the sulphate of atropia appears to have left intact the functional aptitude of the cells appertaining to the submaxillary gland. If, then, the infusion of jaborandi does not exercise a greater sialagogue action, it is because the active principle of this substance does not directly excite the gland-cells, and only provokes an increased secretory work by the medium of the fibres of the chorda tympani. By the help of curare an effect analogous to that brought on by atropine is induced. But to attain that result it is necessary to submit the animal (a dog) to the action of a large quantity of curare. A dog is curarised, and to obtain the effect desired more quickly, a filtered solution of curare, in sufficiently large quantity to annihilate the action of the great sympathetic, is injected into a femoral vein. This degree of curarisation obtained, an infusion of three or four grammes of jaborandi leaves is injected into the same vein of the animal. The injection of jaborandi remains inactive. However, the curare only really acts, in these conditions, on the ends of the glandular nerves, and not on the cells appertaining to the submaxillary gland, of which the functional properties should remain intact. At least, it seems to M. Vulpian that he has a right to reason thus, basing his opinion on what takes place in the nerves and striated muscles under the influence of smaller doses of curare. Consequently, it may still be legitimately concluded from this kind of experiment that the sialagogue action of jaborandi is not owing to an excitation produced by it in the cells belonging to the gland itself. It must thence be admitted that jaborandi acts on the submaxillary salivary glands through the medium of their nervous apparatus; but it remains to be discovered in what manner it acts upon this nervous system. It evidently does not act by paralysing the chorda tympani; for it is known that the paralysis of this nervous branch, such as is produced, for instance, by dividing the lingual nerve above the point whence the glandular filament detaches itself, does not bring on the least increase of the secretion of the submaxillary gland. On the other hand, it might be presumed that the effect of the absorption of the principle of jaborandi is not due to an excitation of the glandular nerve-fibres springing from the great sympathetic, for these fibres retain their action on the secretory work of the submaxillary gland in the atropinised animals; and if the jaborandi acted on the secretion of this gland by exciting these fibres, it should provoke sialorrhoea in animals submitted to atropia, as well as in those which have not undergone that influence. It has already been said that jaborandi does not produce the least sialagogue effect on an atropinised dog; therefore

it is not by exciting the sympathetic fibres leading to the submaxillary gland that jaborandi brings on the flow of saliva provoked by it in a healthy or merely curarised animal. There only remain two possible hypotheses to explain the action of jaborandi on the submaxillary glands. Jaborandi can only produce its sialagogue effect by exciting the peripheral ends of the chorda tympani, or by paralysing the sympathetic fibres leading to that gland. Now, by establishing the fact that atropia would appear to act by paralysing the chorda tympani, and that the sialagogue influence of jaborandi ceases in an atropinised animal, the first of these hypotheses seems to be the one to be adopted; that is to say, to suppose that ptyalism provoked by jaborandi in a healthy or merely curarised animal is due to the excitement of the peripheral extremities of the chorda tympani. Ought this interpretation to be considered as the sole available one? It will be seen immediately whether the sialagogue effect of jaborandi cannot be explained in any other way; but to clearly demonstrate M. Vulpian's opinion on this question, he first examines the mechanism of the action of jaborandi on the sudoriparous glands. He states that the nerves of the sudoriparous glands are but imperfectly known. The only indication given on this subject is due to M. Langerhans, who has seen nerve fibrillæ destitute of myeline penetrate into the sudoriparous glands, and even into the spaces between the cells of those glands. It is necessary, however, to wait for confirmatory researches before pronouncing on the exactness of these data. But whether the relations of the nervous system with the sudoriparous glands be such as described by M. Langerhans, or whether they take place in another manner, their existence is a matter of certainty, otherwise it would be impossible to understand the mechanism of the modifications of the sudoral secretion, which are produced under the influence of the variations of the external medium. Neither would it be possible to account for the action exercised by certain affections of the nervous system on the function of the sudoriparous glands. We know that the secretion of sweat increases when the external temperature rises; this is one of the physiological processes which serve as thermic regulators. Evaporation of a larger quantity of liquid from the surface of the skin takes place, and consequently a borrowing of a larger quantity of heat from the cutaneous tegument. The losses of caloric which ensue as a consequence of that evaporation therefore increase under these conditions, and this is one of the means by the aid of which the organism of man maintains its own temperature at an almost fixed degree, even in an atmospheric medium hotter than itself. This superactivity of the sudoral secretion, which shows itself speedily when the surrounding temperature rises, can only be explained by its being considered as the result of a reflex secretory action, provoked by the impression made on the skin by the heat of the external medium. This impression is conveyed by the centripetal nerves to the ganglionic and cerebro-spinal centres; it there gives birth to an act of reflectivity, to an excitation transmitted by the centrifugal nerves to the sudoriparous glands. It is a matter of necessity that these nerves should enter into relation with the special elements of the cutaneous gland, for such a secretory superactivity of these elements to be able to produce itself so rapidly under the influence of an impression made on the skin.

M. Vulpian recalls to our recollection that M.

Brown-Séguard some time since (July 21, 1869) communicated to the Société de Biologie the observation he had made of perspiration of the face, almost instantaneously produced by lively impressions affecting the nerves of taste.

Well-known experiments likewise show in the clearest way the influence of the nervous system on the sudoriparous glands, as in the experiments of M. Duplay of Alfort. This physiologist, after the extirpation of the guttural ganglia, that is to say, the superior cervical ganglia in horses, discovered that the nape and many parts of the head became covered with profuse sweat.

M. Claude Bernard has confirmed these results, and has seen them produced after the section of the cervical cord in the middle of the neck in solipeds, and he has discovered the fact that the hyperæmia thus induced may be arrested by electrifying the upper extremity of the divided cervical cord. In addition to these facts, M. Vulpian quotes those which have been observed in man by M. Meyer. This physician has seen, under the influence of an electric current, the negative electrode being in contact with the region of one of the superior cervical ganglia, and the positive electrode with the transverse apophysis of the opposite side of the seventh cervical vertebra, a profuse perspiration show itself on the arms, the hand, and finger, on the side of the cervical ganglion excited. Pathology furnishes arguments which also demonstrate the existence of intimate physiological relations between the nervous system and the sudoriparous glands. In a case observed by Dr. Gairdner, of Edinburgh, in which there was aneurism of the aorta and of the brachiocephalic trunk, a contraction of the right pupil was discovered; the right side of the face was often covered with cold perspiration, whilst in the intervals, on the contrary, the face was the seat of a considerable amount of heat. Professor Verneuil, having to remove a tumour of the parotid, placed a temporary ligature on the carotid. After the operation, he noticed congestion of the temple and gums on the side operated on, and at the same time he observed an increase of perspiration over the whole corresponding side of the face. Dr. W. Ogle has recorded a case in which a cicatrix on the right side of the neck was co-existent with a contraction of the pupil on that side, and with a higher temperature and a greater redness of the ear and neck of the same side. After any exercise, such as a quick walk, the left side of the face only was covered with perspiration. This last case is specially interesting, as it shows that, after paralysis of one of the cervical cords of the great sympathetic, the excitations proceeding from the nerve-centres no longer have any action on the sudoriparous glands of the corresponding side of the face. Cases of localised sweat in the face in cases of fracture or alterations of the cervical vertebrae might also be cited. Perspirations have likewise been seen to occur habitually on one side of the body. Cases of this kind of unilateral hyperidrosis have been collected by M. Auguste Ollivier and M. Nitzelnadel, who have also personally observed a certain number of such cases. In a subject who showed the sweats on one side, the right, only on the arm, in the arm-pit, on some portions of the right foot, with a higher temperature than in the homologous regions of the other side of the body, M. Chvostek, after MM. Eulenburg and Guttmann, from whose work M. Vulpian has borrowed the majority of the preceding indications, has established

that galvanisation of the cervical cord of the great sympathetic of the right side caused an increase of the sweat and of the vascular dilatation of that side. In a recent case of this kind, reported in Virchow's *Archiv* by Herr W. Ebstein, and in which a careful necropsy was made, this surgeon found varicose dilatations of the capillaries in the cervical ganglia of the corresponding side, principally in the inferior ganglion. M. Vulpian does not think much importance is to be attributed to this lesion with regard to unilateral epiphrosis; for, as he has mentioned in a memoir published in 1868 in the *Archives de Physiologie*, he has often found ampullary dilatations in the cervical ganglia in women who had not shown the least symptom of this kind. These clinical facts are not, however, the only ones which show the influence of the nervous system on the production of sweat. In cases of hemiplegia and paraplegia, the paralysed limbs have been seen to be covered with sweat, whilst the other limbs remained dry. In the same way intercostal neuralgia, and those of the trigeminal and the sciatic nerve may bring on a diaphoresis localised in the parts to which the nerve, in whose path the pains show themselves, are distributed.

Still further to prove the influence of the nervous system on the sudoral secretion, M. Vulpian finally cites the cases of perspiration of intermittent fevers, those of phthisis, convalescence from acute disorders, the death-agony, etc. The entirety of all these facts tends to show that the superactivity of the function of the sudoriparous glands, in the majority of cases, is a result of weakening or paralysis of the nerves through the medium of which these glands enter into relation with the nerve-centres.

Experiment shows us that it is paralysis of the fibres of the sympathetic which induces the increase of the sudoral secretion, or, at least, this is the course of events with regard to the face. May it not be admitted that it is the same in other regions of the body, and that everywhere it is the great sympathetic which innervates the sudoriparous glands? No physiological or clinical fact proves the existence of excito-secretory nerve-fibres proceeding to those glands. These small organs only seem to receive nerve-fibres exercising a moderating influence over their secretory operations.

(To be continued.)

PAGET ON GOUT IN SOME OF ITS SURGICAL RELATIONS.

In a course of four clinical lectures published (in abstract) in the *British Medical Journal* for May 15, 22, 29, and June 5, Sir James Paget, after observing that gout is rather found in its typical forms in private than consulting practice, stated that in the latter it has been more carefully studied. There is a large number of comparatively trivial diseases, which belong to the gouty constitution, and which commonly pass under the name of incomplete, anomalous, or suppressed gout. Also gout affects the consequences of injuries and diseases other than itself. It is very rare for the offspring of well marked gouty parentage to pass the middle or elder periods of life without manifesting some degree of the gouty constitution. Gout, too, is greatly modified when it is mingled with other constitutions—with the scrofulous, the tuberculous, the cancerous, or any other. One of the commonest methods of developing manifestations of the presence of gouty

tendencies is an injury. A person with a gouty constitution has a fall or other injury, and in a few days there comes a fit of gout. In such cases there has been a condition so justly balanced that, so long as the right nutrition of the several textures is not interfered with they hold their usual course, but that when anything occurs to interrupt the process of nutrition, which makes the various textures feebler, or which tends to bring out any degeneracy, then comes out the special form of disease; for what happens with the gouty occurs also with most other constitutional conditions. As a blow on the breast elicits cancer, so an injury of any kind may bring out gout. If a person with gout about him strike his foot, the gout will appear there; if he wrench his wrist, the attack will come in his wrist. Still more is this likely to occur in rheumatic gout than pure gout. Blows to the hip-joint in such persons are very liable to produce gouty arthritis of that joint. Arnica used externally is apt to produce an erysipelatous condition of the skin in the gouty. Gout, too, modifies many common inflammatory processes, as, for instance, gouty bronchitis, gouty periostitis; and it is of importance to be able to recognise the gouty characteristics in such inflammations. Such gouty tendencies have a tendency to paroxysmal manifestations. The remote consequences of gout after injuries deserve to be carefully noticed. Such persons as are gouty recover more slowly and less perfectly from injuries than others; and in cases where injured parts remain painful, or there is abiding stiffness, gout should be suspected, especially in persons of advanced life.

Gout is sometimes mingled with scrofula. Such is the case in children one of whose parents was markedly gouty, the other markedly scrofulous; and in such patients inflammation which commences as gout may drift into true scrofulous inflammation. Such cases are very important, and the altering features of the case should be carefully noted and the treatment modified accordingly. Instead of passive movement and shampooing, splints and rest become indicated. Even older persons than children may present such changes. A case occurred lately, in which a person who had long been gouty, and whose tissues were degenerate, was at length attacked with scrofula which he had escaped in early life. Blended gout and scrofula form a very bad inheritance. Gout, too, exercises an influence upon gonorrhœa and the progress of syphilis. Gouty persons with gonorrhœa are liable to attacks of inflammation in the joints or the sclerotic. Gout mingles, too, with syphilis, especially in its secondary and tertiary manifestations.

Syphilis in a person with blended scrofula and gout will produce a very different series of events from those which the same poison will produce in a perfectly healthy person. Such modifications have been too little studied in connection with syphilis. It might, for instance, be doubted whether syphilis ever produced destructive ulceration of the nose, except in those who were either tuberculous or scrofulous. Again, that form of chronic synovitis that was associated with tertiary syphilis was generally seen only in the gouty. Mercury must be cautiously administered in cases of mixed syphilis and scrofula. For syphilis mixed with gout, iodide of potassium with alkaline waters form the best line of treatment. Cancer in the gouty is unusually painful, and potash often relieves the pains very effectually.

The minor signs of gout in the hands and feet were next considered. It will not do to build a diagnosis of gout upon any one of these minor ailments alone; the diagnosis must rest upon a number of the smaller features of the case carefully collected and fitted together. If many be found together, or in quick sequence, the diagnosis is almost as certain as if well-marked gouty inflammation of the great toe were found. A very large proportion of the first attacks of complete gout occur in the toe or foot. Less complete forms are common, as darting pains in the toes or knuckles after errors in diet. Still more suggestive is it if the pains be in the heel or tendo Achillis. In the examination of elderly persons, it is quite as necessary to examine their knuckles as their tongue. Gouty hands often look as if they were shortened, especially in the fingers. There are the true globular, rounded, and hot gouty joints, and also the flattened form of more chronic changes. The palmar fascia is very apt to become affected. A number of old people are seen with their fingers drawn down to the palm, and especially their little finger. If they live long enough, all the fingers may become so affected, the index finger being least so. Any man who is in the habit of grasping tools tightly is liable to such change in the palmar fascia. Men engaged in lock and key making, wire-drawing, etc., are very subject to this condition. Gardeners, and persons who use walking sticks much, and more so if the sticks be badly shaped, are similarly affected. Such thickenings must not be confounded with the scars of old abscesses or injuries. In gouty cases, the integuments adhere firmly to the palmar fascia. Similar affections may occur in the foot, and often are very troublesome, requiring the boots to be frequently changed.

For the treatment of affections of the fingers and toes, gentle compression, aided by wet linen and oiled silk, is good, and may be continued for the relief of the resultant thickening in the form of a firm bandage. In contraction of the palmar fascia, stretching the hand out on the table several times a day is good.

When the fingers are drawn down little can be done, and section of the tendons, if giving temporary relief, is apt to produce greater contraction ere long. Operative treatment will generally lead to a worse state of things than existed ere it was resorted to.

Gout is very liable to affect the nervous system, the sensory rather than the motor nerves, however. It produces intense pain oftener than cramp. This is shown in the intense painfulness of an ordinary gouty attack, a painfulness out of all proportion to the other phenomena of the inflammatory attack, and especially disproportionate to the structural changes in the part attacked. Neuralgiæ, as sciatica and brachial neuralgia, are very common in gouty persons. Various shifting neuralgia in a person of or over middle age should always excite a suspicion of gout. Gouty neuralgiæ are more fitful, more quickly and readily affected by indigestion, errors of diet, and other similar influences, than other neuralgiæ. Then there are some morbid sensations of the skin, even more suggestive of gout. Such are (1) burnings in portions of the skin—hot burning patches in the thighs, or other parts, as the palms or soles; these sensations, however, are not limited to any particular localities of the skin. The affected portions of skin look healthy, or only slightly flushed: and though the patient complains much of the pain, as burning or scalding, no organic changes

appear to ensue. (2) Numbness or tingling of a limb, or of any portion of one—the feeling as if the part were asleep—are also gouty indications, and they may exist for months or years. Such feelings cause great distress in nervous persons, who are afraid that they foretell paralysis or other serious trouble. Paralysis, of course, may be so preceded; the fears in the majority of cases, however, are groundless. Gout should be carefully looked for if these sensations be of long duration in persons whose nutrition is good, and if there be no change of temperature or wasting.

In the hypochondriacal and the hysterical gout may supply morbid sensations, to which the mental state is only too ready to give colour and intensity. The pain itself is real, but these patients aggravate it by errors both of observation and judgment; of observation, because they study it with a morbidly close attention; of judgment, because they assign wrong causes for its presence. Probably there is no special connection betwixt gout and hypochondriasis, but they mutually aggravate each other and cause much misery which it is often difficult to cure, or, indeed, even to relieve.

Cramps and sudden 'catches' in overaction are also found in connection with gout; and in some persons they are, at certain times, almost sure to follow any sustained or awkward movement.

The relations of gout to the urinary organs may be traced in its relations to the lithic acid diathesis. Among elderly persons, a large proportion of cases of lithic acid calculi, and lithic acid gravel, are in those who bear marks of gout, a fact which justifies the assumption that gouty attacks are intimately connected with, if not possibly due to, an imperfect elimination of lithic acid by the kidneys. The appearance of lithic acid or of lithates in the urine is suggestive of gout. Acute inflammation of the mucous membrane of the bladder, with pain and distress, chiefly before micturition, extending to the perinæum, rectum, and suprapubic region, and with burning sensations in the urethra, is associated with gout. With these general signs there are more special ones, as the nocturnal occurrence, or dyspepsia, the suddenness of the attack, its sudden subsidence, its relapse, or its metastatic character. Gouty orchitis is not uncommon, and is frequently followed by the presence of fluid in the cavity of the tunica vaginalis. It is prone to relapse; it passes from one testis to the other, and also comes on suddenly. Gout affects the course of urethritis; and in gleet in the gouty, relapses are apt to follow errors in diet or in drinking. True gouty urethritis is found where there has been no infection, and is itself free from infectiousness. Prostatic disease or enlargement is very frequent in the gouty; so, also, are alterations in the penis. There are fibrous thickening and hardening of the corpus cavernosum, and the changes are similar to those of the palmar fascia described above. The affection is chronic, but harmless. Painful and persistent erections at night are also found most commonly in the gouty, especially in the incomplete forms and with excess of lithates. Bromide of potassium or ammonium is here very useful.

Gout, too, affects the skin, in the form of psoriasis, eczema, urticaria, prurigo, pruritus, etc. The relation is not to be found in any anatomical features, or in any peculiarity of appearance. In such cases the patient's constitution is more important than the anatomical characters of the local disease. For example, if eczema be found in a patient who has had regular

gout, there must be a strong suspicion that the eruption depends upon gout, and the case must be treated in this view. Such treatment is as much called for here as in the case of inflammation of a joint in one known to be gouty. The sudden appearance, especially at night, the connection with indigestion or unusual diet, point to the origin. The old rule that such patients should have nothing salt, strong, sweet, or sour, is a good one. The classification of skin-diseases, grown so minute of late, founded mainly on an anatomical basis, leaves out too much the constitutional conditions with which the disease is associated, which is of paramount importance. Ulcers, too, are common in the gouty, especially the eczematous ulcer about the ankle. This is an eczema of which some portion is the seat of thin shallow ulceration. There is much severe pain, especially on lying down and in bed. In the warmth and quietude of bed the pain becomes agonising. Such ulcers are commonly associated with varicose veins; not the large tortuous veins, but small clusters of veins, often of bright hue, collected round the ankle or some portion of the leg. Some think the varicose veins the cause of the ulcer, but this view is a fallacy. Incomplete gout is the cause, and the presence of varicose veins is only a coincidence.

Gouty affections of the digestive organs were next referred to. Many persons can foretell the oncoming of gout by the appearance of their tongue. Psoriasis of the tongue is also a gouty affection. It is difficult to distinguish this affection from syphilitic psoriasis, and the diagnosis rests on the general environment. There is thin opaque white covering over the mucous membrane, like the layer of mucus left by the snail when tracking its way over wood. Diseases of the palate and pharynx are also among the list of gouty affections; and elongated uvula in elderly persons is very suggestive. The gouty dyspeptic is troubled with acidity and flatulence, is easily disturbed by errors of diet, and has 'bilious' headache. Often the dyspepsia so induced is accompanied by burning in the knuckles, or in the palms and soles, or by some neuralgia in the scalp. The ready disturbance caused by certain articles of diet in those persons forms a capital diagnostic indication. Gout affects the circulation, and surgically is most seen in gouty phlebitis. It is, perhaps, one of the most frequent of the forms of irregular gout.

Gout indeed, Sir James Paget remarked, mixes itself with whatever malady is present in the patient. Of course the treatment of a gouty man is different according as it is blended with scrofula, or syphilis, or occurs in the nervous or the healthy. Colchicum often is useful. There are three things that have to be considered for all gouty persons. Firstly, they should drink an extra quantity of water, especially in the early morning, before any food is taken. Secondly, those who have lithic acid or lithates in excess, should take alkaline instead of pure water. Many waters, as Carlsbad and Vichy, are very useful; and those that are purgative as well as alkaline may be employed when the bowels are confined. Often the skin needs good washings with soap, and thorough rubbing as well as mere warm baths. It is a good plan to adopt the German practice of going to bed for awhile after the bath. If English baths were worked with the same care in this respect as is the case abroad, more good would result from them. In conclusion, he said that 'what was in his mind was chiefly this; first, the

broad general rule, that disease is not to be studied as if it could be learned by morbid anatomy alone; and next, that amidst the forms of constitution to be studied in surgery, the gouty is an important one, and that it has not only complete and typical forms but also minor characters, which, if occurring in any number in the same person or in different members of the same family, might be as sure evidence of gout as the most typical inflammation of hand or toe, and that the gouty element is important in the matter of treatment.' J. MILNER FOTHERGILL, M.D.

ANATOMY AND PHYSIOLOGY.

SIEDAMGOVTZKY ON THE THERMOMETRY OF DOMESTIC ANIMALS.—Professor Siedamgovtzky gives the following results of his observations in the *Deutsche Zeitschrift für Thiermedizin und Vergleichende Pathologie*.

1. *Horse*.—The medium temperature of 100 horses was 38° Cent.; the highest reached was 38° 2 Cent. The average was taken of readings in the morning, at midday, and in the evening. Krabbe found the medium temperature to be 38° 1 Cent.; Peters, 37° 5 to 38° 2; Fleming, 38° 75; Davy, 37° 5; Sonnenberg, 37° 38; Prevost and Dumas, 36° 8 Cent. *Influence of Age*.—In a young foal, five days old, the temperature was 39° 3. The average temperature of horses from two to five years was 38° 1 Cent.; from five to ten years, 38°; from ten to fifteen years, 38° 2; from twenty years and upwards, 37° 9 to 36° 9 Cent. *Influence of Sex*.—The mean temperature of stallions was 37° 8; of mares, 38° 2; of geldings, 38° 05. *Influence of Time of Day*.—The maximum was found at 6 P.M., 38° 2 Cent.; the minimum at 4 A.M., 37° 5 Cent. *Influence of Feeding*.—A rise occurred from three to five hours after feeding of from 0° 2 to 0° 8 Cent. *Influence of Drinking*.—Water of a temperature of from 8° to 12° Cent. lowered the temperature from 0° 3 to 0° 5 Cent. Thus feeding and drinking have opposite effects. *Influence of Exercise*.—Exercise raised the temperature, but in different degrees in different animals. *Influence of External Temperature*.—Horses placed in a stall at a temperature of 25° Cent., showed a temperature four hours afterwards of from 31° to 43° Cent. There was a rise of the normal of from 0° 4 to 1° 2 Cent. A draught of air produced a fall of 1° Cent. Great cold in winter, when the air had a temperature near freezing-point, produced a rapid refrigeration of the skin, but showed a rise of 1° 2 Cent. above the normal in the rectum. This occurred while the temperature of the stall was 10° Cent., but after the animal was a short time in the open air there was a reduction below the normal of 0° 5 Cent. *Influence of Bleeding*.—The temperature was reduced 0° 1 Cent. by bleeding to the extent of from 5 to 6 lbs.

2. *Cattle*.—A nine-year old cow gave 38° 9 Cent. (Krabbe found in the cow 38° 8; Davy, 38° 9). The daily fluctuation was small as compared with the horse: the minimum was, at 12, midnight, 38° 7; the maximum at 5 P.M., 39° 1. The effect of food was not noted.

3. *Sheep*.—284 measurements in the rectum of a one-year-old wether gave from 38° 5 to 41° 8—a mean of 40° 2 Cent. (Fleming found 40° 25; Krabbe, 39° 8.) The variation found in successive readings is much greater than in the horse or in cattle. Un-

shorn sheep (157 readings) showed a mean temperature of $40^{\circ}56'$ Cent.; while shorn animals (from three to twenty-four days after shearing, ninety-four measurements) gave $39^{\circ}73'$ Cent.

4. *Swine*.—169 readings taken from four swine gave $38^{\circ}5'$ to $40^{\circ}8'$ Cent., or a mean of $39^{\circ}6'$ Cent. (Krabbe found $39^{\circ}1'$; Flemming, $40^{\circ}5'$; Gurlt, 40° to $41^{\circ}2'$ Cent.)

5. *Dogs*.—190 readings in seventeen dogs gave $38^{\circ}3'$ Cent. (Flemming gives $38^{\circ}5'$; Krabbe, $38^{\circ}7'$ Cent.)
J. G. MCKENDRICK, M.D.

TAYLOR ON PULSATION IN THE VEINS.—In an article in the *Guy's Hospital Reports*, Dr. Frederick Taylor speaks as follows. Pulsation of the jugular veins has long been recognised as of frequent occurrence in the more advanced stages of cardiac disease, but its importance in diagnosis is differently estimated by authors. While some, as Niemeyer, regard a pulsation synchronous with the heart's beat as a pathognomonic sign of regurgitation through the tricuspid orifice, others, as Walshe and Friedreich, are of opinion that a true venous pulse may arise in cases where the tricuspid valve is functionally perfect. All, however, agree that it is in cases of tricuspid regurgitation that the jugular venous pulse is most distinct and most forcible, being easily perceptible to both sight and touch.

The mechanism of the pulsation in such cases is not difficult of comprehension, when the accompanying conditions are taken into consideration. The beginning of the trouble is frequently disease of the mitral valve, in the form of obstruction or regurgitation, or of both together; the interference in the circulation at this point leading to increased tension in the area of distribution of the pulmonary artery, and hence to over-distension, dilatation, and hypertrophy of the right ventricle. The tricuspid valve, then, may become incompetent in two ways; on the one hand, endocarditis affecting it may cause rounding or thickening of its free edges, shrinking of its substance, or adhesion of the cusps to one another, so that the valve is not extensive enough to cover the area of the auriculo-ventricular orifice; on the other hand, dilatation of the right ventricle may involve the valvular orifice to such an extent as to render it impossible for a valve of normal size to close it effectually. Niemeyer believes this is a rare case of incompetence, because, as he says, when the ostium dilates, the valves grow in breadth and length; but at any rate such a dilatation must add very much to the functional derangement produced by endocarditis.

As the valvular apparatus of the heart becomes more and more imperfect, the portions of the circulatory system next behind the tricuspid orifice become in their turn over-distended, and permanently dilated; these are, first, the right auricle, and, secondly, the great veins of the thorax and neck. With increasing distension of the jugular veins the valves at the root of the neck, if at first acting efficiently, will in course of time be rendered useless, and then all the conditions necessary for pulsation of the cervical veins are present. With each contraction of the over-filled right ventricle, blood is driven through the tricuspid orifice, and a movement communicated to that in the right auricle and vena cava; did the large veins contain only a moderate amount of blood, the force of the ventricular contraction might be lost in further distending them, but in their overfilled condition the movement is communicated

through the valves at the root of the neck to the column of the blood in the jugular vein, and a pulsation synchronous with the cardiac impulse is the result.

But the jugulars are not the only veins in which pulsation has been observed: Seidel and Geigel have described cases of tricuspid incompetency in which the inferior vena cava was seen to pulsate, and A. Burns, Senac, and Kreysig long ago showed that epigastric pulsation might be due to regurgitation of blood through the right auricle into the inferior vena cava and hepatic vein.

GRUBER ON THE OS FONTICULI FRONTALIS.—In the current number of Virchow's *Archiv* (Band iii, Ser. 6) appears a note by Professor Gruber, of St. Petersburg, supplementary to a most elaborate paper upon the same subject contributed by him about a year ago to the *Mémoires* of the Academy of Sciences of the above university; of which essay there is a much condensed abstract in the LONDON MEDICAL RECORD of January 6 of the present year. Out of 500 human skulls in course of maceration during the years 1873-4, six crania having the peculiarity in question came under the notice of the professor. In three instances the intercalary ossicle lay between the parietal bones and behind the frontal bone; in another instance it slightly encroached upon the frontal; in yet another case it lay equally between the parietal bones and in the frontal; while in the last instance (*loc. cit.* fig. 2, plate I.) the bone was lodged, as an 'os interfrontale,' in an elongated notch in the median line of the os frontis, quite in advance of the parietals, its hinder angle being immediately in front of the extremity of the sagittal suture.

[From the figures recorded in Professor Gruber's first paper, it would appear that the abnormality in question occurs in man once in 250 skulls. If, however, the figures given in the more recent record be added to these, the percentage of occurrence of the intrusive ossicle would seem to be increased—viz., once in 210 crania.—*Rep.*]

MEDICINE.

MAYER ON THE SYMPTOMS AND TREATMENT OF DIABETES MELLITUS.—Dr. Jacques Mayer of Carlsbad contributes two articles on this subject to the *Berliner Klinische Wochenschrift*, of May 24 and 31, 1875 (nos. 21 and 22), in which he combats the notion that there is any causal interdependence between the great thirst (polydipsia) the increased quantity of urine (polyuria) and the amount of sugar present in

the blood of diabetic patients, so far as his own clinical experience, amounting now to seventy-four cases, extends. He candidly admits the great difficulties which attend the determination of this question, and quotes two cases in illustration of the varieties met with in cases of diabetes mellitus. The first case, a Berlin merchant, aged thirty-six, had been singularly free from any previous diseases, even from those of childhood. He was married, and of late had more than usual, though not immoderate, mental exertion. Simultaneously he noticed that he was losing his previous corpulency. Then he felt great fatigue after slight exertions, great thirst, and frequent calls to pass urine. His medical man examined the urine, and found it to contain 0.5 per cent. of sugar. There was no history of diabetes, neuroses, insanity, or furuncular affections in his family. He was placed on a very restricted diet, and after being under observation four weeks, was sent to Carlsbad. There it was noticed that his pulse was 72°, the heart slightly enlarged, the liver, spleen, and lungs apparently normal. His thirst was extreme; even in the night he drank enormously of water; his appetite was deficient. The urine, in twenty-four hours, amounted to 3,800 cubic centimetres (about 133 ounces), with a percentage of sugar of 0.3 or about 11.4 grammes = 3iij nearly of sugar in the twenty-four hours. The specific gravity of the urine was 1.024. The restricted diet was continued, and moderate quantities of the Carlsbad waters ordered. At the end of May his thirst had almost left him, his appetite was good. He was stronger, had gained five pounds in weight, and was free from fatigue. The sugar in his urine had disappeared; the specific gravity of the urine was now 1.022; its quantity in twenty-four hours was 1,900 cubic centimetres (about sixty-six ounces).

The second case, also a married merchant, living in Berlin, aged thirty-three years, had from early youth been a hard worker, but lived well, or rather freely, for from the age of fifteen he had been a votary of both Bacchus and Venus. He had shared the campaigns of 1864, 1866, 1870 and 1871 with some hardships and exposure, which induced rheumatic pains. Sometimes he suffered from vertigo and epistaxis. He had suffered from some acute disease, apparently not infectious. After his first campaign he became very stout. In 1871 he weighed 210 pounds; he once had a large boil near the anus, which was opened. From the nature of his business he drank a great deal of wine, brandy and beer. His father died at seventy-three from catarrh of the bladder. His mother, aged seventy-four, is still alive. He has nine sisters alive, all healthy. None of the family have had diabetes, neuroses, nor insanity. For about three months he had noticed, but not regarded much, a gradual loss of flesh. Frequent calls to pass urine, and immoderate appetite, led his medical man (Dr. Gumbinner) to test the urine for sugar. He found it to contain 6.5 per cent. of sugar. Its specific gravity was 1.035. He was sent to Carlsbad and arrived there on May 20. He was still corpulent; his heart and lungs were normal; pulse, 90°; the liver and spleen were slightly enlarged. Thirst was only very moderate. Sight slightly impaired. Bodily strength good. He asserted that his virile powers were beyond the average. The urine in twenty-four hours amounted to 2,950 centimetres (about 103 ounces). Sugar 11.9 per cent. = 176.5 grammes (six ounces nearly) in the twenty-four hours. Sp. gr. = 1.0365. His appetite was enormous—he would often eat raw meat by the pound!

After using Carlsbad waters with partially restricted diet, he greatly improved, and by June 10 the sugar had all vanished. The quantity of urine passed became normal, and he soon afterwards returned to Berlin. In November the urine was still free from sugar. In February, 1875, the urine was again examined for sugar with a negative result, though the patient was eating what he liked. He had gained nearly thirty-four pounds in weight.

Comparing these two cases, we find similarity in some external circumstances, and in the mild type of the diabetes in both cases, but a vast difference as regards the thirst and loss of flesh, which were both most marked in the one who had least sugar in the urine. Mayer is therefore inclined to refer the thirst and polyuria to vasomotor disturbances. He quotes a case from Romberg (*Klinische Wahrnehmungen und Beobachtungen*, 1851, p. 8) of a patient in whom a sudden feeling of thirst caused the daily consumption of eight or nine quarts of water. Romberg considers this as a primary neurosis. Pribram (*Prager Vierteljahrsschrift*, 1871, iv. S. 1-31) also considers the thirst in a case of diabetes insipidus as the primary affection. He tried the effect of increasing and diminishing the amount of liquid taken. When the water taken was diminished, the diuresis was correspondingly diminished—and when the water taken was increased, the diuresis was also much increased. But it was very curious to note that the decreased diuresis lasted some days after the restriction was relaxed—even though the patient took more liquid, just as he liked. In the same way the increased diuresis, produced by more fluid being taken than was necessary to quench thirst, remained for some days about the same, though the patient limited the amount of fluid. If we admit the neurotic origin and primary nature of the thirst in a series of cases of diabetes insipidus, there is no reason why we should not admit it in some cases of diabetes mellitus. We know that polydipsia and polyuria often precede the glycosuria by some months. Amongst his seventy-four cases Dr. Mayer has five trustworthy instances of this.

Dr. Blumenthal, of Berlin, has a female patient, aged sixty, who suffered for a whole year from extreme thirst and polyuria; her urine never contained a trace of sugar all that time; latterly sugar in considerable quantity made its appearance in the urine. Quinine given continuously has now nearly cured all three symptoms. Külz quotes three cases of alternating diabetes insipidus and diabetes mellitus in his book (*Beiträge zur Pathologie und Therapie des D. Mellitus*, Bd. i. S. 126). One of these is quoted from Houghton (*Dublin Quarterly Journal*, 1863). Luys and Dumontpallier's case, quoted by Ebstein (*Deutsches Archiv für Klinische Medizin*, Band xi. S. 347) is also noteworthy. The patient, aged thirty-five, had suffered for five years from diabetes mellitus, and was admitted into Trousseau's wards for cough and polyuria. He passed daily six to seven litres (210 to 245 ounces) of urine, of specific gravity 1.001 to 1.007, without either sugar or albumen. He had pulmonary phthisis, and shortly afterwards died. There were great hyperæmia of the walls of the fourth ventricle, and unusual vascularity of all the grey matter connected with the auditory nucleus in the floor of the fourth ventricle.

Mayer concludes that the polydipsia in many cases of diabetes mellitus is quite independent of the per-

centage of sugar in the blood, and must be regarded as a primary affection. He admits, however, that in many cases polyuria precedes and polydipsia follows. Bürger explains this by diminished insensible perspiration (*Deutsches Archiv für Klin. Med.*, Band xi. S. 323). Engelmann, however, objects to Bürger's results, and points out errors in his data. Külz, repeating the experiments on one of Engelmann's patients, confirms Bürger (*Beiträge zur Pathologie und Therapie des Diabetes Mellitus und Insipidus*, Band ii. S. 32). Claude Bernard's well-known experiments render it probable that both symptoms originate in one and the same lesion in many cases. Be the cause what it will, this extreme thirst can often be relieved, either by narcotics or by iodine or creasote, especially when the quantity of sugar is small. Mayer next alludes to the enormously increased tissue-metamorphosis in most cases of diabetes. Pettenkofer and Voit mention a case in which 60.9 grammes (2 ozs. nearly) of urea were passed per diem. In Mayer's first case the solid constituents of the urine (deducting sugar) were over 6 ozs. The large ingestion of water probably aids this. Beneke (*Grundriss der Pathologie des Stoffwechsels*, 1874, p. 112) states that on an average the daily addition of 300 cubic centimètres (about half a pint) of water will increase the elimination of urea by about one gramme (15.44 grains) in twenty-four hours.

The article concludes by a brief analysis of Mayer's seventy-four cases, of which sixty-one were males and thirteen females. The ages were as follows; none under ten years; ten to twenty years, 2 (a lad aged sixteen, no known cause; a girl aged seventeen whose mother died of diabetes); twenty to thirty years, 3, all males; thirty to forty years, 10, eight males and two females; forty to fifty years, 26, twenty-two males and four females; fifty to sixty years, 22, nineteen males and three females; sixty to seventy years, 9, six males and three females; seventy to eighty years, 2, males. Forty-three males and five females, in all forty-eight, suffered from a mild form. The type was severe in twenty-six (eighteen males and eight females). The etiology was often obscure. In eight cases a residence in malarial districts seemed the only feasible explanation. In fourteen cases there was hereditary predisposition, thus confirming Schmitz as to the frequency of this. In nine severe cases the use of Carlsbad waters and residence in Carlsbad proved powerless to check the progress of the disease. They thus failed in one-third of the severe cases, whilst, without exception, successful in the slighter forms. In some of these unsuccessful cases the use of quinine diminished the sugar. This remedy, advocated by Blumenthal (*Berliner Klinische Wochenschrift*, 1873, no. 13), deserves a further trial. For details of several cases, reference must be made to the original article. It is, however, noteworthy that the hereditary case, in a girl of seventeen, who died after drinking immoderately of wine, was found at the *post mortem* examination to have pachymeningitis, enormous dilatation of the fourth ventricle, and a small cyst of the corpus striatum.—[It is not said whether the cyst was in the right or the left corpus striatum.—*Rep.*]

W. BATHURST WOODMAN, M.D.

MORONI ON A CASE OF GANGRENE OF THE LOWER EXTREMITY AFTER DIPHTHERIA.—In the *Giornale Veneto delle Scienze Mediche* for April, Dr.

Moroni relates the case of Luigi Zaramella, a boy, aged seven, who was admitted on December 1, 1874, into the hospital at Monselice with gangrene, which had commenced in the right foot, and extended half way up the leg. His parents were healthy, and he had enjoyed good health till the previous month, when he had an attack of diphtheria, which left paralysis, indicated by a nasal voice and the reflux of fluid into the nares. After a convalescence of some days, his right foot became painful and swollen, and there was a return of fever. The redness, at first erysipelatous, became livid; the end of the toes became mummified; and dry gangrene declared itself, and, as already said, extended half way up the leg. During the first two weeks, the evening temperature was 39.5° Cent. (103.1° Fahr.); the pulse 120. Physical examination of the chest gave only negative results; the child was very restless in consequence of the acute pain in the limb. He refused food, and did not sleep. The pulsations of the right femoral artery did not differ from those of the left.

Anodyne and aromatic cataplasms were applied to the part; and opium was given internally in quantities gradually increased from a grain and a half to seven and a half grains in twenty-four hours. This treatment had no effect; on the contrary, the mortification extended as far as the upper third of the leg. Dr. Moroni bled the patient from the arm to more than twenty ounces; on the following day—perhaps, he says, by an accidental coincidence—the gangrene did not extend, and two days afterwards there was a distinct line of demarcation. Amputation was performed on December 15, the elastic bandage being used. The wound healed well, and the patient was discharged cured on January 25, having also recovered from his paralysis without any special treatment.

Dr. Moroni observes that the occurrence of spontaneous gangrene of a limb in a robust boy, as a sequel of diphtheria, is a fact of very rare occurrence, and one which at first it is difficult to explain. It is not possible to admit the existence of disease of the arterial coats in so young a boy; and, as he was always healthy before the diphtheria, the occurrence of the gangrene must be ascribed to this and to subsequent embolism. Labadie-Lagrave found in cases of diphtheria indications of vegetative endocarditis, most frequently affecting the mitral, and rarely the sigmoid valves. Bouchart, in 1872, called attention to the occurrence of myocarditis and endocarditis in diphtheria. Mosler, in Germany, about the same time, described degeneration of the myocardium as a rather frequent cause of sudden death in cases of diphtheria, even where recovery was apparently to be expected. These observations, and those of Brigidi of Florence, point to the embolic origin of the gangrene in the case now described.

A. HENRY, M.D.

COHEN ON APSITHURIA.—In the *Medical and Surgical Reporter* of May 1 is a paper by Dr. J. S. Cohen, in which he speaks of this rare affection. 'Apsithuria (inability to whisper) is a manifestation of disease not often encountered. Many patients with aphonia (inability to vocalise [phonate]) are supposed to be unable to whisper also, but upon close examination it will be found in the vast majority of instances that the inability to whisper is only apparent. At a short distance from the patient's mouth, not the slightest indication of a whispering

sound can be heard. Still, on placing the ear close to the patient's mouth, or on using an ear-trumpet, a more or less feeble whisper can be detected; and conversation can even be carried on with the patient in that way, though for the ordinary purposes of life the patient is really as bad off as if the debility of the whisper were an actual inability; and is compelled to resort to tablets or finger-spelling in order to communicate with others. Of cases of this kind I have met several examples. In some of them, the very evidence afforded by the experimental examination just indicated, has restored confidence to the mind; and the ability to whisper has at once begun to increase, and its full power become restored before the aphonia has been overcome. In others, the power of whispering loud enough to be heard in conversation has increased *pari passu* with the recovery of the voice. In one case under my care, on the other hand, there was no increase in the power of the whisper, nor any return of voice.

SURGERY.

KÖSTER ON THE PATHOGENY OF SPONTANEOUS ANEURISM.—At a recent meeting of the Nieder-rheinische Gesellschaft, the proceedings of which are reported in the *Berliner Klinische Wochenschrift*, no. 23, 1875, Professor Köster spoke on the origin of spontaneous aneurism and chronic mesarteritis. Against the generally accepted view that the spontaneous and so-called true aneurism is due to chronic endarteritis and the consequent metamorphoses, several facts may be brought forward. An aneurism may be seated on a perfectly healthy artery. In the second place, the frequency of endarteritis is much greater than that of aneurism. Again, there are no anatomical grounds for supposing that a pouching of any part of an arterial wall necessarily follows disease or degeneration of the inner membrane which, especially in the smaller vessels, is much too thin to withstand the pressure of the blood. Finally, as has been proved by the statistics of Lisfranc and Crisp, the frequency of aneurism diminishes towards the end of the middle period of life, whilst arterial atheroma is met with mostly in old people. Dr. Köster, following Helmstedter in examinations of small protrusions of the walls of the aorta, and extending his researches to small aneurismal pouches of other large arterial trunks,

found in the substance of the muscular coat numerous clear patches which he regarded as due to an inflammatory process and to proliferation of connective tissue, and analogous to those met with in hepatic cirrhosis and partial interstitial nephritis. Each patch is prolonged into the adventitia by a small pedicle in which vessels are always to be found, that is to say, each patch is developed around one of the nutritive vessels. The pedicle contains afferent and efferent arterioles, veins, and lymphatics, and moreover at the commencement of the pedicle in the adventitia a cellular connective tissue proliferation is to be found. Thus, according to Professor Köster, the inflammatory process commences around the nutritive vessels in the outer portions of the artery, passes directly into the muscular coat, and there becomes much extended along the branching capillaries. Not unfrequently the inflammatory patches extend through the whole thickness of the muscular coat, always following the course of the small branches of the nutritive vessels, which often extend as far as and occasionally pass into the inner membrane. In the latter case, portions of the inner membrane undergo inflammatory thickening. In consequence of this discrete chronic mesarteritis the muscular coat (elastic fibres and muscle-cells) breaks down, until, finally, but a few small flakes of muscular substance can be seen in the middle coat. The inner coat and the thickened tunica adventitia form one membrane of homogeneous histological structure, which is very vascular. There is no longer any separation of the arterial wall into two coats. These degenerated portions, in which traces of muscular tissue may often still be observed, are protruded, and then aneurism is produced. Aneurism arises not through endarteritis, but through mesarteritis. The distinctions of aneurisma verum, and aneurisma verum externum et internum, and the like, will not, Professor Köster states, hold good, since after the protrusion of a pouch it is impossible to make out what share in the formation of the wall of such pouch is taken by the inner or the outer coat, and since the muscular coat is reduced to mere traces, and is never continuous along the whole wall of the aneurism.

W. JOHNSON SMITH.

MARTINEAU ON SUDDEN DEATH FROM PUNCTURE OF A HYDATID CYST.—At a meeting of the Parisian Société Médicale des Hôpitaux, held on March 26 last (*Union Médicale*), M. Martineau said that a man aged thirty-one was admitted to the Lariboisière on January 22. He had been quite well, according to his own account, till three days before, when he was seized with pain in the right hypochondriac and epigastric regions. Except lead-colic and aguish attacks, beginning in Africa and lasting eight years, there was no history of previous disease. There was no syphilis, nor alcoholism. Hydatid tumours in the epigastric region, and enlarged liver, were diagnosed. On the 24th the tumour was punctured with a capillary trocar. A few grammes of fluid, first clear, then blood-stained, flowed out, and then the cannula became choked with a membrane. Echinococcus-hooklets were found on microscopic examination, which only took three or four minutes. The man then suddenly became ill, had severe dyspnoea, nausea, and vomiting; his respiration and the heart's action were suspended, and long strings of glairy whitish mucus came from his mouth, and filled the bronchi and trachea. His face was pale, covered with cold sweat. Artificial respiration

galvanism, and other means failed to restore him, and he died at the end of about twenty minutes. The *post mortem* examination showed substernal emphysema of the subcutaneous tissues and old pleuritic adhesions. In the apex of the left lung was a nodule of caseous pneumonia. There was some emphysema of the lungs, probably produced by the mode of death. The bronchi were filled and plugged with the strings of mucus referred to. There were signs of old pericarditis, and some old mitral mischief. Two hydatid cysts lay on the lower surface of the liver—one in the right lobe, one in the left; the latter had been punctured. Nothing abnormal was found in the peritoneum. M. Martineau ascribes this death to a reflex paralysis of the pneumogastric nerve. He believes the case to be unique, as regards puncture of the liver, though sudden death is known to follow contusions of the abdomen, and intestinal lesions. In the discussion which followed, M. Gérin-Roze referred to M. Bérenger-Féraud's paper, in the *Bulletin de Thérapeutique*, December 15, 1874, for instances of the harmlessness of capillary punctures; he had known patients walk about the day after. He had punctured one cyst seven times in five months. M. Dumontpallier had seen a frog die suddenly of syncope in M. Claude Bernard's laboratory, when the abdomen was opened, and a portion of intestine was seized, with a view to ligature it. M. J. Simon said that in Iceland, where hydatid cysts were very common, they were not now tapped, but only pricked several times. Many cases have been cured in this way. But it would seem as if even a slight puncture might open the door to death. M. J. Guyot knew of seven or eight deaths within twenty-four hours after tapping hydatid cysts of the liver. He, therefore, had recourse to Vienna paste before tapping. M. Woillez narrated a case in which he had intended to tap what he believed to be a very large hydatid cyst of the liver. It gradually diminished in volume, and at last disappeared without any operative interference. Neither the urine, sputa, nor stools of the patient presented anything unusual. Was this really a hydatid? He had never seen a similar case.

RELIGION AT THE ANTIPODES.—The sickness which has been unusually prevalent at Melbourne during the last three months led some people to ask that a day might be set apart for humiliation and prayer, but their request has not been complied with. The *Argus* published a leader deprecating the suggestion, and for days after its columns were filled with letters upon providential interpositions and the efficacy of prayer, which showed a wonderful eagerness to enter upon the discussion of these questions.

MATERIA MEDICA AND THERAPEUTICS.

SMITH ON ATROPIA AS A NERVOUS STIMULANT. In the *Detroit Review of Medicine* for June, Dr. Curtis Smith writes on atropia from a clinical point of view. After alluding to its effects upon the circulation in increasing the action of the heart and accelerating the blood flow, he says atropia is almost the only reliable respiratory stimulant with which he is acquainted. Under its influence the respirations are increased from six to twelve per minute above the normal standard. This balances the increased circulation. It thus will be seen that atropia will increase the quantity of blood flowing through any given part in a given time, thus giving opportunity for increased nutrition, or the increased stimulation naturally growing out of an increased supply of blood. This is a very important point to gain in very many cases of diminished nerve-energy, where the nerve-centres have become impaired or debilitated from any cause, especially from those causes that rapidly depress the nervous system. Nor can we avoid the conclusion that, if the number of respirations is proportionately increased with the circulation, the blood is all the while sufficiently supplied with oxygen to free it from excess of impurities, and that it goes to the nerve-centres, not only in increased supplies, but as pure and as stimulating as it can possibly be. Atropia exerts a powerful influence over the secretions of mucous membranes, causing a diminished amount of discharge where the secretions are greatly in excess. In excessive diaphoresis, it has become one of our standard remedies.

We sometimes find cases (Dr. Smith says) that, from some cause, are suffering from great nervous debility or prostration. In these we often observe the sluggish condition of the capillary circulation, the heart acting too feebly and not infrequently too slowly, and, in consequence of this interference, with a partial failure of the circulation, the lungs become partially congested, or, in other words, the pulmonary circulation is also sluggish. Growing out of these difficulties, there come on occasional attacks of dyspnoea—a feeling of impending suffocation. It is at once evident that the whole train of symptoms is traceable to a want of tone in the nerve-centres that control both the circulation and respiration, and the indication is plainly to stimulate these. What agent or agents shall we select. Ammonia will answer; so will alcohol, valerian, etc., etc. But are they the best? I think not. Give, in such a case, the sixtieth or even the thirtieth of a grain of atropia, and if your diagnosis of the case is in accordance with the above description, you will soon notice great relief to the patient. With this agent you not only stimulate the general nervous and circulating systems, but you give the very agent that is *par excellence* the stimulant of both, while with almost all other stimulants you fail to reach, except very indirectly, the respiratory nerve centres, and are therefore a much longer time in giving relief, and the relief is not so complete. Of course, in such cases of nervous debility, atropia is not the only agent demanded for the complete cure of the case. I only commend it as a stimulant to be used while the more solid or substantial nerve-tonics are employed to really strengthen the nerves, as strychnia,

phosphorus, iron, quinia, proper food, good hygiene, etc. We doubtless all recognise the difference between a stimulant and a tonic. Atropia is the former, and but feebly, if at all, a tonic for the nerves. But we all know, too, how much more valuable, under some circumstances, a stimulant is than a tonic, and *vice versa*.

I have, at this time, a case of an old lady, whose system, especially the nervous, is broken down by age and recent disease. From her disease she is clearly convalescent, but the nervous exhaustion is so great that if left unstimulated her pulse drops below fifty, is feeble, the capillary circulation is sluggish, and the pulmonary vessels carry blood through the lungs with diminished rapidity, from which cause, with the conditions before named, she suffers from a feeling of impending suffocation, which causes loss of sleep and great restlessness and mental anxiety. In this case, as in others of a similar character, I have found no agent equal to atropia. In the above instance, the patient gets the fortieth of a grain of atropia as often as occasion demands, and with great relief, while alcohol and other stimulants, freely given, do not prove effectual, though they are valuable.

A distinction should be made between cases of dyspnoea like this one and those that are purely hysterical, occurring in a stout female. Whether atropia would be of any value in the latter case, I know not from experience, but infer that it probably would not prove useful.

I have spoken of its great value in arresting profuse alimentary discharges. Let me now merely mention its value as an adjuvant to cathartics in ordinary and obstinate cases of constipation. This point in its value is by no means new. Added to laxative pills, it renders their action more certain and thorough by stimulating the nerves supplying the muscular and mucous coats of the bowels.

In cases of faecal obstruction, it is a most valuable agent, and will cause, or greatly assist in causing, full and free evacuations where cathartics alone would act but indifferently, or even be contraindicated. For instance, take a case where no action has followed the liberal use of active cathartics, after their persistent use, and there is undoubted evidence of faecal impaction. It may become unsafe to give more cathartics, and you turn your attention to giving large enemata. If you now give atropia, it will often greatly assist in causing full and large evacuations. Strychnia may be here given for a similar reason, but, I think, is not as valuable as the atropia, and is not as safe. If the bowels have become inflamed during faecal impaction, atropia can be given with advantage, while it would be unsafe to give cathartics. Whatever good atropia, given for its systemic effects, may accomplish, I think is accomplished only by its being a most powerful nervous stimulant, both to the organic and inorganic systems.

J. MILNER FOTHERGILL, M.D.

MOREY ON STRYCHNIA EATING AS AN ANTIDOTE TO ALCOHOLISM.—Dr. H. C. Morey, of Gilroy, California, sends the following account of a strychnia-eater to the *Pacific Medical Journal*.

The individual in question is a man about fifty-two years of age, about five feet eight inches in height, and weighs about one hundred and fifty-eight pounds. He is of dark complexion, very plain in appearance, very eccentric and peculiar in his habits, and always

keeps his own counsel; has a good intellect, but a limited education.

I first became acquainted with this man in the fall of 1861, and soon learned of his habit of eating strychnia after a long and continued debauch, and in a condition bordering on delirium tremens. The first time my attention was particularly called to it, he wished me to give him a bottle of strychnia, which I did at night, about bed-time. He took the bottle, pouring the strychnia into his hand, and threw it into his mouth as carelessly as though it were salt, and in the course of half-an-hour, not feeling the effects from it that he wished, he repeated it, and continued to do so until he became perfectly sober. The quantity required would correspond to the length of time he had been drinking, and the quantity of whisky he had drunk. I was struck with the wonderful effect it had to completely sober him, and leave his system entirely free of any nervous disturbance, and without the reddened and bloated appearance of the face, the dull heavy eyes, and irritable stomach of the drunkard. After a two weeks' drunkenness, with all the appearances of approaching delirium tremens, he got up in the morning with his mind clear, his eyes bright, his skin clear and fair, and with all the appearance of a man in perfect health and vigour, and ate as hearty a breakfast as usual, and went to his work as though he had never taken a drop of whisky in his life. My curiosity being excited at what seemed so unaccountable an occurrence, I began questioning him as to when he commenced its use, and what induced him to take it, but found him very reticent, and have not to this day ascertained the causes that first led him to its use. All he will tell is that he commenced its use in 1856. From 1861 to 1867, I saw him very frequently, and almost as often have seen him take the strychnia, until it ceased to be a curiosity, except to study its physiological action. In every instance when he took it, every appearance of dissipation would disappear in a very short time. Whether strychnia is an antidote to alcoholic poison, and *vice versa*, was a study for which I could find no authority to guide my conclusions.

From 1867, I did not see him until the month of November, 1874, when he came to this place and called on me for strychnia, as of old. I told my clerk to give him all he wanted. He gave him a bottle, from which he took about twenty grains. In an hour he was all right, and sober as ever.

OBSTETRICS AND GYNÆCOLOGY.

CHOUPEE ON THE EMPLOYMENT OF CHLORAL AS AN ANÆSTHETIC IN NATURAL LABOUR.—Dr. H. Choupee, in the *Annales de Gynécologie*, May, 1875, has collected a large number of cases, recorded by various authors, exemplifying the use of chloral in

labour; and from these, together with his own observations, he concludes that chloral, even in a dose capable of producing complete anæsthesia, in no way suppresses, or even diminishes, the contractility of the unstriated muscular fibres in general, the uterus included. Chloral, which is capable of producing in a marked degree cutaneous anæsthesia, can equally nullify the pains of labour. This suppression of pain is not due to diminution of the uterine contractions either in their intensity or their frequency; on the contrary, all their power is preserved, and, if they seem occasionally to be retarded, that which they lose in frequency they gain in force; so much so, that labour is accelerated and not retarded. When uterine inertia is recognised as the cause of too prolonged labour, which has exhausted the powers of the patient, or when the patient is particularly irritable and fatigued by the useless efforts, and the uterine contractions diminish in frequency or intensity—when inertia is threatened, in fact—chloral, administered in a dose sufficient to produce complete anæsthesia, is generally capable of restoring energy to the uterus, and force and regularity to the contractions.

Neither the infant nor the mother is injured by chloral anæsthesia. M. Pelissier, who has employed chloral largely, states that when administered prudently and in suitable doses, it is perfectly innocuous; indeed, the fœtus runs less risk of becoming asphyxiated. No evil after-effects retarding convalescence have ever been observed; on the contrary, patients seem to rally more rapidly from having been spared so much fatigue.

It remains to indicate more precisely in what cases chloral should be administered, at what stage of labour it ought to be given, in what dose, in what form, and by what channel.

Chloral will agree whenever it procures sleep, induces repose, and lessens the pains of parturition. It should especially be employed in tedious labours, and in primiparæ, because then the pains have an intensity which we only find exceptionally in subsequent confinements. It often happens that, the pains being very intense and the patient very nervous, force is wasted uselessly; and at the moment when they have, above all, need of all their force for the last expulsive efforts, the patients are fatigued, and the uterus ceases to contract. In these cases chloral, which procures repose and which prevents the patient from wasting her strength, is formally indicated.

Among nervous patients, who excite themselves and complain beyond measure, chloral will expedite delivery; and, even if during pregnancy we can promise to materially diminish the pains of labour, we shall lessen considerably the patient's apprehension.

Among hysterical patients, chloral acts beneficially.

The consideration of the employment of chloral in operative midwifery, and in eclampsia, as advocated by Dr. Playfair, is purposely omitted here, in accordance with the title of the paper.

When should chloral be given? In the immense majority of cases, when the dilatation of the os is complete—just as the expulsive pains commence. It is only in exceptional cases, and where patients suffer unusually, that chloral should be given during the period of dilatation.

The dose of chloral necessary will vary with the susceptibility of the patient, and with the effect one

wishes to obtain. The dose generally varies from one drachm to one and a half drachm, given in two doses at half hour's interval, or in fifteen-grain doses every quarter of an hour, if we do not desire too rapid an effect.

The natural channel for its administration, and the one which should always have the preference, unless contraindicated, is by the stomach. The syrup of gooseberry is the best agent for masking the pungent flavour; and the solution should be made of such a strength that a teaspoonful represents fifteen grains. Should vomiting precede or follow its administration, it may be given by the rectum. As regards intravenous or hypodermic injections, they are too dangerous methods for ordinary natural labour.

ARTHUR W. EDIS, M.D.

OPHTHALMOLOGY AND OTOLOGY.

HIRSCHBERG ON CONCUSSION OF THE RETINA, AND ON FOREIGN BODIES IN THE EYE-BALL.—In some observations on injuries of the eyes (*Berliner Klinische Wochenschrift*, May 31), Dr. Hirschberg draws attention to the fact that loss of sight after severe blows in the neighbourhood of the eye during the preophthalmoscopic period was very frequently attributed to commotion or concussion of the retina, terms rarely employed at the present time, when experience has taught us that amaurosis and even extensive amblyopia are usually accompanied by some well-marked anatomical lesion. When amaurosis follows an injury, such as a violent blow upon the parts round the eye, it is nearly always associated with atrophy of the optic nerves, and in many of these cases it is probable that some severe damage has been inflicted upon the optic nerve between the eyeball and the base of the brain, and this assumption is supported by experiments upon animals (*Wochenschrift*, no. 37, 1869). According to the statement and experience of Berlin (*Zehender's Monatsblätter*, 1873), when temporary loss of sight has occurred from a contusion of the eyeball, there will be found a very decided although a transitory amount of opacity in the retina, the result of œdema it is supposed, and which is probably associated with the presence of hæmorrhage between the various tunics of the eye. From experiments upon animals it appears that the immediate effect of concussion upon the eye is a narrowing of the arterial trunks, which in turn is soon followed by their dilatation, and by the establishment of a condition of ischæmia.

In support of Berlin's conclusions, Hirschberg records the case of a man, aged twenty-nine, who received a severe blow upon the right eye from the end of a heavy rope; vision was at once reduced to perception of light, and after the lapse of ten minutes large objects only could be discerned. On the day following the vision was nearly normal again, but there was mydriasis, and a slight rupture of the inner margin of the pupil. With the ophthalmoscope Hirschberg could detect a faint opalescence of the retina, which radiated outwards in all directions from the optic papilla, but which did not involve the yellow spot; this appearance was to be distinguished from that of diffuse retinitis by the optic disc remaining unaltered and the vessels of the fundus being no larger (more congested) than those of the uninjured eye. In one spot, there was the appear-

ance of a slight detachment of the retina. In a few hours these appearances could no longer be seen; vision was perfectly restored, except that there remained slight mydriasis and an impairment of the accommodation.

With reference to foreign bodies, Hirschberg records another instance in which a foreign body had entered the eyeball, where it could be readily seen with the ophthalmoscope, and yet good vision was retained; similar instances have been recorded by Von Graefe and by Jacobson (*Archiv für Ophthalmol.*) In the present case a splinter of steel had penetrated the right eye of a button-maker, and without wounding the lens had imbedded itself upon the retina immediately above and to the outer side of the yellow spot. A week after the accident the foreign body was readily seen; it glistened like polished metal, and with the exception of some membranous films in the vitreous body there was no evidence of structural lesion. On very minute examination it was possible to trace the site of entrance in the sclerotic, at some little distance beyond the margin of the cornea. The patient could read Snellen $1\frac{1}{2}$ with + 6 glass; he was kept in a dark room, and the eye was carefully bandaged and treated with atropia. After an interval of six months the condition of the eye had not materially changed, except that the vitreous opacities were less marked, and the colour of the fundus around the foreign body was almost restored. The vision of the eye had not in any appreciable degree deteriorated.

[The fortunate result which frequently attends such a severe accident as the above, independently of the fact that the ciliary processes and the crystalline lens have usually escaped injury, is in some measure due to the nature and material of the foreign body itself. Thus substances which are not readily acted upon by the humours of the eye, such as fragments of hard and polished metal, and more especially splinters of glass, have been known to remain and to rest inert within the eyeball during long periods, while bodies of a softer texture will speedily react upon the tissues around, by causing rust, etc., and thus induce suppuration and involve the whole eyeball in destructive inflammation.—*Rep.*] BOWATER J. VERNON.

CHIRALT ON EXTRACTION OF CATARACT BY A MEDIAN SECTION THROUGH THE CORNEA.—The editor of *La Crónica Oftalmológica*, of April 12, gives a short account of a method of operation which has been practised since 1869 by his fellow-countryman, Dr. Vicente Chiralt, for the extraction of cataract, and with very marked success. The operation consists of three stages, the first, and most important of them, being the cutting a section transversely across the cornea at the junction of the middle with the lower third, by means of a Von Graefe's knife, which is entered at the sclero-corneal margin and is passed rapidly across the anterior chamber, and made to emerge on the opposite and corresponding point. No iridectomy is performed, and chloroform is considered unnecessary. The capsule is opened in the usual way as the second stage of the operation, and the lens is generally removed without difficulty with the aid of slight pressure upon the upper lid, assisted by Von Graefe's elastic spoon.

Dr. Chiralt considers the operation a complete success, when the patient can read No. IV. Snellen; moderately successful when some letter larger than No. IV. is read; and unsuccessful when the

largest types only can be read. When measured in this way, his results may be thus stated:—

Good, when the patient could read S. IV.	73
Moderate, " " " some larger type	7
Bad, " " " only S.C. or C.C.	5
	85

The editor admits the similarity of this operation to that proposed and practised by Le Brun; but he claims for Dr. Chiralt the priority of its performance. BOWATER J. VERNON.

BACHER ON CHRONIC INFLAMMATION OF THE LACHRYMAL SAC.—In the *Medicinisch-Chirurgische Centralblatt* (nos. 11 and 12) Dr. Sigmund Bacher gives the history and the details of three cases of this kind which are, as he admits, common enough, but whose exciting cause is not always easy to be found. In each instance the inflammatory mischief had commenced elsewhere, and the lachrymal sac had become secondarily affected. The first case was that of a girl, aged twelve, who had a small abscess in the integument of the eyelid, and an obstruction to the escape of the tears with a dilatation of the sac subsequently. The second case occurred in a young woman, aged twenty-four, who had suffered from persistent nasal catarrh after measles; and the last instance occurred in a man, aged thirty-eight, who had suffered from a chronic ozaena of a specific nature. In all three cases the same treatment was adopted, the lower canaliculus was first dilated, and then the passage was slit open with Aert's scissors, and the nasal passages were then explored with the smallest of Bowman's probes. The probe was for some time passed daily, and its use was not altogether discontinued for many weeks. Dr. Bacher does not put much faith in the value of larger probes than Bowman's no. 4, and he does not believe in the use of probes at all when the disease has been of long standing, in which the discharge is purulent rather than muciform, and in which one would expect the walls of the sac to have degenerated and to have become unable to exercise any power of contraction. BOWATER J. VERNON.

BELLIÈRE ON PHTHISICAL OTITIS.—In the *Lyon Médical* for March there is a short review of M. Bellière's work on the otitis of phthisical patients. M. Bellière considers (1) that the otitis seen in such cases is not a tubercular otitis, but a simple catarrh of the cavity, and (2) that this catarrh always follows a pathological state of the pharyngeal mucous membrane. He rejects the opinion of those who, with Ménière and Le Maître, consider tuberculation of the mastoid cells as the point of origin. He has several times determined the integrity of the mastoid cells in such patients while suffering from otitis. On the other hand, he cites in favour of the propagation of the pharyngeal inflammation through the Eustachian tube to the tympanic cavity, the frequency of the glandular enlargements of the throat in such patients, and the fact that the lesions of the otitis of typhoid fever and of tuberculosis are identical.

DERMATOLOGY.

POLLATSCHEK ON MALIGNANT PUSTULE.—Dr. Pollatschek, of Bellatine (in the valley of the Mur, a tributary of the river Drave, in Western Hungary, between the Platten See and Croatia), describes in a short but important communication to the *Allgemeine Wiener Med. Zeitung* (no. 52, 1874) the following eight cases of the disease, rarely observed in man but frequent in domestic animals, which has been variously named *Charbon* by the French, *Milzbrand* by the German veterinary surgeons, malignant pustule, splenic fever, splenic apoplexy, bacterial septicæmia, etc. They all occurred during the latter part of last summer, or in October following.

In the flat and low district above described, it appears that splenic fever is endemic among the cattle, and is most common in the months of August and September, the time when the malarial fever of the country is most rife among the inhabitants. (This connection between malaria and the milzbrand of cattle, both in locality and season, has been noticed by Heusinger.) The plague affects horned cattle, sheep, and swine, horses more rarely; and Dr. Pollatschek has never seen an epidemic except among sheep. In fact, the cases ordinarily observed show little disposition to spread.

The first group of cases began last July. A peasant killed a cow which, he saw, was sickening for splenic fever, and sold the meat. He took care not to touch the carcass himself and escaped the disease; but a man who had helped to skin and cut up the cow was attacked the next day with headache, nausea, and shivering. On the third day he felt worse; his right arm was red and swollen, and on the back of the hand was a hard, whitish, irritable pimple, followed by similar ones on the other hand and on the face. Some of these papules became simple vesicles, which burst and dried up, but a few behaved like boils, the deep layer of the cutis being involved and forming a hard nodule under the vesicle. In a fortnight the man was well again without any special treatment, but he remained weak and pale for some time afterwards.

The second patient had only held the skin with one hand while the cow was disembowelled, but the whole of that arm was severely inflamed. This only began four days after the infection. The same constitutional symptoms as those of the last case were followed by the appearance of a carbuncle on the inner side of the forearm. This was rubbed with caustic, but became a gangrenous sore, and great bullæ appeared over the arm. There was high fever with delirium. After a week's illness, the patient began to recover, under treatment with quinine and carbolic acid internally and nitric acid and carbolic acid lotion locally; the carbuncle healed, and the arm returned to its normal condition, but convalescence was very slow.

The third and fourth cases of the disease occurred in two men who also helped in skinning and dressing the carcass. One was attacked with headache and malaise on the third and the other on the fourth day, followed by an eruption of papules on the inner

side of the forearm. These were at once burnt with caustic (?nitrate of silver); and in a week both patients were well.

The next sufferer was a woman, about fifty years old, who had wiped the flesh, still warm, with a wet cloth, before offering it for sale. A fortnight after the killing of the cow she came to Dr. Pollatschek, looking very ill, and showed him an unhealthy ulcer on the back of her right hand; this was touched with lunar caustic and dressed with carbolic acid. It cleansed and gradually healed, and the patient recovered with the help of tonics.

The sixth and last case was that of a tanner who bought the cow's hide. In a few days he was attacked by rigors, headache, lassitude, and discomfort, without any local manifestation of the disease. He knew from experience what his illness depended on, and had, in fact, been suspicious of the hide when he bought it, for it smelt ill, and turned the lime-bath into which he put it to an unusual colour. He showed Dr. Pollatschek soft spots in the hide which, no doubt, corresponded with furuncles during life. This patient recovered without medicine.

The second group of cases began with a peasant, who came to Dr. Pollatschek last October, with a carbuncle on the inner aspect of the right forearm, which was recognised as due to infection from charbon. He then confessed that, three days before, he had slaughtered a cow which he found suffering from the disease, and with the help of his mother-in-law had dressed the carcass and sold the meat. Caustic was applied to the sore, and the man recovered in a few days. But the old woman was much more severely affected. Beside several deep boils on her left forearm, erysipelas had spread nearly up to the shoulder, and she was very feverish. Next day, in spite of cauterisation and the application of ice, the inflammation had spread over the shoulder and side of the chest. Large doses of quinine with carbolic acid were ordered, but a rigor occurred in the evening; the sores became gangrenous, and the patient (sixty years old) died next day, just a week after the cow was killed. [There seems to have been no necropsy, and in none of the cases is any mention made of the size of the spleen, of purpura, or of the characters of the blood in the persons affected.]

The flesh of both the cows was eaten by several of the villagers, but in no case with any symptoms of the disease. Indeed, the only instance in which it can even be supposed to have done any mischief was in a woman, who had slight diarrhoea for a couple of days afterwards; and her children, 'who had eaten themselves as full as their mother,' escaped entirely.

Dr. Pollatschek draws the following conclusions from these instructive cases. 1. 'Black' or 'bluepox,' charbon-carbuncle, and gangrenous splenic erysipelas, are parts of the same disease. In the above cases there were five of genuine carbuncle, one of blackpox (malignant pustule), and one of gangrenous erysipelas. He thinks that the same specific irritant will fail to injure the thick, smooth, hairless skin of the palm, will produce pustules or bullæ on the thick cutis with large hair-follicles which covers the back of the hand, and outside of the forehead, and will affect the thinner integument of the flexor surface by inflammatory nodules in the deep layer of corium and the subcutaneous tissue, producing characteristic boils or carbuncles. 2. The poison can act through unwounded skin. 3. The infection is greatest when the flesh is still warm. None of the

persons who bought the infected meat, and carried it home, suffered in consequence. 4. The diseased meat when cooked is harmless, or practically so, when eaten.

On Nose, Throat, and Ear Instruments. By T. F. RUMBOLD, M.D.

In a small pamphlet with the title 'Nose, Throat, and Ear: Instruments and Remarks,' Dr. Thomas F. Rumbold, of St. Louis, describes various modifications of instruments already in use, which he has found of service in the diagnosis and treatment of affections of the parts named. Dr. Rumbold finds a tongue-depressor, with a handle and shaft, twelve inches long, the most suitable, as by it the patient depresses his own tongue without having his hand in the way of the surgeon, and thus leaves both hands of the latter free to operate. The tongue-piece is changeable, so that longer or shorter blades may be used, and can be placed at different angles, so that the base of the tongue may be depressed as desired. To the usual pharyngeal mirror he has added hinge-joints and a pivot, by which means any desired inclination of the plane of the mirror, and any direction of the longer diameter of the reflector, may be obtained. Instead of the ordinary hook-shaped uvula-retractor, he uses a retractor which he describes as 'a tube, six inches long and one-eighth of an inch in diameter, having at one end an enlargement of three-sixteenths of an inch transversely, and cup-shaped, for the purpose of receiving the uvula. The other extremity is trumpet-shaped, and one inch in diameter, and covered by sheet India-rubber. In its use, the smaller extremity of the instrument is applied gently to the uvula, whilst the air is expelled from the tube by slight pressure on the rubber extremity. This done, the uvula is drawn into the tube about a quarter of an inch; only slight traction is necessary to lift the uvula, and draw the soft palate forward, thus the antero-posterior diameter of the passage may be increased from one quarter to one half inch. If carefully handled, patients generally do not feel the application of the instrument.' Under the name of the 'spreading soft-palate retractor,' Dr. Rumbold introduces to the profession an instrument which promises to be of great use in operations on the walls of the nasopharyngeal cavity. 'The instrument resembles an ordinary palate-hook split longitudinally; the surface of each hook that comes in contact with the soft palate is made convex by binding the plates; the arms are separated by a lever on the handle, and are maintained in this expanded condition by a retainer or wedge—connected with another lever having a spring under it—which insinuates itself between them. . . . By use of this instrument equal retraction of the velum palati—with both relaxation and tension at will—can be effected by the left hand, while the right hand is engaged in operating, and more room is secured during surgical treatment than by any other kind of retractor.'

As an 'Acou-otoscope' is described an instrument which has been long used in England and on the continent under the name of Siegle's speculum, descriptions of which will be found in various text-books. Dr. Rumbold, however, uses the tube connected with the speculum as an auscultating tube, instead of as a suction or condensing tube, as generally used here, and by this means employs the eye and ear simultaneously for observing changes in the membrane.

The spray-producers which he uses for the application of medicinal agents to the mucous membranes of the nasopharyngeal and laryngeal cavities are modifications of the usual nebulizers, the points being so constructed that they conveniently direct the spray against the locality desired to be acted on. To remove the difficulty found in introducing laryngeal forceps sufficiently long to reach the vocal cords through the pharyngeal space without touching any of the structures close to which it passes, Dr. Rumbold has invented a 'tubular laryngeal forceps,' the vertical portion of which, the forceps being in position, can be lengthened by a mechanism on the handle.

W. LAIDLAW PURVES.

Annales des Maladies de l'Oreille et du Larynx.

A bi-monthly journal with the above name has just appeared under the editorship of Drs. Lacharrière, Isambert, and Krishaber. The first number contains an elaborate essay on the classification of diseases of the larynx and pharynx by Dr. Isambert, and an interesting historical article on amygdalotomy by Dr. de Saint-Germain. Dr. Krishaber contributes two papers, one on rhinoscopy, and a second very interesting article on 'Laryngopathies during the Early Phases of Syphilis.' The author's investigations, made at the Hôpital du Midi in the winter of 1872-73 in conjunction with Dr. Mauriac, are opposed to the conclusions of Dr. Ferrus. In fourteen cases of 'secondary syphilitic laryngopathies,' Dr. Krishaber found *plaques muqueuses* ten times on the laryngeal mucous membrane. Dr. Léon Labbé contributes a case of fibro-mucous polypus in the naso-pharyngeal region. The polypus occurred in a girl aged fifteen, and was removed by electric cautery after incision of the soft palate. The author calls attention to the rarity of 'true fibrous nasopharyngeal polypus in any other class of people than young men, but remarks that 'the possibility of true naso-pharyngeal polypi occurring in the adult, old men, or in women, has not been disproved.' The journal contains an excellent abstract of all that is known of Menière's disease and other short papers on aural affections, which will shortly be noticed in detail in these columns. We heartily congratulate the editors on their undertaking, but would venture to suggest that in so special a journal, appearing at comparatively long intervals, it would be very desirable to have each article complete in itself. In the present number, in some of the best papers, the conclusions follow two months hence.

MORELL MACKENZIE, M.D.

Elephantiasis of the Penis after Urethral Stricture.

By R. F. WEIR, M.D. New York.

Dr. R. F. Weir, of New York, reprints from the *Archives of Dermatology* a case of 'Elephantiasis of the Penis,' from stricture of the urethra, treated by amputation of the organ. From the description and woodcut it might perhaps have been called gonorrhoeal warts with inflammatory thickening of the organ. The treatment was successful.

MISCELLANY.

INTERNATIONAL CONGRESS OF MEDICAL SCIENCES.—The organizing committee of the Medical Congress, which is appointed to meet at Brussels on September 19, gives notice that a section of psychological medicine has been created which will occupy itself with questions bearing reference to mental diseases, the treatment of the insane, etc. The committee has also decided on organising an exhibition, to be open during the congress, and near the building where it meets, of new instruments and apparatus used in medicine, surgery, physiology, ophthalmology, etc.

We learn from *Nature* that a great meeting of German ornithologists took place at Brunswick on May 20 to 23. Brehm, Cabanis, Homeyer, Blasius, Reichenow, Pralle, and many other members of the two ornithological societies, were present. The first meeting led to the union of the two societies. It was resolved to request all the members to report to a committee from time to time all observations of interest to science, agriculture, or the economy of forests, that they may make, on the life, manners, use, etc., of German birds. The committee is to publish the materials thus obtained, after due consideration and sifting.

THE following case of poisoning by aniline dye is reported from Stettin. A gentleman had bought a hat in a shop there, and, after having worn it for one or two days, was troubled with unbearable headache; at the same time little ulcers formed upon his forehead, his eyes were inflamed, and the whole of the upper part of his head was much swollen. It was evident that these symptoms were caused by the hat, and upon examination by a chemist it was found that the brown leather in the inside of the hat was coloured with a poisonous aniline dye. It appears that inflammation is unavoidable when this dye is in contact with any part of the skin.

WE learn from *Nature* that a scientific society has recently been established in Caius College, Cambridge, for the diffusion of scientific knowledge among the members of the college, for the reading of essays on scientific subjects, and for the holding of scientific discussions. The society admits within the range of its discussions all sciences of observation. An interesting feature in the scheme of the society's proceedings is that the first half-hour of each meeting is to be devoted to open discussion, to the answering of questions proposed by any member either at the time or at a previous meeting, or to the exhibition of specimens. The first president of the society is Mr. B. Anningson, M.A., M.B., the newly appointed medical officer of health for Cambridge, and the secretary is Mr. Wm. Ewart. A number of papers have been read during the present term. The meetings have been well attended and the discussions well supported.

FLOWERS IN HOSPITALS.—E. A. H., secretary to the Flower Mission, writes to the *Daily News*: 'Having read in the *Daily News* for June 9 a suggestion by a correspondent that flowers should be sent to the sick poor in London, we beg to send you the address of our two depôts, where we most thankfully receive any contributions of flowers and fruit for distribution on Tuesday and Thursday forenoons. Since March 29 we have been supplying hospitals, unions, and missions in various parts of London at the rate, on an average, of from 3,000 to 4,000 little bouquets a week. The intense joy and gratitude of the many recipients passes description, and would well repay all the trouble our kind country friends have taken in sending them. We shall be happy to answer any communication addressed to the secretary of the Flower Mission Home of Industry, Commercial Street, Spitalfields, E.: or Conference Hall, Mildmay Park, N. All parcels should be carriage paid.'

A GOOD EXAMPLE.—The Medical Association of the Gironde has formed a committee of eighteen members, whose special duty it is to take legal proceedings against the unlawful practice of medicine in the department.

A DELUSION EXPOSED.—A 'Spirit Photographer's' trial has taken place before the Correctional Tribunal of Paris, which has resulted in the conviction of certain 'Spirit Photographers' for swindling. Buguet, a photographer, of No. 5, Boulevard Montmartre, allied himself with M. Leymarie, the editor of the *Revue Spirite*, who wrote about him and published fac-similes of his portraits, and with an American named Firman, from whom he learned the art of persuading people that he could, if they only willed strongly enough, conjure up and photograph a likeness of any deceased relation or friend. For a long time the firm did a large business. Twenty francs was the ordinary fee, but many wealthy people voluntarily paid 2,000, 3,000, and even 4,000 francs. Never was fraud more clearly proved. The operator's spirit-box was produced in Court; it contained hundreds of portraits of men, women, boys, and girls of all ages. When customers came desiring spirit-portraits, a young lady, who acted as cashier, adroitly engaged them in conversation in the waiting room, and generally contrived to find some indications of the physiognomy of the person whom it was desired to evoke. Then one of the numerous heads was selected, stuck upon a doll dressed up in muslin, and a hazy portrait of a spirit was produced from it. Buguet guarded himself by saying he could never guarantee a likeness, because much depended on the strength of faith of the applicant, and, moreover, spirits were very capricious, and sometimes when one was called for another would come; but in very many instances the force of imagination was so strong that his dupes believed they saw the portraits of their relations. They burst into tears, fell upon their knees, kissed the photographs, and were profuse in expressions of gratitude to the professor as well as lavish of gifts to him. Notwithstanding the palpable exposure of the imposture in open court, a host of respectable witnesses, including a Russian Marquis, the Comte de Bullet, Mr. Sullivan (formerly United States Minister at Madrid), two French colonels, and several ladies, appeared for the prisoners, and protested that they really had seen unmistakable portraits of deceased relatives. The counsel for the defence, M. Lachaud, spoke for two hours, and alluded to Moses, Isaiah, Tertullian, and other eminent authorities on spirits. The Court, however, thought the charge fully proved, and sentenced Buguet and Leymarie to one year's imprisonment, and Firman to six months.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.: free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, JUNE 30, 1875.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

VULPIAN'S EXPERIMENTAL PATHOLOGICAL STUDIES ON THE PHYSIOLOGICAL ACTION OF TOXIC AND MEDICINAL SUBSTANCES.

(Continued from page 383.)

With regard to the influence of jaborandi and atropine on the sudoral secretion, it is known that jaborandi induces a considerable diaphoresis in man. The secretory work of the sudoriparous glands is therefore increased during a varying time, and it can be prevented or arrested completely by administering, either previously to or in the course of the sudoral hypercrinia, a small dose of sulphate of atropine. Physiological data only furnish us with one admissible interpretation of the effects of these substances on the secretion of sweat. We are forcibly led to admit that jaborandi acts on this secretion by paralysing the peripheral extremities of the sympathetic nerve-fibres which proceed to the sudoriparous glands; and that atropia, on the contrary, excites those fibres. M. Vulpian is of opinion that no other explanation can be admitted, because, basing his conclusion on what has been ascertained with regard to the salivary glands, it cannot be supposed that jaborandi and atropia act on the cells of the sudoriparous glands. Notwithstanding everything however M. Vulpian has arrived at two different theories to explain the effects of jaborandi on the sudoriparous and salivary glands, for it will be remembered that he has accepted the notion that the excessive secretion of the submaxillary gland induced by jaborandi is an effect of the excitation produced by that substance on the chorda tympani—that is to say, on the excitatory nerve of the gland—and he has put aside the hypothesis of a paralysis of the sympathetic nerves of that gland. M. Vulpian thinks that such a result is very unsatisfactory; it is repugnant to him to admit, if not absolutely forced to do so, that a substance acts on a system of glands by influencing the sympathetic fibres which innervate those organs, and that the same substance acts in the same manner on another system of glands by the medium of other nerve-fibres than the sympathetic fibres which are also received by these secretory organs. M. Vulpian then proceeds to endeavour to resolve these difficulties, and for that purpose recapitulates the manner in which the sudoriparous glands act, and their physiological relations with the nervous system.

The sudoriparous glands must, he says, be looked upon as having a tendency to secrete continuously in the normal state. The sympathetic nervous system not only intervenes as a check, but it acts in a persistent manner in variable degrees in restraining, moderating, or keeping down the secretory work of those glands. It is in a state of constant activity, which may be compared to the similar state of the

nerve-fibres which keep up the vascular tonus. The variations of this moderating tonic action of the sympathetic fibres proceeding to the sudoriparous glands produce corresponding effects in the activity of the secretory work of these glands, a work which increases when the same action of the sympathetic fibres is relaxed. If the curb be tightened, that is, if the great sympathetic be excited, the secretion stops. If the check be relaxed or abolished, as, for instance, by cutting the great sympathetic, the sudoral secretion is increased. The action of jaborandi and of atropia are actions of that nature; jaborandi acts by paralysing the sympathetic fibres, which innervate the sudoriparous glands; the sulphate of atropia stops the perspiration by exciting these fibres.

M. Vulpian does not here bring into question the cutaneous vascular modifications which may be produced by division and excitation of the sympathetic or the action of the two substances, the effects of which it is sought to explain, for probably these modifications do not here play any essential part. In the first instance, congestion of the skin without concomitant sweats is often observed. M. Vulpian contents himself by citing the congestion of the face and that presented by the skin of all parts of the body in certain cases of febrile affections, such as pulmonary phlegmasiæ and typhoid fever, and the period when exanthematic pyrexia make their appearance. In these cases, as we know, the skin of the congested regions is quite dry. The same thing occurs in the hot stage of intermittent fever. If this hot period be compared with the third stage of marsh-fever, it will be seen that in this last period the skin is generally less congested than in the hot period; and, nevertheless, the sudoriparous glands are in an active secreting condition. It may also be added that, in the human subject submitted to the action of atropia the integuments are rather congested than anæmic, although that toxic agent prevents all sudoral secretion during a certain period. Here are satisfactory arguments to prove that the hyperhidrosis produced by jaborandi is not due to the action of that substance on the cutaneous vessels. It is true that it might be supposed that the congestion does not take place throughout the whole thickness and extent of the cutaneous integument, and that there is only increased depletion of the vessels of the glomeruli of the sudoriparous glands. But this is a supposition which nothing justifies; and even if it had any foundation, M. Vulpian thinks there is no ground for attributing the increased secretion of sweat to that congestion of the vessels of the sudoriparous glomeruli, induced by the absorption of the active principles of jaborandi, for the researches which have been made into the action of the other glands have shown in the clearest way that the sanguineous afflux, which takes place in these organs at the moment of the functional erethism, is only an adjuvant condition. The principal and essential part belongs to the modifications of the physiological action of the secretory elements themselves, and these modifications are most generally effected under the influence of a change supervening in the activity of the nerve-fibres, which are in more or less direct relation with the secretory elements. A more complex state of things occurs in the salivary glands. The submaxillary gland, which M. Vulpian takes as a type, receives numerous filaments proceeding from the great sympathetic, but it is also innervated by the fibres which spring from the chorda tympani. The sudoriparous glands do not possess any analo-

gous filaments; at least up to the present nothing of the kind has been discovered. The salivary glands may, however, be considered as presenting, up to a certain point, a similar physiological condition to that which has been noted in the sudoriparous glands. The submaxillary gland may be considered as tending to secrete in an uninterrupted manner. The fibres of the sympathetic filaments which go to that gland act on it as physiological curbs. These fibres are in a state of continuous activity, and feed the secretory action of the cells of the glandular *culs-de-sac* in a persistent manner. The proof of this fact is, that the almost complete destruction of all the nerve-elements which are in relation with this gland are followed by an incessant flow of saliva. If the filaments of the sympathetic which proceed to the gland be cut, a slight increase of the salivary secretion is produced; but this increase is very slight, because these filaments, before penetrating into the gland and into the gland itself, place themselves in relation with numerous ganglionic cells, which may further keep up their state of tonic activity, and consequently their restraining action. This tonic activity can only be paralysed by the medium of the chorda tympani. The filament furnished by the chorda tympani to the submaxillary gland is, so to speak, a perfecting nerve. It is intended to act on the nerve-cells situated on the line of the sympathetic fibres which distribute themselves to the gland, and when it is excited it paralyses the inhibitory action of these cells. Immediately on this the gland, restored to functional independence, sets to work, and a continuous salivary secretion is produced.

The effect produced on the sympathetic fibres by the excitement of the chorda tympani may still manifest itself if a substance introduced into the circulation paralyses either the nerve-cells which have just been spoken of, or the peripheric extremities themselves of the sympathetic fibres which innervate the gland. And this is precisely the manner in which *jaborandi* may be supposed to act. *Jaborandi*, according to this view, would paralyse the peripheric extremities of the fibres furnished to the submaxillary gland by the great sympathetic. The inhibitory action of these fibres ceases under its influence, and the gland, having recovered its independence, acts; that is to say, secretes continuously. The atropia acts in a reverse way—draws the curb tighter, excites the peripheric extremities of these sympathetic fibres, and increases their inhibitory action; the check is thus strongly tightened, and the secreting activity of the gland is forcibly restrained. A common conclusion is therefore arrived at as to the manner in which both the salivary and sudoriparous glands are acted upon by *jaborandi*. However, M. Vulpian thinks that too much importance ought not to be attached to these views. They are, he thinks, hypotheses which are not unlikely to be true, but to which the stamp of direct experiment is wanting.

(To be continued.)

HUGHLINGS JACKSON ON DIFFICULTIES IN THE DIAGNOSIS OF THE CAUSES OF APOPLEXY.

The following remarks are reprinted from the Hospital Reports of the *Medical Times and Gazette* for May 7. They appeared before the recent 'police cases' of apoplexy occurred.

In his article on Apoplexy (Reynolds's *System of Medicine*, vol. ii. second edition), Dr. Hughlings Jackson insists that it may be not only difficult, but impossible, to tell whether a patient's apoplexy be owing to alcohol or to some far graver cause. (As implied in this sentence, the term apoplexy is not used in these remarks as synonymous with cerebral hæmorrhage. Large cerebral hæmorrhage is only one of several causes of apoplexy.) What is meant is, that it is often impossible to make a diagnosis in the scientific sense of the word. It is not asserted that we should often be wrong by mere routine guessing, aided by superficial examination. No doubt the police are nearly always right in their so-called diagnosis of drunkenness. The following is an illustration of the difficulty in diagnosis. It is true that there was no difficulty in declaring correctly that the man was dead drunk; that 'diagnosis' had been made by the men who brought him to the hospital, for it was known that he had swallowed a vast quantity of intoxicating liquor. But from the symptoms (supposing, for example, the man had been found lying comatose on the pavement), a diagnosis in the real sense of the word would not have been easy.

H. M., aged twenty-one, was admitted comatose at 7 P.M., October 17. For the notes of his case we are indebted to Mr. Lewis Mackenzie. The patient had passed both fæces and urine in his trousers before admission. This is considered by some medical men to be valuable evidence in favour of drunkenness and against cerebral hæmorrhage as a cause of apoplexy. But, although a help, it, like the smell of drink, is not to be trusted. Besides other reasons for not trusting the smell of drink (strong in this case), we know that drunken men in apparently trivial falls suffer hæmorrhage into the arachnoid 'cavity.' The patient was universally powerless and profoundly unconscious. Had it been possible to rouse him in part—as, for example, to resist examination, or to swear, or even to put out his tongue—there would have been no evidence of decisive value towards the diagnosis of drunkenness. It is not true that patients fatally ill from cerebral hæmorrhage cannot be roused to some extent; sometimes they can be roused. It is perfectly certain that such things as we have mentioned are done by those who are fatally ill from intracranial hæmorrhage. Moreover, certain elaborate actions are gone through by some patients fatally ill from intracranial hæmorrhage. For example, a patient who died in a few hours of cerebral hæmorrhage was seen by Dr. Sutton, Mr. Lewis Mackenzie, and other good observers, to twirl his moustache frequently. More recently, a patient, two hours and a half before he died of enormous cerebral hæmorrhage, tried to button his brace with his left hand, and succeeded in doing it in about a minute. He nodded and shook his head when told to do so, although after a long interval; half an hour later he was deeply comatose, and could not be roused. Some patients with fatal meningeal hæmorrhage are very uproarious. In cases of cerebral hæmorrhage there are seen all degrees from confusion of thought to deepest coma; there are cases in which, as the phrase goes, the patient is 'perfectly conscious.' This is not *à priori* remarkable, as there are all sizes of clots, from that of a pea or less upwards.

To return to our case. The patient's pupils were minutely contracted to the size of a pin's head. This is not a mere routine expression. The reporter of

the case is fully aware that in many cases of apoplexy the pupils cannot be said to be either contracted or dilated. Extreme contraction of the pupils most often occurs in hæmorrhage into the pons. It is, however, only the sign of a very grave lesion in any part of the encephalon. (In the 'gravity' of a lesion there are two factors: size—quantity destroyed; and suddenness—rapidity of destruction). It is most important to note that the state of the pupils varies very much with the temporary condition of a comatose patient. Thus it often happens that if we disturb a patient, comatose from many causes, if not from any cause, his pupils if contracted will dilate. Hence two observers must differ in their reports, if one examine the pupils first of all, and the other after the necessary disturbance of the patient to ascertain if any of his limbs are paralysed, etc. In this case Mr. Mackenzie noticed that 'pulling the ear and hair of the left side dilated both pupils, and that at the same time the face became flushed.'

The pulse was eighty-four, irregular, and at times intermittent. This is a common kind of pulse in cases of severe cerebral hæmorrhage. The skin was dry and cold, the hands, feet, and tips of ears, and nose especially so. Two thermometers were used. The temperature was taken in each axilla; the reading was 96°. The thermometers were kept in a quarter of an hour. Perhaps even this time was not long enough. In cases of cerebral disease with a probability of a low or a normal temperature, the thermometers should be kept in a long time. As to the diagnostic value of the temperature, we may find a low temperature soon after an attack of cerebral hæmorrhage; later the temperature rises above normal. The patient's respirations were abnormal in character. The upper part of the chest rose when the epigastrium sank.

After pinching, the respirations were accelerated, irregular, and jerking. There was some dullness at both bases, at the left especially. The patient coughed incessantly at times, but did not seem able to raise phlegm for a long time, and consequently became very livid in the face. Sonorous rhonchi were heard all over the front of the chest.

The urine was acid, of specific gravity 1.006, and contained no albumen.

The optic discs were normal, except that the large veins were much distended. They were black and round, and after the comatose stage it was noted that they showed the 'light streak.' Probably they would have showed it during the stage of coma. This condition of the discs may be found in cases of cerebral hæmorrhage, but often there is in such cases no obvious alteration in the fundus of any kind.

It was noticed by Mr. Lewis Mackenzie in this and in some other cases of alcoholic poisoning, that the eyes were divergent during the stage of coma. In a subsequent case of alcoholic poisoning, this was observed by Dr. Hughlings Jackson; but the divergence is not diagnostic of apoplexy from alcohol, for the eyes were noted as divergent in the case of fatal cerebral hæmorrhage alluded to earlier in these remarks (the man who buttoned his brace).

Next morning the patient's temperature was 101°, and so in the evening. He recovered rapidly. Dr. Hughlings Jackson has only seen two deaths from acute alcoholic poisoning. The patients nearly always recover, however deep the coma may seem to be.

CHIENE AND COOPER FORSTER ON BLOODLESS OPERATIONS.

As the expression of almost diametrically opposite opinions on Esmarch's method of bloodless operating, the recently published remarks of Mr. Chiene in the *Edinburgh Medical Journal* for April, and of Mr. Cooper Forster in the just issued twentieth volume of the *Guy's Hospital Reports*, are worthy of notice.

Mr. Chiene observes that the thoroughness of action of the elastic bandage is the chief objection to its use; the smaller arteries being so completely emptied that natural arrest of hæmorrhage by the formation of external clot during the operation cannot take place. As a consequence, when the compressing agent is removed, many vessels bleed which would have been otherwise closed; and before the surgeon has time to secure them by ligature, much blood is lost, and the operation is unnecessarily prolonged. The complete anæmia of the limb takes away that guide which oozing of blood gives to the situation of the smaller arteries, which cannot, therefore, be tied until the circulation is restored. And when it is restored every small artery bleeds freely, and leads to further loss of blood. Mr. Chiene considers the plan of simply raising the limb to be preferred, because it is not so complete; a gentle oozing as a guide to the smaller arteries is not prevented, and enough blood is left to allow external clot to form. In cases where there are putrefaction-products in the limb, the compression of the bandage is hurtful, and here, again, raising the limb is to be preferred. He objects to the elastic tubing that it does not allow of being relaxed and tightened at the pleasure of the operator, a serious obstacle in private practice where the number of assistants may be limited; and he would rather use Petit's tourniquet than the band of Esmarch. While Mr. Chiene regards the new method of operating as no improvement in surgery, Mr. Cooper Forster, on the other hand, is much in favour of the practice; for from his experience the advantages of Esmarch's method appear to be numerous, and the ill-effects are hardly appreciable. He supports this view by the considerations: firstly, that the surgeon is enabled to see what he is about, an important thing in the exploration of doubtful tumours of the limbs; and secondly, that a certain quantity of blood is saved for the patient, which he thinks to be always of advantage, notwithstanding the opinion of some that an active and plethoric circulation favours inflammatory change and excites surgical fever. He holds that loss of blood means lowered vitality and slow repair, feeble resistance to any putrefactive change that may arise, rapid absorption of such products when formed, and increased chances of pyæmia; and, accordingly, any method of saving blood seems to him an unmitigated good. Mr. Forster denies the force of the objection that the bloodlessness of the operation leads to want of care in the use of the knife, remarking that in the removal of limbs the incisions are made after recognised methods, the main vessels are at once secured, and while the smaller vessels never trouble much, the mere oozing from paralysed capillaries is so easily arrested that it cannot for a moment be imagined to be harmful. He sees a danger in the squeezing out of putrid matters, but with caution

this can be guarded against; and if other things are greatly in favour of the method, it should not influence us much.

HERBERT PAGE.

FRESH EXPERIENCES OF THE OPERATION OF THE WATERS OF NAUHEIM ON RHEUMATISM OF THE JOINTS, AND THE ACCOMPANYING AFFECTIONS OF THE HEART. BY DR. BENEKE.*

Since I wrote my pamphlet on this subject in 1872, I have treated forty-five cases of rheumatism of the joints associated with heart-affection, and eight cases of acute rheumatism of the joints with no heart-affection. Several also of the cases treated before 1872 returned to Nauheim for further treatment.

As to the chief questions, the quieting the action of the heart by baths of the temperature of 88° to 93° of our waters (which contain 2 to 3 per cent. of solids, chiefly common salt, and a little carbonic acid), and as to the disappearance of exudations into the joints, I consider it scarcely necessary to re-discuss two such well-established facts. But I shall give an account of a remarkable case of heart-disease, as an example of the first fact.

The patient, aged forty-one, had an attack of rheumatism ten years ago, and one for three successive seasons afterwards. He had not had an attack for six years, but for four years had had a most distressing affection of the heart, the exact date of the origin of which was not known. The patient was cyanotic, and suffered from dyspnoea; had troublesome cough with œdema of the lungs; his urine was highly albuminous. The hands, feet, and face were usually very cold; the points of the fingers and nails bluish. Going up stairs was very difficult. His pulse was very irregular. The heart was slightly hypertrophied. There was distinct insufficiency of the mitral valve with stenosis of the corresponding aperture.

The patient commenced by drinking the Kurbrunnen diluted. He took his first bath, lasting ten minutes, of the strength of $2\frac{1}{2}$ per cent., at a temperature of $90\frac{1}{2}^{\circ}$. The pulse at once became slower, and more regular in the bath, and the patient declared himself more comfortable. These baths and the drinking were continued with intervals of rest, and the improvement went on: the dyspnoea and the cough especially were relieved, the pulse was quieter, and the patient on July 7 remarked that, if he did not go away, there would be nothing to cure next season. The patient left on July 22, after having had altogether twenty-five baths. He wrote in August an encouraging account of himself, but his urine remained highly albuminous. The amount of albumen rather increased than diminished during his bathing. This, case, nevertheless, illustrates well the quieting effect of the baths on the heart, under the most unfavourable circumstances.

I am glad to find that Röhrig agrees with me, and says that baths of a temperature of 86° to 93° , of middling strength and used for a moderate time, can be borne without the slightest excitement of the vascular system, and further that such baths have a soothing and refreshing effect upon the patient, and usually cause a very distinct retardation of the pulse (10 to 35 beats), and these effects are much more marked in baths of salt than of plain water.

I think it right to mention one exception to the above results, in the case of a lad sixteen and a half years old; but he was in a wretchedly anæmic state, had previously suffered from effusion into both pleural cavities. Besides mitral insufficiency with stenosis, there is little doubt that there was adhesion between the heart and pericardium, and between the pericardium and pleura. In this single case the frequency of the pulse not only was not diminished, but was distinctly increased by the bath. Even this single case is sufficient to show, that the operation of the bath on the pulse should be carefully observed when it is first used.

As regards the next point, or the disappearance of joint-exudations, the efficacy of the waters was proved over and over again; but I must say that this was displayed far more in cases of recent acute attacks, than in the chronic form of arthritis deformans.

In the first class of cases, the exudations often disappear after a few days; and this is a most striking effect of the Nauheim waters. The general treatment is, the use of baths of 88° to 93° temperature, and the daily drinking of fifteen to twenty-four ounces of the diluted Kurbrunnen. It may be said that such recent cases get well of themselves, but they undoubtedly do so much faster under this treatment. Perhaps the greatest virtue of the Nauheim treatment consists in its preventing in a great measure the occurrence of relapses. Of this I am able to speak positively from the experience of many years in particular cases. On the whole, the treatment appears to diminish the susceptibility to catch cold, and patients indicate this by frequently remarking that 'their skin has grown stronger.'

I must, however, say, that as I consider that the alteration of the constitution of the blood is a material part of the treatment, I endeavour to maintain it in patients after they have returned home. I recommend the diminished use of albuminates, the exclusion of eggs, a large consumption of fresh vegetables and of light wine, and I make the patient drink every morning six or eight ounces of a solution of about 1 per cent. of common salt. I thus diminish the amount of albumen and of phosphates in the blood, and increase the alkaliescence of the serum of the blood. The patient must guard against sudden exposure to cold. With such aids he is pretty secure from relapses.

A fourth point to which I would draw attention, is the continued improvement of the circulation and the great amelioration of the general condition, which follow bath-treatment; no doubt such results occur without any bath-treatment. But I do not think I am mistaken in believing that the latter treatment has special advantages, and I could enumerate a whole list of patients whose continued improvement could not have been effected by any other mode of practice known up to the present date.

A fifth point, to which I alluded slightly in my pamphlet, I can now affirm more positively. This is the disappearance of recent endocarditic effusions on the valves of the heart, as a consequence of bath-treatment. I have only had three such recent cases. But the general condition has been wonderfully improved in all; and in one, a girl, the heart-affection seems to be almost entirely removed. On the whole, I am of opinion, that rheumatic patients, in whom heart-disease has been developed, cannot be sent too early to Nauheim.

* *Berliner Klinische Wochenschrift*, nos. 9 and 10.

I have only a few words more to say as to the diet of patients. It is so important that, although I have shortly alluded to it above, I must return to the subject.

One mode of dietetic treatment is by no means applicable to all cases of rheumatism. In it, as in other constitutional diseases there is much variety in the constitution of the blood and of the humours. The appearance itself of the patients would imply this. While one class are pale, another are of a fresh healthy hue. One set are lean and haggard, while another are well nourished and even fat. Nevertheless a few general changes, which have been made out, occur in most rheumatic patients. These deviations consist in a relatively small amount of water, and relatively too great amount of nitrogenous compounds, on the one hand, and, on the other hand, in a relative poverty in alkaline bases, especially in potash, and, as a consequence of this, in an excess of free acids, organic and inorganic. Granting these principles, it follows, as a pretty general rule, that rheumatic patients should consume but a small amount of nitrogenous or of albuminous food, and eat fresh vegetables rich in potash salts. But, as by the deprivation of animal food the patient loses a certain amount of stimulation, I allow him some light wine and black tea. Patients who are not fat may drink beer; but they must not use Liebig's meat-extract, on account of its richness in phosphates. I must observe that the great majority of sufferers from heart-complaint bear well small doses of beer or wine. When this is not the case, I use the gentle stimulus of small doses of quinine. But, although these are the general principles in dieting rheumatic patients, they have to be constantly modified, according to individual peculiarities. For instance, in the case of rheumatic children of scrofulous constitution, large quantities of meat are a necessity, as well as fresh vegetables.

It is high time that some such principles should be applied to the treatment of rheumatism, so as to place it on a more rational footing, and that this regulated diet should not be confined merely to the period of a bath-cure.

Still more necessary is such systematic regulation of diet in chronic forms of rheumatism, and especially in arthritis deformans. The general principles laid down above apply to it also. But there are marked differences between it and simple acute arthritic rheumatism. In it the nervous system is more deeply engaged than in the other. The general want of power of resistance, the great irritability of temper, the tendency to get sudden acute attacks of local inflammation, the extreme sensibility to changes of atmospheric pressure or of temperature, all distinguish it from the other form; I regret that we have no more precise knowledge of the nature of the affection of the nervous system in it. But it is certain that patients of this class, undergoing bath treatment, require baths of the higher temperature of 97° to 100°. It is also certain that the chloride of sodium waters are of much less importance in the treatment of this form than of the sequelæ of the acute forms of rheumatism. It is also almost always the case that arthritis deformans requires tonic as well as alterative treatment. That here, too, a deficiency of potash in the fluids plays a great part in the causation of the disease, I have no doubt. The deposits of uric acid in the joints, and the sediments of uric acid and of urates in the urine, seem to point

to something more than a mere pathological excess of uric acid in the system. But how much have we still to learn concerning this and other constitutional affections!

J. MACPHERSON, M.D.

ANATOMY AND PHYSIOLOGY.

RANSOME ON THE GRAPHICAL REPRESENTATION OF THE MOVEMENTS OF THE CHEST-WALL IN RESPIRATION, AND ON THE POSITION OF THE HEART'S IMPULSE IN DIFFERENT POSTURES OF THE BODY.—In this paper, Dr. A. Ransome describes and comments on the tracings of the movements of the ends of the ribs in respiration.

To take these tracings he has constructed a stethograph. This consists of a lever of the first order, connected at one end by a ball-and-socket joint with a pad. This fits upon the rib; at the other is a marking-pencil. The fulcrum is a pin, passing through the centre of the lever, fixing it to a vertical frame, so that its only movement is up and down. The vertical frame itself fits into another, so that it can move backwards and forwards. To this second frame is attached the writing-frame, against which the point of the pencil presses lightly. This apparatus is lodged by a pivot on a stand, allowing free rotatory movement. Thus the pad is kept in position against the rib, and forward and upward movements and the reverse are traced by the point of the pencil.

The tracings show what was before gathered from observations with the three-plane stethometer: that the forward is the most regular movement; that in man the upward movement takes place chiefly towards the end of inspiration, this irregularity being much less in women and children.

Moreover, the rib does not descend in the same course as it ascends, the tracing of the end of a rib forming a more or less irregular figure inclosing a space. Hence Dr. Ransome argues that the rib does not move as a rigid body, but that its chord-length is altered by the contraction of the respiratory muscles.

He finds that the relation of the upward and forward movements can be voluntarily altered to such an extent as to leave small doubt of the bending of the rib.

Interesting variations in coughing and sneezing are given; and others, taken during disease, make it probable that such tracings will be of considerable pathological importance.

Dr. Ransome, in his paper on the position of the heart's impulse in different postures of the body, takes the measurements of Mr. W. A. Patchett on fifty-one patients.

A full table is given of each case, the length of the sternum, the position of the nipple, with regard to two ordinates, one the central line of the sternum, and the other a line at right angles to this; the position of the maximum impulse of the heart-beat with regard to the same two ordinates in four positions of the body, viz., on the back, upright, on the left side, on the right side.

Various other particulars are also given, as age and disease of the patients.

From the table Dr. Ransome draws the conclusion, that the position of the heart's impulse-site with regard to the nipple varies considerably, thus from immediately under it to one and a half nearer the median line.

It may be noticed that the length of the sternum has no constant relation to the size of the other parts of the thorax, nor have the mammæ a constant relative position.

The impulse-site varies considerably with different postures of the body.

The difference in its position is greater in the change of posture from side to side than from up-right to lying down.

In many cases the latter change made no difference in the level; in some the level fell on standing up; this was apparently unaffected by the size of the individual. As a rule the impulse-site moved slightly to the left on rising.

The mean extent of its movement along the ordinate at right angles to the sternum, in changing position from the right to the left side, in the thirty-nine cases observed, was three inches and three quarters; the maximum was five inches and three quarters; the minimum two inches.

In the majority of cases this movement increased in degree with the length of the sternum.

J. N. LANGLEY.

MUSCULUS AND DE MERMÉ ON A NEW BODY FOUND IN THE URINE AFTER THE INGESTION OF CHLORAL HYDRATE.—MM. Musculus and De Mermé (*Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences*, no. 14, April 12, 1875) state that foreign substances introduced into the human organism are rejected in states which may be divided into three groups. 1. Bodies which pass unaltered through the system, such as creatin, acetamid, etc., and are found unchanged in the urine. 2. Bodies which are decomposed, and whose decomposition products are found in the blood, the saliva, and the urine, such as leucin and glycocoll, which yield urea. 3. Bodies which combine chemically with some product of the organism, and thus pass into the urine. The type of this group is benzoic acid, which combines with glycocoll, and is eliminated as hippuric acid. In the urine of dogs poisoned with chloral hydrate, Feltz and Ritter have recently discovered chloral, sugar, and another organic substance precipitable by the basic acetate of lead. It is an acid which forms stellar groups of crystals resembling those of tyrosin, and containing carbon, 31.60; hydrogen, 4.36; chlorine, 26.70. It is not expelled from its salts by acetic acid. At the boiling point it reduces alkaline solutions of copper and bismuth, and salts of silver, and decolorises sulphate of indigo. It turns the plane of polarisation to the left. The authors hold that chloral should rank in the third group with benzoic acid, and propose for the acid found the provisional name of urochloralic.

PATHOLOGY.

DURET ON THE CIRCULATION OF THE BRAIN.—M. Duret (*Archives de Physiologie Normale et Pathologique*, Nov. and Dec., 1874,) writes to the following effect.

It may be seen at once, without having recourse to the microscope, what are those affections of the brain in which we find softening of the hemisphere over a space of greater or less extent, but in which it is impossible to establish its precise relation to a known arterial region. Certain soft gliomata of the brain present the same kind of independence. Some

softenings are found to be absolutely limited to the ganglia of the cerebrum—the corpora striata or the optic thalami; others, and these in greater number, affect the convolutions and the subjacent white substance. Softening of the cerebral peduncles, of the pons, of the medulla oblongata and cerebellum is made a subject of especial study.

Softening of the Corpus Striatum.—All the nutrient arteries of the corpus striatum take their origin from the first three continuations of the Sylvian artery, and ascend perpendicularly into its substance. They form no anastomoses with arteries of the peripheral regions, and it is this circumstance which leads one *à priori* to imagine the existence of softening involving only the whole of the corpus striatum. On the other hand, each of the arteries of this body communicates but very imperfectly with its neighbour (which is limited to the external part of this body), and in reference to this peculiarity, the author points to softenings which affect only certain portions of the corpus striatum.

But a difficulty presents itself; how can softening affect the whole of the corpus striatum, without involving the convolutions to which the branches of the Sylvian artery are distributed? Two hypotheses may be possible; either the embolism, situated at the superior wall of the trunk of the Sylvian artery, at the point where it gives off the arteries of the corpus striatum, obliterates them, and allows a sufficient quantity of blood to pass for the nutrition of the convolutions; or the peripheral anastomoses of the Sylvian artery suffice to restore the current of blood.

According to the author's investigations, the peripheral anastomoses of the convolutions are incapable of fulfilling this function, unless they have already been progressively dilated; moreover, numerous observations have shown that, if the plug of embolism be situated beyond the arteries of the corpus striatum, the cortical region of the Sylvian artery is the seat of a well-marked softening. The first hypothesis, therefore, is the only one that is admissible. Sometimes at the necropsy there is found an old plug, above which there has formed, during the last moments of life, a recent deposit of blood which has completed the obliteration of the calibre of the artery, but has had no influence over the extent of the softened region.

MM. Prévost and Cotard have reported the following case. In the right hemisphere there was an area of softening about the size of a large nut, and occupying the whole thickness of the corpus striatum, except a small portion anteriorly; on the outer side this softening extended as far as the grey substance of the convolutions of the insula, which was unaffected; and behind, it extended beyond the level of the anterior border of the optic thalamus, which was also healthy. The clot extended as far as the divisions of the Sylvian artery, adhering to its wall, but having a certain friability.

It is not uncommon to find the corpus striatum the seat of a softening, which involves at the same time the convolutions which are nourished by the Sylvian artery; in such cases there is complete obliteration of this artery.

Optic Thalamus.—This body is very often the seat of empty spaces, or cavities, which are due to obliterations by small embolisms of the very small thromboses of the branches supplied by the choroidean arteries, or the terminal branches of the ophthalmic arteries.

Cerebral Ventricles.—In these cavities many kinds of softening are found. 1. Hollow places and yellow patches, or little areas of softening. They occupy either the corpus striatum, the optic thalamus, or the roof of the corpus callosum. They are produced by obliteration of either the small arterial branches in the neighbourhood of the ventricular walls, the terminal branches of the arteries of the corpus striatum and of the optic thalamus, the perforating branches of the choroidean arteries, or branches of the artery of the corpus callosum, or of the pillars of the fornix.

2. Complete softening of the walls of the ventricles, of the roof of the corpus callosum, of the fornix, commissures, etc. The vessels which supply the ventricular walls are ramifications of the choroidean arteries. These arise from the Sylvian and from the posterior cerebral. It is not, therefore, surprising to find them obliterated by a meningeal exudation or by a mass of tubercular granulations which surround the origin of the Sylvian or the posterior cerebral arteries.

J. LOCKHART CLARKE, M.D.

BRYAN ON A CASE OF UNILATERAL SWEATING OF THE HEAD.—Some cases of unilateral hyperidrosis are quoted by M. Vulpian, in reference to the influence of the nervous system on the sudoriparous glands, in the section of his *Studies on the Physiological Action of Toxic and Medicinal Substances*, published in the LONDON MEDICAL RECORD for June 23.

The case of a similar character communicated by Dr. Alonzo Bryan to the *Clinic* of June 5 is interesting as a further contribution to the study of the physiological problem enlarged upon by M. Vulpian. Dr. Bryan prefaces his case by the following remarks.

Only a few cases of unilateral sweating of the head have been observed, and, it appears, not with the care which their rareness would seem to demand. Dr. Bartholow, I believe, has reported several instances of the affection to the New York Neurological Society. The affection in question is generally regarded as being due to a pathological state of the thoracic or cervical portion of the sympathetic nerve. Intrathoracic tumours (aneurism, etc.), from the pressure which they may make upon the sympathetic, have been supposed to play an important part in the production of this affection.

The original notes of the case which I present were made nearly a year ago; and I draw from them as follows.

June 27, 1874.—Mrs. M. J. C. has unilateral sweating of the head. To day I saw her, when the temperature of the room was 92° Fahr. The parts of the head and face to the right of the median line were sweating freely. The parts to the left were ordinarily moist, as is the skin during a state of common insensible perspiration. The temperature of the right and left temples differed to the extent of 1½° Fahr., under the following circumstances: A good medical thermometer was pressed upon the left temple a little back of the external angle of the eye (by applying over the bulb of the instrument, for the purpose of excluding the atmosphere, very thick folds of woollen flannel), and the temperature was found to be 98½° Fahr. At the corresponding spot on the opposite or sweating side the temperature was 97¼°. When the bulb was not covered in by flannel in the still atmosphere the relative dif-

ference of temperature was the same. The temperature at the bend of each elbow, with the arm flexed so as to cover in the bulb of the thermometer, was on each side alike, 99½° (the person had been taking active exercise). Within the mouth, on both sides, the temperature was uniform, exactly 100°. The touch, sensibility, and motility were uniform and perfect. The two radial pulses were alike; when the patient was sitting against the back of a common chair eighty-eight pulsations in the minute. The sudoriferous glands only were more active on the one side. The sweating extended very slightly to the left of the median line of the mouth and chin; but the median line of the forehead and nose was an exact line of demarcation. The difference of sweating did not extend below the head and face.

Only two pathological states could be ascertained to exist—unilateral neuralgia of the face and head, and psoriasis; the latter occurring in spots on the head and extremities. Contrary to what I had expected, the neuralgia was upon the right side, *i.e.*, the sweating side. This latter point, to my surprise, I recently ascertained. I presume that in this case the functions of the affected sympathetic filaments are rather exalted instead of being depressed. It should be observed, though, that the transudation of perspiration seemed to be held in abeyance on the side unaffected with neuralgia. On the neuralgic side the degree of perspiration seemed to be that which ought normally to have been excited by the temperature to which the person was subject at the time of the examination.

The psoriasis may have been due to nervous influence also.

It may be observed in this case that only one vital action seemed to be interfered with: the transudation of perspiration. Touch, sensibility, and motility were uniform and perfect upon the two sides. The special senses were perfect. The chemical and organic changes in the tissues did not seem to be retarded or hastened, as the temperature within the mouth was the same on either side, 100°. The difference of temperature of the two sides, externally, was doubtless owing to the difference of the cutaneous evaporation.

MEDICINE.

SOUPLIER ON A CASE OF HEMIANÆSTHESIA, WITH CROSSED PARALYSIS.—Dr. Soulier records the following case (*Journal Médical de Lyon*, May 30, 1875).

C. L., a dyer, aged forty-three, had during his early life enjoyed average health, free from any morbid hereditary predisposition; his family history was good, and himself of temperate habits, and free from syphilitic disease. The origin of his malady dates back to 1856, when, being in military service, he suffered from a fall of his horse, under which he lay stunned. On his being released, it was found, on the return of consciousness, that the limbs on the left side, and the right side of his face, were paralysed. The insensibility had lasted two days. There was a depression on the right temple, inability to speak, and strabismus with diplopia of the right eye. The left half of the body had lost its sensibility. Crossed paralysis (*paralysie alterne*) declared itself gradually during the first fifteen days, then remained stationary for four months. The patient was then sent to Bourbonne-les-Bains, where

he remained until September of 1856. By the use of these waters his condition so far improved that, at the end of about ten months, he could walk without support. He remained thus until September, 1873, engaged in various employments.

In the autumn of each year he suffered from attacks of the head, giddiness, and stiffness of the left side, lasting for about ten minutes at a time. From 1865 his memory began to fail; and then his mind became so confused that he could not attend to any business. In 1873, however, these last symptoms passed away. At the time of his admission into the hospital, March, 1873, he was the subject of malaise, vertigo, etc.; he had facial paralysis on the right side, and diminution of muscular power on the left side of the body. The saliva ran from the right side of his mouth. In September of the same year he suffered another attack, which augmented all the previous symptoms. In October, 1874, his general health was good; but the facial paralysis was persistent, as was also the impairment of the muscular power on the left side.

The most striking symptoms were those furnished by the cutaneous tactile sensibility, which was but slightly diminished on the left side, whilst there was complete anaesthesia as to pain or heat, both of the skin and of the mucous membranes, conjunctival, nasal, buccal, lingual, etc. This anaesthesia ceased exactly at the middle line of the body, except on the cornea of the left eye, which retained its sensibility, owing to its special innervation.

Electrical sensibility was diminished on the left side. The senses of taste and smell were lost on the left side of the tongue. Sight was impaired on the right side; the pupils were equal; there was almost total loss of accommodation in the two eyes, but there was no change perceptible in the interior of the globe of the eye. Hearing remained unimpaired. Subjectively, the patient experienced sensations of cold with changes of weather, and gyratory vertigo on lying down to sleep at night and on waking in the morning.

All these symptoms, observes M. Soulier, point to a lesion of the right side of the pons, and give rise to reflections upon the great question of the day, viz., the localisation of cerebral lesions. If we trace in their ascending course the fibres which constitute the peduncles of the brain, we observe them leaving within and behind them the optic laminae, spreading out and forming on each side between the two centres of the corpora striata the 'double semicircular centre' of Vieussens, the 'internal capsule' of Burdach; then disengaged from the two grey nuclei of the corpora striata, the fibres of these laminae spread out in all directions, forming the 'couronne rayonnante' of Reil. The point then affected in these cases of permanent hemi-anaesthesia, of cerebral origin, is the posterior and superior portion of the internal capsule, *i.e.*, the foot of the 'radiating crown.'

Moreover, it is an important fact, that M. Veysière produced the same condition of anaesthesia by the injection of a destructive fluid into the part under consideration. This point of localisation is evidently not a centre; it is a strait, a pedicle through which the centripetal fibres of special and general sensibility pass. The knowledge of this fact may serve as a guide in our researches after the centres of sensibility.

The phenomena in the case now related, M. Soulier adds, lend countenance to the theory of M. Vulpian, which places the centre of sensitive impressions in the

pons and the peduncles. Certain structural conditions may ultimately explain the ordinary seat of the lesion of hemi-anaesthesia; but, since the conducting fibres are implicated, it may be imagined that there may be injury to another point also. The insensibility to pain and heat, while the tactile sensibility remained perfect, had an hysterical aspect. The simultaneous existence of paralysis of taste and smell was in accordance with the views of Brillat-Savarin, to the effect that these two senses are fundamentally one; the decussation then of the olfactory nerves is thus both possible and probable.

W. B. KESTEVEN, M.D.

MILLIKEN ON DROPSY.—In the *Cincinnati Lancet and Observer*, for June, Dr. D. Milliken writes:—Dropsy may be defined: A morbid extravasation or transudation of water from the blood, with more or less of the constituents of blood-serum, into the cavities and areolar tissue of the body. This morbid transudation might occur in two conceivable ways: that is, either by reason of a morbid permeability of the vessel-walls; or, on the other hand, by reason of a morbid change in the blood, whereby its natural power or tendency to permeate the vessel-walls is exalted. Of such a morbid change in the vessels nothing is positively known, though it has been asserted that paresis of the capillaries is an invariable precedent event in every dropsy, general or local. But it is very certainly known that morbid changes in the blood bring about the dropsical effusion, and with these we have now to do.

There are two highly distinct abnormal conditions of the blood—one physical, the other chemical, and both tending to dropsy. The blood is liable to an increase of tension in the veins and capillaries; or it is, in the second place, liable to a change of chemical composition.

Abnormal tension of the blood, in a degree sufficient to produce general dropsy, is found only in the veins. The chemical changes in the blood which may cause dropsy result in hydræmia, which term, well defined by its etymology, signifies a watery state of the blood. Now, since the amount of water in the blood-vessels can be very rapidly diminished by drainage through the kidneys, a watery state of the blood would be promptly corrected if it depended on an actual increase of water. The fact is that the increase of water in the blood in hydræmia is not actual, but relative to the amount of solids, and the condition is brought about by the loss of some portion of these solid elements.

After describing the pathology of different forms of dropsy, and giving the most successful plan of tonics and chalybeates, he says: 'While studying the connection of dry and cardiac maladies, it is difficult to suppress a regret that the serum is forced through the capillaries by venous congestion. If the pressure were brought to bear from the arteries, we could easily diminish the vigour of the action of the heart by a selection from the great armoury of sedatives. But, as it is, and since the heart is behindhand with its work in every case, we are compelled to stimulate, and unfortunately the available heart-stimulants are few in number and hard to manage. The ethers and some other stimulants may answer in brief emergencies, but when it is desired to whip up the heart for a long time, we are reduced practically to one medicine—digitalis, "the heart-tonic."

'What is the probable mode of death of dropsical patients, and how shall we treat the crisis? Leaving

out of view a great number who die by asthenia, worn out rather than killed, we observe that nearly all of the remainder perish by the extension of the dropsy to vital organs. They are "drowned in their own fluids." In other words, they die of oedema of the brain or lungs. Treatment in these cases depends very much upon the cause of the dropsy. If hydræmia exists, little more can be done than to give vigour to the heart's action, and favour the brain by position when the brain is involved. It is recommended, also, to ligate the lower extremities and make them reservoirs of blood and serum for the time. If the dropsy is caused only by cardiac disease, and the blood remains of fair quality, we may boldly set to work to diminish the volume of the blood by active purgation, or even by venesection. We may in any case attempt this by diaphoresis and diuresis. If there exist a large collection in the abdomen, so large as to interfere with the play of the diaphragm, and consequently to interfere with the free return of blood from the brain, tapping will relieve the heart and lungs from pressure. The same procedure is of course proper in threatened oedema of the lungs. May we bleed patients who are absolutely dying from pulmonary oedema? We may, even when their blood is impoverished and watery. The operation in such a case is the forlornest sort of a forlorn hope. It should be done when there is not the shadow of a chance of recovery without the venesection, and with the understanding that there is not the ghost of a chance of recovery from a second attack after the venesection.'

ROGERS ON MILK DIET IN TYPHOID FEVER.—Dr. L. R. Rogers, of Albany, sends to the *New York Medical Record* the following account of his management of a severe case of typhoid fever on the milk-diet principle.

'The point to which I wish to call attention is the diet part of the treatment. As soon as I felt sure that the patient was to have a regular "run" of fever, I commenced to give milk—fresh, raw, cow's milk, from one cow, and not more than twelve hours' old at any time. I gave, during the height of the disease, from one and one half to two quarts per day; every hour at first, then every half hour, and for over two weeks every quarter hour, without any water or other food, except a few times when I tried beef-tea and other dietary preparations. The latter, in every instance, raised the pulse and fever, and thickened the fur on the tongue. The patient's bowels gave no trouble, moving by injections once in four or five days, the dejections like those of an infant. Quinine and stimulants made her worse every time when tried, and the severe pain in the back and limbs, which came on every day about 6 P.M., was quieted in ten or fifteen minutes by a mild current of Faradic electricity from the back of the neck to the sacrum or feet, which was continued twenty or thirty minutes.

'This treatment I used for thirty-two consecutive days, giving each time a good night's rest, free from pain, without anything in the shape of opiates. I had the best counsel the county afforded, and the case was considered by all who saw it one of the most severe.

'Small doses of the sulphite of soda were all the medicine she took that did not disagree, and I gave this simply to prevent decomposition in the milk.

'There were many fatal cases in the epidemic, but all who bore milk well recovered. In this case, al-

though she had the nourishment in one and one half to two quarts of the best milk, she continued to get weaker and weaker for over four weeks, which shows very plainly that any other diet would have failed to meet the emergency.

'Milk contains all that is needed to nourish and keep up every part of the system, nearly, and is always the same; while our best dietary mixtures are wanting in many things needed by the economy, and cannot be made twice alike. I have since that time used milk very freely in all stages of various diseases, and have had reason to be well satisfied with it as the best diet, for both adults and children.

'I do not put forth this case as one to copy from in the particular treatment, but simply to show that the best article of diet the world contains, either in disease or in convalescence, and one always obtainable, is too often neglected, and complex dietary compounds used instead. The patient in this instance was confined to the house over eight weeks, and made an excellent recovery. She was thirty-six when it occurred, and is now forty-three, and has never been sick since.'

MINICH ON A CASE OF PURPURA HÆMORRHAGICA IN A CHILD SUCCESSFULLY TREATED BY THE HYPODERMIC INJECTION OF ERGOTIN.—Dr. Andrew K. Minich (*Philadelphia Medical Journal*, May 8) gives an account of a severe case of purpura hæmorrhagica, in a boy seven years old, successfully treated by the hypodermic injection of ergotin in grain doses. Four hours after the first injection the vomiting of blood had entirely ceased, there being only oozing of blood from one nostril. Two more injections were subsequently given, and half-drachm doses of the fluid extract of ergot, with sulphuric acid and opium, every two hours. The child was convalescent, without relapse, on the seventh day. Dr. Minich regards purpura, in its various forms, as separated from scurvy by a broad line of distinction. Arguing from the effects of ergotin in purpura hæmorrhagica, and the physiological action of the drug in producing contraction of the blood-vessels, as shown by experiments on animals and ophthalmoscopic observation of the retinal vessels, Dr. Minich suggests that purpura hæmorrhagica may be a neurosis, *i.e.* a vaso-motor paralysis. This would explain why ergot, which causes vaso-motor spasm, should cure the disease. [The fact that the artificial production of vaso-motor paralysis by section of the sympathetic is not followed by hæmorrhage from the dilated vessels, shows conclusively that this condition alone is not sufficient to account for purpuric extravasation. Even if vaso-motor paralysis be one of the factors concerned in its production, there must be others in addition, such as changes in the vascular wall or in the circulating fluid. If the power of ergot to abate purpuric hæmorrhage should be established, its styptic effect, by causing vascular contraction, would be perfectly intelligible without supposing pre-existing paralytic dilatation.—*Rep.*]

SURGERY.

HAKENSCHMID ON STRANGULATED HERNIA WITH PERFORATION.—Dr. Carl Hakenschmid reports a case in which recovery followed perforation of a small strangulated hernia (*Medicinisches Centralblatt*, no. 21, 1875). The patient was a woman, aged thirty-six years, who, for some time before the attack of strangulation, had noticed a small painless and irreducible swelling in the right groin. This had been regarded as an enlarged gland, and treated accordingly. Four years ago the woman was suddenly seized with pain in the abdomen, and became sick and feverish, the bowels at the same time being constipated. Dr. Hakenschmid, on examination of the right groin, found the skin over the swelling somewhat reddened, and the swelling itself painful, and on percussion, quite tympanic. Reduction could not be effected through manipulation. On the following day the symptoms were much more severe; the patient was delirious, and suffered much from abdominal pain and tympanites; there were profuse stercoraceous vomiting with hiccough, coldness of the extremities, and a thready and almost imperceptible pulse. Herniotomy was then performed. After the superficial structures had been divided, a dark-coloured gland was observed, and next, under this, a small congested hernial sac which contained about two drachms of brown and turbid fluid, and a strangulated loop of intestine, about the size of a cherry. The surface of the strangulated intestine was of a very dark colour, and had lost its polish. After division of a tight stricture, there was a sudden discharge of about three ounces of fecal fluid from the orifice of the sac. The upper portion of the wound in the skin was brought together by sutures, and the lower half left open and covered by charpie and a tightly round compress. When next seen, eight hours after the operation, the patient was much better, the bowels having been relieved, and the abdominal pain much diminished. On the fourteenth day, the wound had healed along its upper half, whilst the lower half had contracted to a small fistulous opening, from which there was a constant discharge of fecal fluid. Eight days later the whole wound had closed, but two days afterwards a painful red swelling was suddenly formed in the region of the scar. This soon burst and discharged fecal fluid. The discharge ceased in the course of a few days, and the opening then became permanently closed. During the past four years the parts at the seat of operation have remained quite sound, and the woman, whose diet has consisted mainly of fluid and easily digested articles of food, has not suffered from any affection more severe than an occasional attack of colic.

ENGLISCH ON PLUGGING OF THE NOSTRILS.—At a recent sitting of the Medicinische Doctoren-Collegium of Vienna, Dr. Englisch exhibited an apparatus for plugging the nostrils (*Allgemeine Wiener Medicinische Zeitung*, 1875, p. 191). This

is an improved form of Kuchenmeister's rhineuryntor, which consists in a caoutchouc tube about twenty centimètres in length, provided at one extremity with an elastic ball one centimètre and a quarter in length and one centimètre and a half in breadth. The tube and the empty and collapsed ball are to be passed into the nostril on a conductor, and the latter pushed far backwards into the pharyngo-nasal cavity. The ball, having been distended by injected water, is pulled forwards by traction in the tube, so as to occupy the posterior part of the nostril in the same manner as the plug of lint or charpie applied in the ordinary way of Belloc's instrument. The use of this apparatus has not always been attended with success, and the failure is thus explained by Dr. Englisch. The ball, which becomes quite round when distended by water, does not press equally on all parts of the walls surrounding the posterior orifice of the nostril, and interspaces are left through which there is a free flow of blood. In order that this posterior orifice may be completely closed, it is necessary that the plug press equally on all parts of the surrounding walls. This the ball of Kuchenmeister's instrument does not effect; and it is stated, as a further objection to its use, that there is a tendency for it to fall backwards into the pharyngeal cavity. The apparatus devised by Dr. Englisch consists of two caoutchouc balls mounted by a piece of elastic tubing. To the lower extremity of the lower or anterior ball is fixed a second piece of tubing, through which water may be injected. The upper ball is intended to be pushed to the back part of the nostril, so as to act as a posterior plug. The lower ball remains at the external nasal orifice, and completely closes that when water has been injected. The tube connecting the two balls is short, so that the posterior plug cannot project far beyond the margins of the posterior orifice of the nasal cavity. Dr. Englisch insists on the coats of this connecting tube being made of some firm and tough though flexible material. The posterior ball is flask-shaped, and its walls are thicker than those of the anterior or lower ball. Dr. Englisch states that the introduction of this apparatus is not attended with any difficulty.

JURIÉ ON THE ENDOSCOPE.—In a paper read before the Gesellschaft der Aerzte of Vienna, and reported in the *Allgemeine Wiener Medicinische Zeitung*, p. 192, Dr. Jurié endeavours to show that the endoscope, although not to be rejected altogether as an useless instrument, has hitherto failed to do such service as was at first expected from it. He states that it is difficult, if not impossible, to examine with the endoscope every portion of the urethra, and that he has never been able to obtain a sight of the caput gallinæ. It is equally difficult, whether with a straight or a curved instrument, to see every part of the inner surface of the bladder. In cases of disease of the bladder an examination of the mucous surface may be rendered impossible by turbidness of the urine. It is evident that the endoscope can do no service in cases of acute inflammatory affections of the bladder or urethra, since under such conditions the introduction of any instrument would hardly be justifiable. In those rare cases of valvular fold at the neck of the bladder causing impeded and difficult micturition, the endoscope can give little if any help in the diagnosis, as the fold is pushed backwards by the point of the instrument so as to be closely in contact with the inner surface of the bladder. Foreign bodies in

the bladder are not in all cases to be discovered, even on close and skilful endoscopic examination. According to the author, the size, form, and situation of an impacted foreign body can always be well made out by placing a strong light behind the slightly transparent penis. In cases of stricture the endoscope can afford but very little help; the anterior surface of the stricture may indeed be seen; no lumen, however, is to be observed, but merely folds of mucous membrane, the arrangement of which might possibly indicate the point for the introduction of a small catheter or sound.

The endoscope is of real service in the treatment of chronic inflammation, ulceration, and a granular condition of the mucous membrane of the urethra, when it is necessary to apply to the affected spot some caustic agent which it would be prejudicial to bring into contact with the whole urethral surface. In cases of disease of the prostate, the introduction of the endoscope is very difficult, and no good can be derived from it. One cannot diagnose papillomatous and cancerous growths of the bladder by means of the endoscope, as the introduction of this or of any other instrument causes hæmorrhage and turbidity of urine.

DOUTRELEPONT ON SALIVARY CALCULUS.—In a report of the last meeting of the Niederrheinische Gesellschaft, held at Bonn (*Berliner Klinische Wochenschrift*, no. 23, 1875), is a case recorded by Professor Doutrelepon, in which two salivary calculi were removed from the Whartonian duct, the most frequent seat of such bodies.

The patient, who was a woman aged forty-six, came under the notice of the author on December 9 of last year, with a large hard swelling under the tongue on the left side. This had been observed for fourteen months, had increased rapidly in size, and had given much pain. The submaxillary gland was neither painful nor swollen. The duct having been slit up a calculus was removed, which was 0.32 inch in length, 0.2 inch in breadth, and 0.16 inch in thickness. No other calculus could be felt at the time of the operation; but six days later the patient again applied, with the statement that the whole of the calculus had not been removed, and then a second body was found and removed from the same duct. This calculus was 0.48 inch in length, 0.24 inch in breadth, and 0.16 inch in thickness. It was olive shaped, and at its anterior extremity had a facette corresponding in form and size to one at the posterior extremity of the first and smaller calculus. Each calculus was found, on section, to be made up of yellowish-grey strata surrounding a white nucleus. In neither stone was any foreign body constituting a nucleus to be discerned, or any fine canal. The following is the statement of the chemical analysis of these calculi.

Soluble in water	{ Organic material	0.19
	{ Chloride of sodium	0.06
Soluble in hydrochloric acid	{ Tribasic phosphate of lime	81.65
	{ Carbonate of lime	12.60
{ Traces of iron, magnesia, soda.		
Organic material insoluble in hydrochloric acid, together with traces of silicates		5.02

MATERIA MEDICA AND THERAPEUTICS.

DAUVERGE ON THE EFFECTS OF DIETETICS.—In the *Bulletin Général de Thérapeutique*, March 30, 1875, Dr. Dauverge (père), continues to speak of some of the effects and results of dietetics. He alludes to a recent article by Professor Bouchardat, which concluded, 'As they advance in life, young practitioners will find, like myself, that pharmaceutics do not fulfil all their promises, and they very frequently return to the employment of well-directed hygienic modifications. Such is the history of all reflecting and observant practitioners.' In illustration of this, he gives what he terms a most remarkable and illustrative case. A lady, aged about fifty, delicate and nervous, already long past the menopause, suffered for six months from intermittent pains in the left hypochondrium, the pain being sometimes insupportable. The patient was pale, cold, the pulse small and corded, and the suffering intense. On exploring the abdomen, a fulness was found filling the right hypochondrium, but without much sensibility to pressure. Was it tumour or spasm? Inclining to the latter belief, a calmative was administered, and the pain ceased. The attendant, with good intentions, gave without permission a copious allowance of soup. In the night, the pains returned more urgently than ever. By diet and the continuation of the calmative mixture she again was relieved, and the diet was renewed in the form of light panada, with cream and rice. One night she was worse, and thought she was about to expire. Next day the lady was in a most pitiable condition. She complained of pain, acute and torturing, always at the same spot. The skin was cool, the pulse imperceptible, the eyes hollow, and the tongue dry, with a very bad taste in the mouth like fæces. On palpation of the right hypochondrium, a piece of bowel was found, probably the ascending colon, on which was a tumour either around or within the intestine. Cataplasms containing laudanum and belladonna were without effect, and cold water on a well-folded napkin was applied. Immediately there followed a deep inspiration, and the patient felt relieved. The application was continued, and some whey and carbonated water formed the diet. Under this treatment the pain became supportable, but returned from time to time. There was much weakness without fever, and feeding by the mouth brought back the pains; nutritive enemata were therefore employed. In a little time cream with corn-flour, etc., could again be taken, and in a year the patient assumed her ordinary diet. The fulness in the hypochondrium entirely disappeared. Other cases are given, as of a boy with enlargement of the mesenteric glands. After divers plans of treatment had failed, he was put upon a diet of white grapes, after which he recovered, and is now a robust peasant. In another case of jaundice, the patient was not yellow but orange-coloured. After six months of futile treatment, the patient was put upon a frugal dietary of water-melons, grapes, fresh figs, etc., without bread or soup. After two months and a half of this he was again white and well. Syphilitic ulceration of the palate, and a phagedenic bubo, had also yielded to an Arab diet.

A milk diet is especially suited to dropsies, either anasarca or ascites, and by perseverance in it even grave cases may be much relieved. In a case of

persistent vomiting, with heartburn, cold milk, cold soup, and fresh carbonated water procured a perfect cure. In a case of general anasarca, with continual drowsiness and dyspnoea, with confusion of ideas, milk, with purgatives and digitalis, produced most desirable effects. In a case of diarrhoea and sthenic bronchitis in a lady, most irritable and difficult to deal with, after a diet of milk and syrup of morphia failed to give relief, lentil-meal with milk was successful. In another case, where a condition of wandering, delirium, hot skin, with frequent pulse and high-coloured urine, followed typhoid fever, cold baths and abundant fluid with milk cleared the urine, and brought about perfect recovery. In typhoid cases, with hæmorrhage from the gums, intestines, or uterus, with feeble pulse and general prostration, wine may be added with advantage.

The dietetic treatment is in practice the most essential matter in many illnesses, and is that part of therapeutics which is most difficult to determine upon, and is a problem which presents itself in each and every malady. M. Jaccoud has declared that a milk-diet will work miracles. The relations of resolution and absorption to nutrition and assimilation are being very much better understood than they were, with good results in practice.

SMITH ON GRINDELIA ROBUSTA IN ASTHMA.—Dr. Q. C. Smith, of Cloverdale, California, writes to the *Pacific Medical Journal* as follows.

Several months since, at the suggestion of Dr. W. P. Gibbons, of Alameda, we procured a small package of the solid extract of grindelia robusta, with the intention of giving it a trial in the treatment of diseases of the respiratory organs. We have used the remedy in one case only, and that was a case of spasmodic asthma. We could detect no organic lesion, either in the lungs or in any other part of the patient's body.

Mr. M., the patient referred to, is thirty-seven years of age, tall, rather spare habit, with narrow chest; a stock-rancher by occupation. He had lived in California since he was eleven years of age; he was born in Missouri, and lived there prior to his emigration to this State. He had suffered from severe and frequent attacks of asthma since early childhood, for the relief of which he had taken many remedies, with little and only temporary and partial relief, never being entirely free from asthmatic symptoms. Much of the time he was unable to walk more than a few paces at a time without stopping to get breath. About five months since he commenced to take the extract of grindelia in pills; taking, when the attacks came on, two or three grains three times a day, for two or three days, then taking two or three grains at bedtime only, for eight or ten days longer.

Under this mode of treatment the attacks became lighter and more remote; and during the interval between the attacks he gained flesh and strength, and improved greatly in his general health.

More than two months has now passed since Mr. M. felt any symptoms of his old enemy, the plague and terror of his life: and now he is heavier and stronger than ever before in his life, and can climb the rugged mountains of his sheep-ranch and the surrounding country, looking after stock and hunting game, with an endurance, agility, and speed unsurpassed by any of his neighbours. We think this happy change due entirely to the virtues of the remedy mentioned, as our patient took no other me-

dicines and continued to follow the same employment, and was circumstanced just as he had been for years before. He thinks he is permanently cured; but we entertain serious doubts of it, although the remedy has already been of invaluable benefit to him. We know 'one swallow does not make a summer,' but only give this as our limited experience with what we hope will prove to be a valuable remedy.

J. MILNER FOTHERGILL, M.D.

GARNIER ON A DEATH FROM EATING STRAWBERRIES.—M. F. Garnier relates, in the *Lyon Medical* for June 20, that on the 8th instant he was sent for to see a girl who was reported to be dying. The patient, who was a strong and healthy girl aged fifteen, but of a lymphatic and nervous temperament, was lying insensible on her bed, in a state of complete prostration; her respiration was stertorous, her face pale and livid; the pulse depressed, excessively weak, small, and intermittent. She had eaten, at twelve o'clock, a bowl of strawberries without any addition of sugar, cream, etc. It was not known whether they had commenced to ferment at all, but M. Garnier believes that such must have been the case, from the considerable distension of the epigastrium. M. Garnier immediately administered two emetics at an interval of from twenty to thirty minutes, covered her with hot linen, to endeavour to get some warmth into her icy-cold body, whilst he kept the jaws apart by mechanical means, so as to make her forcibly swallow warm water; and tickled the uvula with a feather, but could only obtain a very trifling regurgitation of the strawberries. Finally, a profuse and viscous sweat broke out all over the body, and the girl expired, her illness having lasted but three hours. M. Garnier had the coffin opened twenty-four hours afterwards, and found most distinct evidences of cadaveric decomposition and an incredible distension of the stomach and abdomen.

M. Garnier states that it is not an isolated case in his practice. He has saved four patients by emetics, but has lost more than he has saved. He has arrived at the conclusion that, if not more than two hours have elapsed between the eating of the strawberries and medical treatment, emetics may be safely administered; but, if this space of time be exceeded, he believes this means to be more hurtful than useful. The emetic remains inert in a stomach thus distended, of which it can no longer provoke contractions, and perhaps only increases its distention. M. Garnier therefore thinks that in such circumstances it would be better to give a large dose of ammonia.

He takes the opportunity of giving some advice how to eat strawberries without injury to the health. He recommends persons who can eat this fruit in its natural condition with impunity not to eat many at a time, and is of opinion that a certain amount of sugar singularly facilitates their absorption and, still more, their digestion. The juice and scraped rind of a lemon mixed are sometimes useful for the same purpose, but generally this mixture, even if compounded with powdered sugar, does not agree with everyone. It is the same with strawberries and cream. M. Garnier thinks it better to sprinkle the strawberries with a good and strongly alcoholic wine. Debilitated stomachs should not venture on Bordeaux wine; Kirschenwasser, rum, or cognac being in his opinion preferable. His last recommendation is never to eat strawberries alone; they should always be accompanied by other food, which should precede them in the digestive tube. All that has been said

of strawberries applies with greater force to raspberries, which are still more indigestible; but is not true of cherries, currants, and gooseberries, inasmuch as in their case chemical decomposition is much slower.

DRASCHE ON SERRONIA JABORANDI.—The *Pharmaceutical Journal* for June 26 contains an account from the *Zeitschrift d. allgemeinen österreichischen Apotheker-Vereines*, of May, of a sitting of the Vienna Medical College, at which Professor Drasche described the results of numerous experiments on men and animals with 'Serronia Jaborandi.' Not only were an infusion and a tincture used, but also an alkaloid which Dr. Drasche alleges that he was the first to prepare, and to which he has given the name 'serronine.' Of this alkaloid he reports a yield of about one and a half grains from a drachm of Serronia Jaborandi leaves. All of these preparations caused profuse sweating and excretion of saliva, and induced striking physiological symptoms generally similar to those which have been attributed to the use of the jaborandi yielded by the genus *Pilocarpus*. But although at present the materials for forming a judgment are very meagre, it would appear probable that what Dr. Drasche terms 'Serronia Jaborandi,' and which he states to have been imported from Brazil through France, is yielded by a piperaceous plant; *Serronia jaborandi*, Guill., being a synonym of *Piper jaborandi*, Vell. The editor of the *Pharmaceutical Journal* has seen specimens of the leaves that were imported into France, and is of opinion that, although they present characters showing they have not been derived from *Piper jaborandi*, they certainly have been yielded by an allied species. This similarity of name and all that is said concerning the source from which Professor Drasche obtained his supply, would seem to indicate that he experimented with the leaves of a species of *Piper*. Whether, however, the alkaloid is identical with that known under the name of jaborandine, or whether another powerful medicinal agent has been placed at the service of medical men, can only be decided by the aid of fuller information.

OBSTETRICS AND GYNÆCOLOGY.

BUCKINGHAM ON THE CARE OF NEW-BORN CHILDREN.—Dr. Buckingham (*Boston Medical and Surgical Journal*, March 25) says that, under ordinary circumstances, the first thing to be done for a child is to clean it; to get rid of the salve-like vernix caseosa by rubbing the body with oil, and then washing with soap and water. He has sometimes used the oil alone, working it well in at all points, and then rubbing dry with a towel. Oil is as clean as soap. The object of washing is to get rid of dirt, and whatever will remove the particular kind of dirt in question, whether soap or oil, is the best thing for its removal. Alcohol is objectionable, as it dissolves the oily matter from the skin, and has a tendency to chill the child. Once being made clean, it is not necessary that the child should have an entire bath daily. The nates and neighbouring parts should be kept clean, even if they have to be washed with every change of napkin. A very important point is the necessity for drying the skin thoroughly before dressing. A good rubbing with the hand after the rubbing with the towel is agreeable to the child.

Flesh-powder or powdered starch is not so good, and, besides, these applications frequently become acid and irritating.

The still adhering umbilical cord should be cut short, and covered sufficiently to protect the clothing. If it is not tied until the pulsations in it have ceased, there will be no risk of hæmorrhage from its cut extremity. Dr. Buckingham would never cut the cord till all pulsation in it was stopped. The cord should be short, the ligature small, the covering ample; and if the latter become offensive, in a day or two it should be removed. The belly-band should not be too tight. Strings on it are better than pins, if either be used; but the best band requires neither, being broad, thick, loose, and elastic, woven or knit of good woollen yarn.

JENKS ON RECTAL DISEASE IN WOMEN.—In the *Detroit Review*, February, 1875, Dr. Edward W. Jenks describes the association of rectal and uterine diseases in women. He says many of the disorders to which the rectum is subject are, without doubt, of much more frequent occurrence among women than men. The association of uterine and rectal diseases is quite common, as may also be said of uterine and vesical disorders. The truth is, that the continuity of tissues, the distribution of nerves and vessels, and the intimate relationship existing between the pelvic organs, render it obvious that disorder either of function, structure, or place of one may produce analogous condition in another. To treat symptoms alone in diseases of the pelvic region, as in any other part of the body where viscera can be subjected to physical exploration, is most thoroughly unscientific. There are certain symptoms common to all pelvic diseases of women; others are peculiar to certain individual diseases. He has known many cases of disorders of the rectum where the patient had been treated alone for uterine disease, and *vice versa*. He gives several illustrative cases of vaginismus and nymphomania cured by attention to the anal ulcers and fistulas which co-existed with the disease of the reproductive organs. In one case, the transition from a bed-ridden patient to a lady of active habits was quite rapid; nor did she require much further medical treatment.

PSYCHOLOGY.

ATKINS ON A CASE OF ACQUIRED IDIOCY WITH UNILATERAL CONVULSIONS.—Dr. Ringrose Atkins reports, in the *Journal of Mental Science* for April, 1875, a case, of which the following is an abstract.

J. R., a lad aged ten years, had been of average development and intelligence until three years of age, when it began to be noticed that he frequently turned his head to one side and shook it. His head appeared to increase in size. He became foolish, dumb, cross, and unmanageable.

At six years of age he had a fit of insensibility without convulsions; from this he recovered. During the next four years he had several severe convulsive seizures, and he grew extremely unmanageable, biting and tearing anyone who interfered with him. He was strong and active, and his limbs were well developed. If not constantly watched he was always wandering away from home and running into danger. His family history is good,

and free from instances of insanity, but his father is passionate and intemperate.

At the age of ten years the measurements of his head were: circumference, twenty-one and a half inches; from root of nose to occipital protuberance, fourteen and a half inches; vertex, from ear to ear, twelve and a half inches. His expression denoted want of power of attention and comprehension. He was dirty in his habits. He could not articulate, but uttered a sharp prolonged cry. He evidently understood what was said to him.

Dr. Atkins witnessed one of his fits in August last. 'He first became unconscious, lying on his back with his eyes directed upwards. As the convulsion came on, the outer angle of the left eyelid was drawn upwards and outwards, both eyes simultaneously moving in the same direction. Almost at the same moment, the left angle of the mouth was drawn in the same direction by the action of the zygomatic muscles. As the spasm proceeded from above downwards, the left arm was drawn up and jerked across the chest, and the left leg was bent and drawn towards the body by the muscles passing from the trunk to the thigh, at the same time the whole left side of the body was jerked upwards, and partially rotated from left to right. During the time these convulsions lasted, the whole right side of the body was entirely motionless, not one of the muscles of either the face, arm, or leg twitching in the slightest degree. The spasms were throughout clonic, the contractions subsiding almost instantly, and recurring again with as short an interval. The pupils were widely dilated, the right one reacted to the influence of a candle held close to the eye. These unilateral left-sided convulsions lasted, from being almost momentary in the face, for about seven or eight minutes elsewhere, the pupils at the same time becoming smaller and resuming their natural size. The twitching of the eyelid and mouth continued for some minutes after that of the arm and leg had subsided; in a few minutes more the patient returned to consciousness, and in a little time was as bright and lively as before, there being no drowsiness or stupor, as is usual after epileptic attacks.' In October he had another seizure, in which the convulsions were right-sided, commencing on the left side; and subsequently one similar attack followed by hours of sleep.

Dr. Atkins offers some remarks upon the pathology of the case. The history and symptoms lead him to regard it as one of 'hydrocephalic idiocy.' On the causes and origin of the convulsions the author adopts the line of reasoning repeatedly and ably expounded by Dr. Hughlings Jackson, viz., that all cases of convulsions and paralysis should be regarded 'as experiments made by disease on particular parts of the nervous system of man.' This method of study, he adds, is essential to a correct understanding of these cases of nervous disease, as a 'destroying' lesion of a circumscribed portion of the cerebrum may produce no obvious effects, while a 'discharging' lesion of the same portion may produce very striking results.

Taking the foregoing case as an example of this mode of investigation, Dr. Atkins observes that the convulsions were seen to follow the same course and in the same ratio as the palsy in a case of left hemiplegia. Knowing, as we do, from the recorded results of many cases, that the 'destroying lesions' causing the paralysis are situated in or near the corpora striata and optic thalami, we may fairly

localise the 'discharging lesion' giving rise to the convulsions affecting similar groups of muscles, in somewhere about the same region of the organ. The loss of speech, the author considers from the history of the case, was ataxic, from a loss of co-ordinating power in the muscles of articulation.

W. B. KESTEVEN, M.D.

OPHTHALMOLOGY AND OTOLOGY.

GRAND ON THE PERFORMANCE OF IRIDECTOMY FOR THE EXTRACTION OF CATARACT.—The performance of iridectomy during the operation for modified linear extraction has for its principal object the formation of a passage by which the lens, or any *débris* of lens-matter, may readily escape from the eye; and in order to make this passage sufficiently free a very large section of the iris is made, and the result is seen in a pupil of oval shape, and in some instances much too large to be screened by the upper eyelid. That this is very frequently the case will be admitted by most surgeons who have had any considerable experience of such operations. According to Dr. Stephane Grand (*Lyon Medical, March*), the cause of this imperfection is to be found in the manner in which many operators make the section, and he endeavours to point out this error in practice. Dr. Grand considers that it is the general custom to draw out the iris from the corneal wound and to excise all that protrudes; by this means a great deal too much of the sphincter is removed, and the result is a pupil which is too large for the immediate purpose, the removal of the lens, and may be in itself a source of impairment of vision. In order to remedy this, Dr. Grand advocates the performance of the operation in such a manner that a key-hole aperture in the iris is the result, and when this is accomplished, a pupil which is nearly circular, and which is capable of considerable mobility, remains, and at the same time the gap in the peripheral portion of the iris, which is amply large enough to permit the free escape of the lens, is yet completely hidden and protected by the upper lid. With care this may be accomplished by a ready operator if the iris be not withdrawn from the corneal wound, that is, divided with the scissors in such a way that the sphincter is spared as much as possible, in fact, provided no bridle of tissue be allowed to remain, the narrower the section can be made through the pupillary margin and the wider it is through the peripheral portion the better. The division of the iris while it rests within the lips of the corneal wound, is admittedly a matter of some difficulty, and for this purpose Dr. Grand recommends, and himself makes use of, the scissor-forceps, as suggested and employed by M. Wecker in his operation of iridotomy.

BOWATER J. VERNON.

MISCELLANY.

It is with regret we announce the death of M. Demarqay the well-known surgeon of Paris, which took place on the 21st inst., at his birthplace, Longueval, in Picardy. The cause of death was an organic affection of the stomach.

THE last census taken in the United States shows that there are 525 women practising the medical profession in that country.

DR. HORNER, the medical officer on board the *Pandora*, which recently left England for the Arctic seas, will take upon himself all the meteorological duties of the expedition.

THE TRANSPORT OF POISONS.—An American contemporary states that recently a vessel arrived at New York, containing a large quantity of fine table salt, stored in sacks in the hold, and about a hundred kegs of arsenic between decks. During rough weather on the voyage the cargo shifted, and some of the arsenic escaped from the kegs and was washed by the sea down into the hold amongst the salt. After a portion of the salt had been disposed of and removed, the captain remembered this, and began to speculate as to the possible nature of the mixture. An examination of the salt by Professor Doremus removed his doubts by showing that it contained a considerable proportion of arsenic. Fortunately, by promptly telegraphing to the purchasers, all danger of poisoning was averted.

A FRENCH LADY-PHYSICIAN.—We learn that Madame Brès, whose reception into the Faculty of Medicine, of Paris, is recorded in our impression of the 16th inst., is the first French lady who has taken such a step. She passed all her examinations in a most creditable manner, and M. Wurtz, the president of the examining board and dean of the faculty, addressed her in the following terms: 'Madame, you have not only raised women from the secondary position they have held in medicine, but your thesis is one of the best that the faculty of Paris has ever received, and it will be consigned with honour to its archives.' The title of the thesis is 'La Mamelle et l'Allaitement,' a very appropriate subject for a doctress; it is treated in an anatomical, a chemical, and a physiological point of view. From the new world, a similar occurrence is reported in the case of Mrs. J. K. Tout, of Toronto, who has passed her examination at and obtained a licence to practise from the College of Physicians and Surgeons, Ontario. Mrs. Tout is the first lady who has obtained a licence to practise medicine in all its branches in Ontario.

'BEN TROVATO.'—Dr. W. F. Atlee writes to the *Philadelphia Medical Times* as follows. 'In a letter recently received from Lancaster, Pennsylvania, where my father resides, it is said, a queer thing occurred just now. Father was in the office and heard a dog yelping outside the door; he paid no attention until a second and louder yelp was heard, when he opened it and found a little brown dog standing on the step upon three legs. He brought him in, and, on examining the fourth leg, found a pin sticking in it. He drew out the pin, and the dog ran away again. The office of my father, Dr. Atlee, is not directly on the street, but stands back, having in front of it, some six feet off, a stone wall with a gate. I will add that it has not been possible to discover anything more about this dog. This story reminds me of something similar that occurred to me while studying medicine in this same office nearly thirty years ago. A man named Cosgrove, the keeper of a low tavern near the railroad station, had his arm broken, and came many times to the office to have the dressings arranged. He was always accompanied by a large ferocious-looking bull-dog, that watched me most attentively, and most unpleasantly to me, while bandaging his master's arm. A few weeks after Cosgrove's case was discharged, I heard a noise at the office door as if some animal was pawing it, and, on opening it, saw there this huge bull-dog, accompanied by another dog that held up one of its front legs, evidently broken. They entered the office; I cut several splints of wood and fastened them firmly to the leg with adhesive plaster after straightening the limb. They left immediately. The dog that came with Cosgrove's dog I never saw before nor since.'

PRACTICAL CHRISTIANITY.—During the warm season of the last two years the board of government of the Boston Young Men's Christian Union has furnished carriages to the various hospitals of the city, so that many of the patients were enabled to enjoy a ride in the country, and derive the benefit of the fresh air as they could not otherwise have done. This charity has not only been extended to the inmates of hospitals, but has also included many an invalid living in circumstances too limited to allow of such an indulgence. To enable the Union to meet the expenses thus incurred, a public appeal for special donations was made, as of course the furnishing of rides for convalescents does not legitimately belong to the work of the Union, and the *Boston Medical and Surgical Journal* states that hitherto a generous response has been made to the appeal.

MESSAGES FROM THE SEA.—Mr. Garside, of Southport, describes, in the *Pharmaceutical Journal* of the 19th instant, the method he successfully employed for restoring the legibility of a letter which had been submerged in the wreck of the *Schiller*, and which was quite illegible until submitted to the process described. The letter was carefully brushed over with solution of sulphocyanide of potassium (one in twenty), and then, still damp, held over a dish containing hot hydrochloric acid. The writing was thus developed of a deep red colour. The *rationale* of the process is this: The iron of the ink is precipitated as peroxide upon the fibres of the paper, and remains when all other colouring matters are washed away. Being in an insoluble form, however, no effect is produced by the reagent until the fumes of the acid have rendered it soluble. Probably ferrocyanide of potassium would answer as well or better than sulphocyanide.

THUNDERSTORMS.—Herr von Bezold, of Munich, has published some interesting researches on the periodical changes in the frequency of thunderstorms during long periods of time. A German correspondent of *Nature* thus summarises the results of Herr von Bezold's investigations. High temperatures, as well as a solar surface free from spots, cause a greater number of thunderstorms during a year than the reverse. Now, as the maxima in the frequency of sunspots coincide with the maxima of the intensity of aurora borealis, it follows that both groups of electrical phenomena, thunderstorms and aurora, complement each other, as it were, so that in years with many thunderstorms aurora will be rare, and *vice versa*. From this connection between sunspots and thunderstorms an immediate electric action between the earth and the sun does not necessarily follow, but it may be simply a consequence of the magnitude of insolation, which depends on the frequency of spots. These changes in the insolation are not felt simultaneously but successively in the different latitudes. The phenomena of thunderstorms, however, do not only depend on the conditions of temperature at a given locality, but also on the state of the atmosphere at far distant points, belonging to another zone; and this is most evident with thunderstorms accompanying strong currents of wind or tempests. In this manner the peculiar intermediary position which the thunderstorm curve occupies between the curves of temperature and sunspots might perhaps find its explanation eventually.

PRACTICE OF MEDICINE BY WOMEN.—The General Medical Council of Great Britain, having received a communication from the Government asking their opinion as to whether women ought to be admitted to the Register of Practitioners of Medicine in this country, and if so, what alterations would be required in the examination rules of the licensing bodies, have had the matter under consideration for several days during their recent annual session in London now just concluded. A committee was appointed consisting of Professor Turner, Edinburgh; Sir William Gull; Professor Rolleston, Oxford; Professor Humphry, Cambridge; Sir Dominic Corrigan, Dublin, and others. They prepared a report which, after a long debate, has been adopted by a majority of fourteen to seven; it sets forth that in the opinion of the council the practice of

medicine presents many special difficulties for women which cannot safely be disregarded, but that the council are not prepared to say that women ought to be excluded from the profession and practice of medicine. They add that the education of women for medicine ought always to be conducted in separate schools; and that if the existing universities and corporations should be unable or unwilling to admit women to examination and to confer on them a license, it would then be sufficient for the Government to invest the Medical Council with the necessary powers for holding examinations and conferring on women a registrable title to practise medicine. They are of opinion that the course of education and examination should not in any respect differ from that of men. Of the importance of this resolution it is hardly necessary to speak; it is probable that with this authoritative sanction from the highest medical authority in the kingdom, such of the examining bodies as are not precluded by legal difficulties will announce their intention of admitting women to a medical examination and give them a registrable title. A short enabling Act of one clause would overcome any technical difficulty which may exist with any of the examining boards. If it should be found by the Government that none of the existing licensing bodies are willing to license women, it will then be easy to adopt the last suggestion of the General Medical Council. There are twenty-four ladies studying in the London School of Medicine for Women, Henrietta Street, Brunswick Square, under teachers of eminence selected from the hospital medical schools, and before long they ought to find that all artificial barriers to their entering on professional duties have been removed.

THE NEW SYSTEM OF INTERMENT.—On the 15th instant a number of perishable coffins, made on the principle advocated by Mr. Seymour Haden, were exhibited in the garden of Stafford House. The coffins were simply wicker baskets, of the ordinary coffin shape and of various sizes. Two of them had their meshes filled by moss, but the rest, which were supplied by Mr. Kirby, a basket maker at Derby, were left with their meshes open, like those of an ordinary waste paper basket. Two or three were double, with a space 2in. or 3in. in width between the inner and the outer basket; and this space is intended to be filled with charcoal, for cases in which any precaution against infection and decomposition may be required. Mr. Seymour Haden was himself present, and was eagerly questioned about many details of his plan, but the following handbill, which was given to each visitor on entrance, contains all the necessary explanation.—‘It is necessary, perhaps, to explain that the models shown are merely suggestive, and that the majority of them do not as yet fulfil all the conditions essential to their practical use. 1. The mesh in most of them should be larger than it is, and as open as is consistent with strength, and the perfect retention of their contents, which contents, again, should consist of the larger ferns, mosses, lichens, herbs, fragrant shrubs, and any of the coniferae, willows or evergreens, which are always to be had. 2. The osiers composing the baskets should be light (two thin ones being better than one thick one), and no more solid wood should enter into their construction than is necessary to preserve their form. 3. They should be of white, or stained willow, without varnish or other preservative covering. 4. Accompanying each of them should be a narrow leaden band or ribbon, pierced with name and date of death, to be passed round the chest and lower limbs, and through the sides, and over the top of the basket: (i), for retaining the body in its position; (ii), for the subsequent identification of the bones; (iii), for sealing the coffin, as a guarantee that the contents have not been disturbed. 5. In special cases linings of some imperishable material for a few inches upwards from the bottom will be necessary; and, in other cases, such modifications of the ordinary form as may insure a complete inclusion of the body in wool, charcoal, or other disinfectants. Of these exceptional models, No. 3 would seem to be, on the whole, the best for its purpose. 6. Other materials which are light, strong, perishable, in-

expensive, adapted for carriage, and favourable to the dissolution of the body, may do as well and possibly better than these wicker baskets. Readiness of carriage and the insurance of resolution being the main objects aimed at, several such materials do, in fact, suggest themselves, and may afterwards come to be employed.’

MEDICAL CONSULTATIONS.—The following quaint and sensible advice to young surgeons called to meet in consultation is extracted from an article by Dr. Gillespie, ‘Medical Notes about Shakspeare and his Times,’ published in the *Edinburgh Medical Journal* for June, 1875. Dr. Gillespie quotes it from a rare tract by John Halle, a surgeon at Maidstone, entitled ‘An Historical Expostulation against the Beastly Abusers, both of Chyrurgerie and Physyk in our Tyme,’ published in 1565, and edited by Mr. T. J. Pettigrew, and reprinted by the Percy Society.

‘When thou art calld at anye time,
A patient to see;
And dost perceive the cure to greate,
And ponderous for thee:
See that thou laye disdeyne aside,
And pride of thyne owne skille:
And thinke no shame counsell to take,
But rather with good wyll
Gette one or two of experte men,
To helpe thee in that nede;
And make them partakers with thee
In that worke to procede.
For in so doinge, thine honestye
Thou shalt well kepe and save;
Also thy patiente therby
Righte greate comfôrte shall have.

And also if oughte goe a wrye,
Or hinder in thy cure,
The one maye mende the other's faulte,
While frendship dothe endure.
The wounded or sore man also,
Shall have no cause to grudge,
In you such uniformitye
Whyle he may see and judge.

But one thinge note, when two or moe
Together joynged be;
About the paynfull patient,
See that ye doe agree.
See that no discorde doe arise,
Nor be at no debate;
For that shall sore discomfort hym
That is in sycke estate.

Wherefore what so ye have to saye,
In things aboute your arte;
Let it be done among your selves,
In secrete and a parte.
Wyth one consent uniformlye
Comfôrte the wounded man;
But unto some good frend of hye
Expresse all that ye can.’

NOTICE.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BISSANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The Second Volume of the LONDON MEDICAL RECORD is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for each year may be had for 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON THE LOCAL TEMPERATURE OF PARALYSED PARTS. BY PROFESSOR MAURIZIO SCHIFF, OF FLORENCE.

[The subjoined is a translation of a letter addressed by Professor Schiff to Dr. Bursesi, and published in *Lo Sperimentale* for March and May.]

Three years ago, in 1871, you did me the honour to address to me a letter, which was published in the *Osservatore Medico* of Siena, and in *Lo Sperimentale*. The nature of the researches to which I was led by your request, will show everyone who is acquainted with the history and the conditions of our laboratory in Florence, that it is not through my fault that the reply has been delayed until now. I must also confess that I should have still expected other more complete and demonstrative facts, if circumstances over which I had no control had not interrupted the course of my experiments.

You speak to me of a pathologically interesting case, in which a man, after a wound of the spinal cord which, in your judgment, paralysed him on one side, had paralysis of motion in the limb, the foot being notably *paler* and *colder* than the other; and while the latter perspired habitually and profusely, in the foot of the injured side perspiration was rare, difficult, and scanty. The patient experienced a constant sensation of cold in that foot, and alleged that he could not get it warm even in the heat of summer.

In this state you found him about two years after receiving the wound, when the mobility of the limb was in great measure re-established, so that the patient could walk ten or twelve miles. He could not, however, run. There was still a slight difference in walking between the right foot (that on the injured side) and the left, and the muscles of the right lower limb were somewhat wasted.

In the morning, while at perfect rest, the patient showed, between the great and the second toes, a temperature on the left side of 98.6° Fahr., on the right of 84.7° Fahr. In the evening, after he had been walking about all day and was still perspiring, the temperatures were: right foot, 91.4° Fahr.; left foot, 96.8° Fahr.; right popliteal space, 96.4° Fahr.; left popliteal space, 97.16° Fahr. At 11 A.M., after the patient had been walking about barefooted in the house for about an hour, the temperature of the right foot was 82.4° Fahr.; of the left 96° Fahr.

You rightly observe that these results differ much from those obtained in animals, after hemisection of the spinal cord, which I had the honour to show you in a dog. In the animals operated on, the terminal part of the lower limb of the side on which the semi-division of the cord is made, becomes much warmer

than the terminal part of the limb of the side on which the cord has not been cut.

In the first days after the receipt of the wound, you found the temperature in the popliteal space on the paralysed side nearly a degree (0.9°) Fahr., lower than on the sound side; but you did not observe the temperature in the more peripheric parts. As regards the popliteal space, I found the paralysed side colder in dogs in which hemisection of the cord had been performed.

The difference in our observations seems then to be only in regard to the terminal part of the limb. At first, the question appears to be somewhat complicated by the fact that the paralysed part has not been found the colder in all cases of spinal hemiplegia in man; in two cases related by Brown-Séquard, the paralysed part was warmer, just as in the dog. In Brown-Séquard's first case, which he examined nine years after the receipt of the injury, the primary symptoms had already much diminished, but there still existed some loss of motion in the leg and arm of one side, and a high degree of loss of sensation on the other side of the body. The paralysed leg was 1.8 Fahr. warmer between the toes than the other. The upper limb on the paralysed side was 1.8 to 5.4 Fahr. warmer than the other. Perspiration was more abundant and frequent on the paralysed side—contrary to what was observed by you. Three years later, *i.e.*, twelve years after the injury, Dr. Hughlings Jackson examined the same patient. There was a slight increase of motor power on the right side, and the temperature of the paralysed leg was lower than that of the opposite limb. In another case, at which a knife penetrated the posterior part of the cervical region, it is said that the paralysed side was 2° Fahr. warmer than the other; but, in the translation from which I quote (Borrelli, 1869) it is not stated where the temperature was measured. Further on in the history, the author says that, on the fourth day of the illness, he compared the temperature of the two ears (the wound was above the origin of the cervical sympathetic) and found it 95° Fahr. on the injured, and 93° Fahr. on the sound side. . . .

I will pass on to the experimental facts which appear to give an explanation of these apparent anomalies, and which prove that there is no real contradiction between the results of clinical observations and pathological experiment. In the first place, however, I will refer to a phenomenon of which I treated in 1854 and afterwards, but of which I have not yet given a sufficient explanation.

Many authors have admitted that the local increase of temperature on the paralysed side, being produced by paralytic dilatation of the vessels, ought to remain unchanged as long as the paralysis of nerve which caused it still exists; that is to say, until the nerves or the nervous centres that have been divided are regenerated. In the very first experiments which I made on the vascular nerves of peripheric parts of the body, I was obliged to recognise the fact that this opinion, although supported by the highest authorities, was contrary to fact. The increase of temperature, and with it the vascular dilatation, is great immediately after division of a vaso-motor nerve; but diminishes after one, two, or three days, in more rare cases after a week; so that, without any suspicion of regeneration of nerve-matter, the definitive increase of temperature which remains for some time after the injury is only one-tenth, sometimes only one-twentieth, of the difference which existed at first.

But I did not perceive that the effect of vascular paralysis *entirely* disappeared, or that a part after the section of the vaso-motor nerves became *permanently* colder than the sound part; that is, that it was colder when there was no general excitement of the dilating nerves of the vessels.

These observations, made in 1854, were for some years the theme of lively discussions. In spite of many attempts, I was at first unable to give a sufficient explanation of this paradoxical fact; and many denied it, notwithstanding that clinical observation on man confirmed the results of physiological experiment. Little by little my observation was confirmed by some authors, and the discussions ceased; and, believing that the fact was generally admitted, I continued to seek for its explanation. I was, however, mistaken in supposing that the fact was generally admitted; for, twenty years later, a physiologist of such high repute as F. Goltz, of Strasbourg, published it as a new discovery of his own, adding, however, what I had not said, that the increase of temperature, which always continues to diminish for some time after the division of the vaso-motor nerves, may disappear entirely, or that the temperature of the paralysed part may become equal to that of the sound side, and even lower. Goltz's observations are exact; but we shall see that he has erred in his conclusions.

To explain this diminution of temperature, and to show its compatibility with the persistence of paralysis, I may be permitted to refer to more general considerations. An organ which has been for some time accustomed to a certain amount of irritation will not immediately re-act when that amount of irritation has been reduced to one-half, but will be at first like an unirritated inert organ. Little by little, if the irritation be not renewed, the part becomes accustomed to the new stimulus, its activity recommences, and increases up to the degree corresponding to the reduced amount of irritation. After exposure to the sun's light for some time, we see nothing if we enter a darkened room. Gradually the eye accommodates itself to the lessened amount of stimulus, the outlines of objects become more and more visible, and at last we begin to see them plainly. In order to ascertain if the same rule holds good for the motor nerves, we have made experiments on the nerves of the lumbar plexus in frogs. There are almost always certain muscles of the posterior limb which receive motor filaments, proceeding not from only one of the spinal nerves composing the lumbar plexus, but from two—and more rarely from three. If these muscles be rapidly deprived of the influence of one of these nerves, certain muscular fibres, which might be simultaneously under the influence of the two nerves, will immediately after the division of the nerve be under the influence of a reduced number of nerve-fibres; and, if our theory be correct, these fibres should be as if they were paralysed, and regain motion when they have become accustomed to the reduced amount of stimulus. A first series of experiments, made in 1863, with the assistance of Dr. Annibale Norsa, of Mantua, confirmed and surpassed our expectations. At a later date we repeated the experiments on frogs and on dogs, with the same result. The frogs being etherised, the lumbar plexus is exposed on one side, and a loop of silk is placed under one or two of the nerves which compose it, so that they may be cut without danger of injuring the others. When the effect of the division is observed immediately, and is watched from half an hour to six

hours, many of the frogs will show an increase of voluntary motion in a double sense: certain movements that were very feeble become stronger and more energetic; and it is seen also that in parts, such as the thigh, the muscles of which appeared entirely paralysed after the section, there is a considerable return of motor power. It was already known from the researches of Schiess-Gemuseus, that the distribution of the muscular nerve in the *Rana esculenta* presents many irregularities; but the facts now mentioned indicate that many muscular fibres receive nerves from different sources. We have been able to observe an analogous fact in dogs and cats in which we have divided the sciatic nerve high above the trochanter. Immediately after the awaking of the animals from etherisation, paralysis was distinct, and was much more extensive than from one to three days afterwards; at first the whole limb, with the exception of some of the flexors and adductors, appeared paralysed, while later on the animal used the limb to support itself and scratch its neck, although, in consequence of the permanent paralysis of the part, it could only do so with difficulty. In these experiments it was observed (1) that the return of motion in the muscles not definitively paralysed required a variable time in different individuals; (2) that the phenomenon was independent of the wound made in laying bare the nerve—a fact which is further proved in dogs, by laying bare, under ether, the nerves of both sides and dividing one only; (3) that the phenomenon was independent of any uncomfortable sensation which might be produced by traumatic irritation of the central end of the freshly divided nerve. This was proved in dogs in which many movements had returned one or two days after the section was made. The dogs were again etherised, and a centimètre or half a centimètre was cut away from the central end of the nerve. After the animals had awoken, their movements were not more imperfect than before the second etherisation. It is evident (4) that the return of motor power is not dependent on regeneration of nerve: for the section was made in such way that generally after death (three weeks to four months after the operation) no reunion was found; and in the few cases in which there was union, it was not formed by nerve-matter but by connective tissue.

I am sure that the phenomenon here described occurs also in man after a wound of one of the motor nerves of a limb. If surgical observation has not hitherto recorded such facts, it is without doubt due to the difficulty of making a complete examination of the patient immediately after the receipt of the injury. When in 1869 I made a search in surgical literature, I could not find an undoubted fact; and since that time I have not been able to return to these bibliographical researches. I regret that I have not been able to compare the latest American researches, especially those of Weir Mitchell.

I come now to sensibility. If a part of the surface of a body transmit its impressions to the centre by two or more nerve-trunks, and one of them be suddenly interrupted, it will be understood from what precedes that sensation may become extremely feeble, and after some time be renewed. I am convinced that many cases occurring in man are explained in this way, in which, after division of a nerve, there is supposed to be partial repair or regeneration after a few days. Bécларd and Descot (*Affections Locales des Nerfs*, 1825) mention a case in which the ulnar nerve

was cut through, along with the tendon and the artery. Sensation was lost in the little finger and along the side of the ring-finger; but within a very few days it reappeared, commencing in an indistinct manner, as if objects were touched through a glove. Laugier, in 1864, observed a case of complete division of the radial nerve and incomplete of the median. A suture was applied to the median nerve in the morning, and in the evening sensation had returned to the parts supplied by this nerve. This could not be attributed to the suture. From 1850 to 1852 I was occupied for a long time, perhaps before Laugier and other surgeons, in the suture of nerves. I found, indeed, that this greatly aided healing, but I will not venture to say that it was followed by restoration of function before the eleventh day; indeed, so small an interval as this was a very favourable exception.

Richet describes (*Gazette des Hôpitaux*, October, 1867), a case in which sensation was present in all parts of the hand twenty-four hours after section of the median nerve; but it is not clear to me what were the symptoms immediately after the injury.

Arloing and Léon Tripiér (*Journal de Physiologie*, 1869), have made on dogs a series of experiments which prove the same fact for the cutaneous sensibility of the ends of the digits. We regret that these authors thought it necessary to make their experiments without the use of anæsthetics. M. Tripiér would become convinced by a visit to our laboratory, that the success of an experiment is much more decisive when the animal is spared the pain of the operation.

In one of the experiments (twenty-third of the first series) a branch of the radial nerve was divided in a dog at the level of the metacarpus. An hour after the operation, punctures in the skin of the corresponding part were not felt; but there was sensation in the deeper parts. Next morning, punctures were felt. In another experiment (twenty-third of second series) the trunk of the ulnar nerve was divided, and certain parts of the little toe of the forefoot were insensible after the operation; but the next day sensation appeared to be a little more extensive, and on the third day it had returned on the outer side of the toe. On the following days it steadily increased. In another similar experiment sensation returned on the fourth day after the operation; and other experiments made by the same author led to similar results. Arloing and Tripiér sought in these researches to find how sensation was transmitted when the nervous communication was interrupted; they have, indeed, given a correct answer to this question, but I do not doubt that they would have discovered the true theory of the process, if, instead of taking into account only the return of sensation, they had inquired why it was absent immediately after section.

Among my experiments relative to this argument, I will here refer to those of section of the lingual nerve of one side. Immediately after the section, in adult dogs, there is insensibility of the entire half of the tongue, as far as the base. On the second or third day it is seen that, in the neighbourhood of the apex, a narrow space near the median line becomes sensible, and the sensibility increases daily. We have here evidently one of the cases illustrated in other nerves by Jeffreys Wyman, in which the ramifications of the symmetrical nerves encroach a little on the median line in such a way that each of them passes a little beyond it. Our theory explains how it is that the limits of the anæsthetic part vary

a little according as the examination (with a pointed instrument or a pincer) is made from the insensible border towards the sensitive or the anæsthetic half. In the first case, the insensible part appears a little more limited.

We have thus seen that, for the special senses as well as for motion and sensation, the general law remains the same. When the stimulation is rapidly, powerfully, and lastingly diminished, it fails for some time to produce an effect, until the excitability has raised itself to a level with the excitant. It is evident that, when diminution of stimulus is produced by paralysis of a portion of the nerves, the restoration of motion or of sensation will be only *partial*, and will only take place in those portions of the periphery which receive nerves from more than one source.* Essentially the same, without doubt, holds good for the vaso-motor nerves. If, for the present, we take into consideration that portion only of their properties which is generally called *tonus*, this *tonus* reaches all the organs not by a single nerve-trunk, but by two or more different ways. If the chief of these nerves be cut, the muscles of the vessels lose their tone over a great extent, and as it were completely. This occurs because the various vascular nerves proceeding to an organ are not distributed to the organ separately, but are intermixed like the sensory nerves of the skin (the vaso-motor nerves of the spleen are an exception to this rule), so that the same vascular branch in an organ is under the influence of different nerves. If all the vessels be not dilated, most of them are; and thus there arises a great increase of local heat, and a redness of greater extent than that which corresponds with the distribution of the nerve which has been divided. After one, three, or even five days, the tone returns in that part of the vessels which still possesses some other communication with the centre, and the local increase of temperature becomes less. As we found in our first researches, the decrease is very considerable, and generally returns on the first day, to increase on the second, in rabbits and guinea-pigs. In the toes and ears of dogs, the difference of temperature between the sound and the paralysed parts diminishes more slowly, and remains more marked than in herbivora (see Schiff, *Untersuchungen zur Physiologie des Nervensystems*, 1855.) We have thus seen that in the rabbit, after division of the sympathetic in the neck, and after extirpation of the superior cervical ganglion, the initial difference of temperature in the ear diminished in four days down to 1° 17' Fahr., and remained at this point during the life of the animal. In dogs, the difference of temperature in the hind toes and in the ear was 18° Fahr. on the first day; it then sank in nine days to 10° 8' and 12° 6' Fahr., and this difference continued through life, provided that there were no new lesion nor regeneration of the nerves.

Hitherto we have considered the vaso-motor nerves as subjected to a *tonus*, a reflex excitement proceeding from the centres. If this were their only stimulus, it would be understood why a part which receives its vaso-motor nerves from different trunks becomes very warm, and then cools a little, after the

* The experiments of Vulpian and Philippeaux, which show that the chorda tympani becomes a motor nerve of the tongue some time after section of the hypoglossal, belong, we think, to the same category of facts. The chorda tympani is always a motor nerve of the tongue; but in the normal condition its isolated influence is not sufficient to produce visible movements of the muscles.

division of the first trunk, and why the same thing is repeated if the second be cut, and so on to the last nerve but one. The cooling after the initial increase of temperature ought to always become less as long as any of the vascular nerves remain; but if the last be cut, the part ought to remain at an increased temperature through life, without cooling, just as the whole of a cat's paw remains insensible after division of the last of the nerves in the fore-arm (Arloing and Tripier). I had, in fact, thought that this was so; but a series of experiments on various animals and on various parts of the body have shown me that in this case the elevation of temperature falls a little during the early period, although the maximum temperature of the first day may often be found to have returned months after the operation. The dilatation of the vessels proceeds *pari passu* with the temperature.

This shows that there are oscillations in the medium state of contraction of the vessels. These oscillations indicate a variable condition of irritation; and as this varying irritation cannot proceed from the centre, when all the vaso-motor nerves are divided, we must seek its cause in the periphery. Here we may irritate either the vessels directly, or the terminal ramifications of the vaso-motor nerves, which probably do not partake of the paralytic change. This peripheric irritation must be variable in intensity, and the variation may depend either on the general conditions of the animal or on local conditions. We leave out of the discussion the question whether these oscillations are produced by the peripheral ganglia in the course of the vaso-motor nerves.

Before entering on the discussion we would say that, although these oscillations were first observed by us in peripheric organs in which all the vaso-motor nerves up to that time known were divided, we have also found them after section of one or more vaso-motor trunks, and in the posterior extremities after transverse division of the spinal cord at different heights.

To the first question, whether the peripheral irritation acts on the nerves or on the fibres of the vessels, it is not possible to give a decided answer. Generally, the oscillations do not manifest themselves on the first days, but, on the contrary, there is an uniform increase of temperature. I have observed this in the sole of the foot, after section of the sciatic nerve, for twelve to twenty hours, on examining the temperature every three or four hours. At a later period the oscillations appeared. After division of this nerve along with the branches of the sacral and lumbar sympathetic, I have found traces of oscillation at the end of ten hours. After rupture of the sympathetic branches which proceed to the brachial plexus from the last cervical ganglion and the first thoracic, there was a slight oscillation at the end of sixteen hours, and a second at the end of ten hours.

These facts, however, are somewhat uncertain, since the animals were not constantly watched, and he dogs were allowed to run about freely in the intervals between the observations. Thus, a rapid oscillation might escape notice, or be masked by the unequal condition of the two extremities immediately before the observation. If the dog sleep, and have one limb nearer to the abdomen than the other, the latter will for some time be the colder. If the dog run, and touch the ground more with the sound limb, this will lose more heat, and will for some time be colder. On the other hand, an absence of oscil-

lation for ten hours is of little importance, since this time approaches closely to the duration of an oscillation in some dogs, whether sound or operated on. I can, therefore, only say, with very great reserve and in a doubtful manner, that in dogs there appears to be an absence of periodical oscillation in the vascular contraction during the first period after the paralysis of the vaso-motor nerves. This proposition gains a little strength if we extend the observation to the ear of the rabbit. Here there is seen an at least *analogous* periodicity in the contraction of the visible vessels and in the temperature in the healthy animal, with very frequent oscillations and very short intervals. As I have pointed out elsewhere, this periodical contraction ceases after division of the cervical sympathetic, and is entirely absent for three or four days or more. A certain periodical movement is then re-established; but it is not *synchronous* in all the vascular divisions of the ear, and sometimes takes a peristaltic form.

Admitting, then, the analogy which we seek to establish, the facts do not yet entitle us to conclude with certainty that the periodical peripheric irritation does not act directly on the muscles of the blood-vessels; but the temporary arrest of all movements immediately after section, after a lesion which affects no tissue but the nerves, indicates with a certain degree of probability that the peripheric agent *must* act on the nerves, and *may* act simultaneously on the nerves and on the muscular structure of the vessels.

This probability would be greatly increased, if we might take into consideration another still more remote analogy. The movements of the posterior lymphatic hearts of the frog are interrupted after section of the spinal motor nerves. The arrest of movement lasts from eight minutes to ten hours. Then there commences a new movement, arising from a periodic peripheric cause; and this movement, which I described in the *Jena Annalen*, in 1850, is normal, just like the movement of the central artery of the rabbit's ear, five days after extirpation of the inferior cervical ganglion. In the lymphatic heart, which is a striated muscle, the neuro-muscular form of the movement indicates clearly that the peripheric cause which produces it acts on the terminations of the nerves and not directly on the muscles.

We may give a more decided answer to the question whether the peripheric cause which produces the oscillations acts simultaneously on the whole body or independently on each part. The reply will be easy, if I first give an idea of the manner in which these oscillations were shown in two dogs rendered paralytic by transverse section of the whole spinal cord in the lower dorsal region; in this way, the two posterior limbs were placed in similar conditions. Both were independent of the medulla oblongata and upper part of the spinal cord; both remained motionless, unless excited by some external cause, which generally could be easily avoided. The animals were placed in a rather narrow box containing hay, with both legs exposed to view and lying apart from the body. The observations were made in summer in a room that was cool enough when there were no considerable variations of temperature. On the fourth day of the second elevation, there was a considerable rise of the surrounding temperature, and therefore the record from the morning of the fourth day to the evening of the seventh is suppressed. In both animals, the temperature in the posterior limbs underwent an elevation up to 97° Fahr. in the first three days after the operation,

in which no oscillations could be detected; these then appeared, at first being very feeble, and then gradually stronger. The appetite and the general temperature of the animals did not indicate the presence of traumatic fever. Eight hours after the operation, the temperature in the rectum indicated a rise of 1.8° Fahr.; this continued for only two hours, the appetite remaining good. The observations were made on the first dog nine days after the operation; on the second in the third week; and they were made each hour from 1 A.M. to 12 P.M. To save time, the temperature was not measured by the thermometer; and, as exact measurement was not necessary, it being desired only to know the general character of the oscillations, I contented myself with noting the impressions which the contact of the side of the foot made on my left hand, which is very sensible to oscillations of temperature, and which during the whole time of the observations was kept warm as far as possible. These observations, and others made on paralysed animals, show that—

1. The temperature in the terminal part of the paralysed limb is not invariable, but is subject to slow and rather considerable variations.

2. Each of these variations extends over a period of several hours; sometimes there are only two, sometimes three, in twenty-four hours.

3. Sometimes other oscillations of short duration alternate with the greater ones.

4. These oscillations in two limbs placed in the same external conditions and equally paralysed, do not always run parallel; sometimes one extremity is very warm and the other very cold, which indicates that the cause which produces the oscillations does not depend on a general condition of the body, but acts locally on each part.

5. To determine if a paralysed part be in general rendered warmer or colder than the normal state by paralysis, two measurements daily at stated times are not sufficient; the medium temperature must be ascertained.

In a series of thermometric measurements made on the first dog every two hours, and continued for twenty-four hours, in the third week after the operation, I found the medium temperature 8.6° Fahr. above the normal—the latter being 87° , as ascertained on the day before the operation. Frequently repeated measurements before operation in the case of the second dog gave a temperature of 73.4° Fahr. in the hind limbs; I believe, however, that this figure is rather too low, as the animal stood on a cold table in the intervals. The medium temperature taken at the end of the second week was found to be 82.4° Fahr.; and a second series of measurements taken from 12 at noon to 12 at midnight gave 82.2° . This dog, from 7.30 to 9 o'clock on the morning of the day when the second series of observations was made, had shown an average temperature of 63.5° ; we thus see how isolated measurements of temperature may mislead, and that observations should be made continuously, day and night, to ascertain the true influence of a paralysis.

In paraplegic dogs with pale feet, it is readily seen that the vascularity is increased when the temperature is raised, and diminished when it is lowered; indicating a periodical oscillation in the contractions of the small vessels.

It will be interesting to follow out the same fact in hemiplegic paralysis, in which a comparison can be easily made with the corresponding non-paralysed limb. Such observations, however, are so difficult

and laborious, that I have been obliged to content myself with observations more scanty and less prolonged than those on paraplegia. The difficulty in hemiplegia, when we wish to compare the temperature on the two limbs, consists in making all the conditions alike except the paralysis. When only one hind limb is paralysed, and the animal moves about freely, there are, beside the paralysis, two other conditions of inequality of temperature; muscular movement, which tends to raise the temperature of the sound limb; and contact with the ground, which tends to cool the foot; to these is added the circumstance, that the sound limb is often a little moister than the paralysed one. All these conditions tend to make the sound limb too cold. If, to equalise the temperature, the animal be placed with its legs extended on a piece of woollen, continual watching is necessary to prevent it from drawing them under its body. To avoid this inconvenience, I have often used a fishing-net, in which the dogs were suspended in the air, while their four legs, projecting through the openings, were extended. Even here continued watching is required, for the dogs sometimes succeed in drawing up one or both legs and bringing them towards the belly, and thus increasing the temperature, especially in the sound limb. The observation of unilateral paralysis is, then, attended with difficulty; but it promises such an interesting result, that an attempt should be made to overcome the difficulty, at least partly, so as to be able to arrive at an approximately correct measurement of the temperature during twenty-four hours.

If dogs and cats, when operated on, were supplied with a large quantity of food, a tendency to sleep during digestion was produced, so that they remained stretched out during the greatest part of the day. They were accustomed to lie on a woollen cloth or on American leather covered with a layer of tow. In order to extend the two legs equally and to prevent them from being drawn under the body, a somewhat stiff sleeve of paper was placed over each limb from above the knee to the heel. It was so arranged as not to press on the limb when extended; but when flexion was attempted, resistance was felt. This plan succeeded with many dogs, which in a few days became accustomed to the apparatus. In this way I succeed, with many interruptions, in taking a series of measurements by means of a very sensitive thermometer, which indicated a variation of $.18$ of a degree Fahr., at a temperature of 104° . The temperature was generally measured by subtraction; that is to say, by warming the thermometer in my axilla to a point above that which could be found in the dog, and then beginning to take the temperature of the leg which seemed the warmer to the hand. In this way I succeeded in ascertaining that in unilateral paralysis, which for some days after the operation produces an uniform elevation of temperature in the leg, the interdigital membrane showing a heat of 96.8° or 98.6° , there appear after a certain time oscillations in the temperature and in the turgor of the vessels, analogous to those found in paraplegia.

The paralysis in these experiments was produced either by division of the sciatic nerve, or by simultaneous section of the sciatic and crural nerves, or by dividing half of the spinal cord in the lumbar or lower thoracic region; or paralysis was produced only in that portion of the vaso-motor nerves which arise from the thoracic and superior lumbar portion of the cord, and pass in the abdominal sympathetic

to the lumbar and sacral plexus. For this purpose, the continuity of the abdominal sympathetic was divided at a higher or lower point. For the upper limb the result was obtained, either by dividing the sympathetic under the first or second rib, or by interrupting the communications of the inferior cervical ganglion with the brachial plexus. These experiments on the sympathetic presented the advantage of producing vaso-motor paralysis alone, while the movements of the limb were preserved. But the integrity of the movements increased the difficulty of accurate observation. In the other experiments, in which the spinal cord or the nerves was divided, the animal was always observed when the wound was healed, and voluntary motion had returned in an incomplete manner in the whole limb. In the experiments where the spinal cord was half divided, voluntary motion was often absent in the toes at the time of observation, while extension and flexion could be performed in the tibio-calcaneal joint, and in the knee the movements were normal. The observations were made when there was no trace of fever.

The first fact shown in these researches was, that the sound limb manifested oscillations of temperature very similar to those in the limb operated on, but having a more regular rhythm. Generally in the morning the sound limb, the animal lying with its legs extended, was cold, or its temperature was not elevated. The temperature was generally 68° to 78.8° Fahr., and sometimes remained at this point till three or four P.M., while in other cases it had already risen at 11 A.M. This increase was of variable duration; a rise of five to seven degrees continued for two to five hours, and then there was a fall. From seven to nine P.M. there was generally a rise of 9° or 10.5° ; if the animal slept during the time, the temperature increased still more, reaching a maximum which it maintained till midnight, or even longer. I have no record of observations made on the sound limb during the second half of the night, but between five and six A.M. its temperature generally fell. In many dogs I could only observe a single oscillation, the temperature rising towards the evening. In a few others, there seemed to be more than two oscillations of short duration; but the fact could not be well followed out, in consequence of the difficulty in always keeping the paws uncovered and immovable. Taking food (which was given twice in the twenty-four hours) did not seem to me to interrupt the course of the curve in most of the dogs; but in some it was evidently attended with a lowering of temperature, perhaps because they endeavoured to stand on the leg.

While the sound leg was cool, the paralysed one, the animal being stretched out, generally had a temperature of from 5° to 14° Fahr. higher. When the temperature of the sound limb rose, that in the paralysed limb might remain stationary; but the temperature on the two sides did not become equal, since before this equality could be reached there was a rise of temperature in the paralysed limb, at first more rapidly than in the sound one; but towards the end of the rise the heat of the paralytic limb somewhat abated and at last became stationary, while that in the sound limb continued to increase, until at last it for a time slightly exceeded that of the paralysed limb. I have thus often found that late in the evening the paralysed limb had a temperature of 95° or 96° , while the healthy limb had one of 98° , and even in some cases 100.5° or more.

When the animal was allowed to run about in the room in the morning, the temperature being relatively low, and, if the weather were dry, in the garden, the temperature of the paws fell a little; and in animals which had recovered from the first effects of the operation, and moved with their two hind limbs, it was seen without exception that the temperature of the paralysed limb fell more rapidly. Sometimes it reached a point a little above that of the healthy limb; but most frequently I observed it to fall to about 1.5° or 1.8° or 2.7° lower. If the animal then rested, the temperatures became almost equal; but it was some time before the temperature of the paralysed limb again became higher than that of the sound one.

If the animals lay well stretched out in their box, the temperature of the air being above 86° or 89.6° Fahr., the two hind limbs became warmer, the sound limb becoming 1.8 or 3.5 degrees warmer than the paralysed one. The same was observed in paralytic animals, in which the hind limbs, which were warmer before the animals were placed in a stove, remained colder than the fore limbs when the temperature of the animal was in equilibrium with the surrounding atmosphere.

From these facts, it may be concluded that, in animals at rest and not tied down, paralysis of the vaso-motor nerves limits the oscillations of temperature, inasmuch as these oscillations, both upwards and downwards, remain inferior to those of the corresponding sound part. In an animal at rest, the oscillations *below* the medium are more limited in the paralysed part than those *above* the medium; thus, when the two extremities become moderately cool, the paralysed limb remains considerably warmer than the sound one, and when the limbs again become warm, the sound limb may become only a little warmer than the paralysed one.

It is difficult, from various causes, to make a correct observation of the medium temperature; and it is necessary to make several observations to obtain a satisfactory result. In a dog, on the first day after removing the inferior cervical ganglion, I have found a difference of nearly 22 degrees in favour of the affected limb. When the wound was healed, and the animal had become accustomed to lie stretched in its box, there was found in the fourth week an average difference of about 11 degrees in the same direction. When the two limbs were at their highest temperature, the sound was about 1.6 degrees warmer than the paralysed one. Under the same circumstances I have found in a dog, three months after division of the sciatic nerve, an average difference of more than 7 degrees in favour of the paralysed limb. If the animal were then allowed to run about in the garden, the difference at first diminished, and after some days rapidly increased. But with this increase ulceration was observed to commence on the dorsum of the toes. After division of the abdominal sympathetic on one side between the third and fourth lumbar ganglia, the permanent average difference was only 3.5 degrees, when the animal ran about freely in the garden in the intervals of measurement, and when each measurement, made every second hour, was preceded by rest for twenty minutes in the extended position on a piece of woollen. In the same dog, placed *permanently* on woollen, the average difference rose to 7.5° . The maximum rise of temperature was about 1.8 degrees less in the paralysed than in the sound limb.

(To be continued.)

VULPIAN'S EXPERIMENTAL PATHOLOGICAL STUDIES ON THE PHYSIOLOGICAL ACTION OF TOXIC AND MEDICINAL SUBSTANCES.

(Continued from page 398.)

M. Vulpian proceeds to describe the action of jaborandi on the heart and on the iris. He illustrated his lecture by experiments on frogs. Taking some frogs whose hearts were laid bare, he introduced a considerable quantity of the aqueous extract of jaborandi leaves under the skin of the tibial region of one of the legs. Another frog, whose heart was also exposed to view, but which had not been poisoned, was placed on the same board as the first frog. The subcutaneous insertion of the extract of jaborandi leaves had been made for a longer or shorter space of time on the frogs submitted to the action of that substance, so that the different degrees of that action could be seen. In the frogs most recently operated on, the movements of the heart were much agitated, but not stopped; the auricles were gorged with blood, and did not contract themselves completely at every systole. The systoles of the ventricles were more complete. Jaborandi acts more rapidly on the auricles than on the ventricles. On the frogs in which the subcutaneous insertion of the extract had been made for about a quarter of an hour, the heart stopped; the auricles and the ventricles remained motionless in full diastole. The state of the heart entirely represents that which is produced by muscarine. M. Vulpian then placed one drop of a slightly concentrated watery solution of sulphate of atropia on the heart of one of these frogs. After some moments, spontaneous and rhythmic movements reappeared in the auricles and ventricles. These movements, at first weak, became gradually stronger, and soon, sometimes at the end of a minute, became as strong as and even stronger than in the normal condition. In other frogs he injected, under the skin of the tibial region of one of the hind legs, one drop of the solution of atropia, which had been used to revive the movements of the heart stopped by the extract of jaborandi. Ten minutes after this injection had been made, and whilst the previously exposed heart was beating regularly and strongly, M. Vulpian introduced into the tibial region of the hind leg of the opposite side a large quantity of extract of jaborandi. The heart was not in the slightest degree disturbed, the atropia having completely protected that organ from the ordinary effects of the extract of jaborandi. This constitutes a point of resemblance between the watery extract of jaborandi and muscarine. If the watery extract of jaborandi be placed in direct contact with the exposed heart of other frogs, the effects will not be precisely identical with those of muscarine. Muscarine, in these conditions, arrests the heart in full diastole, as when it is subcutaneously introduced into a limb the heart brought into contact with the extract of jaborandi will also stop in a few moments, but the ventricle will be contracted in tonic systole; that is to say, in a similar state to that produced by the action of digitaline or any other analogous poison on the heart. It is very evident that this kind of stoppage of the heart, in the case of direct application of the extract of jaborandi to that organ, is due to a direct irritant action on the myocardium. If a drop of the solution of sulphate of atropia be placed in contact with the heart thus stopped, the effect will be different, according as the stoppage is quite recent

or has lasted for a certain time. If the stoppage have only lasted a few instants, the spontaneous rhythmical movements of the heart may revive. If the systolic stoppage of the ventricle have lasted for some minutes, the sulphate of atropia may remain inactive.

In mammalia, it is by the help of intravenous injections of jaborandi leaves that the paralysing action of the active principles of this plant on the heart may specially be shown. M. Vulpian, in one of his experimental lectures, showed an experiment which left no doubt on the subject. An index was placed in contact with the heart of a dog, which had not been subjected to any preliminary drugging, through the thoracic walls; then forty grammes of water, in which four grammes of pulverised jaborandi leaves had been infused, were slowly and carefully injected towards the heart.

By the aid of the index the movements of the heart were seen to be agitated, become very irregular, and at the end of some seconds very much slackened; from 120 to 130 per minute, their number had fallen to five or six in the same space of time. Almost immediately two centigrammes of sulphate of atropia in a solution of about fifteen grammes of water were injected into the same vein, by the heart. In less than half a minute the movements of the heart had regained their frequency and their normal condition; they even became more rapid than before the injection of the jaborandi.

Similar effects are observed if a watery infusion of two or four grammes of jaborandi leaves be injected into one of the crural veins of a dog previously chloralised by intravenous injection of hydrate of chloral. If sulphate of atropia be injected into the subcutaneous cellular tissue of a dog twenty minutes before giving it an intravenous injection of a watery infusion of three to four grammes of jaborandi leaves, this injection will not exercise the least influence over the movements of the heart. An analogous result is registered when the experiment is made on a dog curarised and submitted to artificial respiration. Under these conditions, the intravenous injection of a watery infusion of three or four grammes of jaborandi does not, as a rule, produce any slackening or notable disturbance of the heart's movements.

Curare retards, weakens, or even also prevents the action of the extract of jaborandi on the heart of the frog. If a strong dose of this extract be introduced under the skin of the tibial region of one of the hind legs in a previously curarised frog, the movements of the heart may not show any modification either in energy or frequency during the whole time (one, two, or even more hours) that the animal will remain under observation. This effect of curare is explained by the weakening of the movements of the heart produced by this poison. As to this weakening, it is itself due on the one hand to a certain amount of paralysing action exercised by the curare on the intrinsic nervous system of the heart, on the other to the slight paralytic dilatation it brings on in the peripheral vessels. As the dilatation of the peripheral vessels and the weakening of the movements of the heart result in a slackening of the circulation in the capillary network, the absorption of the substances introduced subcutaneously should be slackened. As the quantity of blood which flows after each systole into the cardiac cavities is smaller than in the normal condition; as on the other hand this blood contains less of the active principles of jaborandi, since the absorption is slower, a considerable diminution of the action of these principles on the heart

necessarily results. These remarks are also applicable, at least in great part, to the mammalia, and may afford an explanation of the influence of the preliminary curarisation on the cardiac effects of the intra-venous injection of a watery infusion of three or four grammes of jaborandi leaves.

M. Vulpian cannot declare himself certain whether the substance which in jaborandi produces the slackenings and the diastolic arrest of the movements of the heart is different from those which bring on sialorrhoea and diaphoresis. He, however, points out that the watery extract of jaborandi retains its sialagogue and sudorific properties a long time after its preparation, whilst it loses nearly entirely at the end of a few days, the property of acting on the heart of the frog by subcutaneous absorption. This observation will evidently have a certain importance from this point of view. But it should be added that in mammalia the difference between the freshly prepared extract and that a little older, with regard to action on the heart, has been much less striking. The extract which has been prepared for one or two months still acts powerfully on the heart of dogs, into the crural veins of which it has been injected. The extract of jaborandi acts then on the heart of the frog by subcutaneous absorption, by producing a diastolic arrest of its constituent parts, like muscarine. It is probable that the mechanism of its cardiac action is the same as that of the action of this last-named poison. Like muscarine it seems to bring on diastolic arrest of the auricles and ventricles in the frog, by exciting the peripheric extremities of the moderator nerves of the heart, that is to say, the cardiac filaments of the vagus. But it is allowable to ask if there is not an error of interpretation here, and if its true action does not consist in a paralysis of the peripheric extremities of the sympathetic nerves, of those which are exciters of the cardiac movements.

Finally, M. Vulpian refers to the considerable amount of myosis brought on in mammalia by jaborandi. This contraction of the pupil is as marked as that produced by the extract of Calabar beans. It is, likewise, only distinctly present, as we have seen, when the extract of jaborandi is applied directly to the eyeball, between the lids. M. Vulpian reminds his hearers that the injections of infusion of jaborandi leaves into the veins provoke on the contrary a dilatation of the pupil, due, without doubt, to the irritation originating in the viscera, especially in the gastro-intestinal canal, under the influence of these injections.

The extract of jaborandi therefore acts on the iris in a manner totally opposed to the action of atropia on that organ. These two substances are still more antagonistic with regard to their influence on the iris than they are with regard to their influence on the secretions and on the heart. Atropia dilates the pupil by exciting the peripheric extremities of the sympathetic nerve-fibres which distribute themselves to the iris; at least, this is the theory admitted by the majority of physiologists. It may therefore be presumed that jaborandi acts in an inverse fashion to produce pupillar contraction.

According to this hypothesis, it would be by paralysing these same peripheric extremities of the sympathetic cardiac fibres, that the active principles of this plant induce the considerable contraction of the pupil observed after the application of the extract of jaborandi to the eye. It is a question whether the sympathetic nerves of the iris may not be considered,

up to a certain point, as moderator nerves, preventing the filaments of the motor oculi communis from displaying all their activity, and inducing a permanent constriction of the pupil. This is a question which is raised by the study of the comparative actions of the extracts of jaborandi and atropia on the iris, and the examination of which is reserved by M. Vulpian for his lectures on the action of belladonna and atropia.

HEWSON ON THE TREATMENT OF FRACTURES BY SUSPENSION.

The following lecture by Dr. Addinell Hewson, of Pennsylvania Hospital, on the treatment of fractures by suspension, and the mechanical principles involved in it, has recently appeared in the *Philadelphia Medical Reporter*.

As I stand very much alone among the teachers of surgery in Philadelphia, in advocating the method of suspension in the treatment of fractures of the lower extremities, I will avail myself of the occasion of showing you, to-day, the results of such treatment in a case of fractured thigh, to discuss some of the mechanics involved in it. This case was admitted six weeks ago, with an oblique fracture of his right thigh, at about the junction of its middle and upper third. When admitted, there was one inch and a half shortening, the lower fragment being drawn up under the upper, which was rotated and tilted forward. Immediately on admission he was put in the apparatus most generally in use here. Sand-bags and extension by pendent weights (that of two of our Philadelphia bricks suspended over a pulley of two inches diameter) secured at the foot of the bed. This apparatus having been applied before I saw him, I made no change until two weeks had elapsed, when it was evident to all that a bad result would ensue if the plan were continued. You will remember that I then brought him before the class, and after pointing out the deformity and shortening, still one inch and a half, I also stated briefly my convictions that no plan of treatment in the horizontal position could make a perfect cure in such a case; that the plan to be adopted must be one which would bring the lower fragment into the plane of the upper, for there was none by which we could reduce such an upper fragment to the line of the lower. The plan for this, then, was evidently that known as flexion, and of its varieties. I briefly stated my preference for the suspended splint of Professor N. R. Smith, of Baltimore. This splint I then applied in your presence, and to-day I have to show you the result of its four weeks' continuous use. The patient, you see, seems perfectly comfortable with the limb suspended. He sits up in bed, and moves about from side to side, and would seem to have no forces exerting their influence on his limb. In a former lecture I referred to the value of fixing the neighbouring joints in the treatment of fractures, and here you will notice the knee has been controlled by a small angular splint in the ham, and there has been applied laterally a large piece of binder's board, to keep the fragments in the same plane, and so let him have the use of his hip to sit up or change the angle of his body when desirable. Otherwise, we should have had to fix the hip-joint.

On removing the apparatus and straightening the limb on the bed, you see there is no deformity at the seat of fracture, and little if any shortening. By close examination, we can detect callus at the seat

of fracture, but no distortion in the line of the limb. And as to the shortening, measurements by the most accurate means do not reveal anything over half an inch, a result, in that respect, far better than we had any right to expect, for you will remember that this has all been accomplished in the last four weeks. When I direct the patient to rotate the limb from the hip-joint, and compare this motion with similar motion in the other, you will notice some little difference; that is, he averts the foot of the fractured limb to a less extent, and inverts it to a greater extent than he does the one of the sound side. This we see constantly after the best of cures of fractures in the upper part of the thigh, and always in a more marked manner where the cure has been made by extension on the horizontal plane; this is from the fact I have stated to you before—the rotation of the upper fragment, which is not met at all in the latter method of treatment as it is in the former. The cure in this case may, therefore, be unhesitatingly pronounced a perfect one.

I remarked to you a moment ago, before disturbing the dressing, that the patient seemed, with his limb suspended in the air, to have no forces whatever exerting their influence on his limb. Now I will show you, by a simple experiment of suspending his nude limb in a sling below the knee, attached to a cord passed over a small pulley wheel, and a movable force attached to the other end of that cord, that it requires a considerable amount of force to hold the heel sufficiently off the bed to allow the limb to swing. To maintain so slight an elevation as this, you see the weight of three whole bricks (over thirteen pounds) is required; and as the segments of the cord from each side of the pulley are parallel, and the pulley is fixed, we know, by a law of elementary mechanics, that the resistance and power are just equal in gravity. To raise the limb still higher, we have, as you see, to add more bricks to the cord; and to overcome such gravity as exists in the limb, flexed at the knee, and raised high enough to make the axis of the thigh form an angle of about twenty degrees with the plane of the bed, we have to use six bricks, or twenty-seven pounds weight. Effects of such resistance and power are to be seen in this man's ham, by the condition of the tissues there; they are reddened from the pressure. I will now re-apply the dressing, and as I do so you will notice that I first, after supporting the bent knee on a pillow, secure the wire splint on a dorsum of the limb by a number of strips of bandage, two at the knee-joint, retaining the angular splint in the ham; two at different points of the thigh; two, for the same purpose and manner, in the leg portion, and one for the heel. I then suspend the whole from the pulley by the cord, using, as a counteracting force to the resistance offered by the limb, a check-block on the two parts of the cord, so that we do not have the movable force, as with the bricks. I am not only careful now to see that the tension in each of these strips is the same, but move the frame from which the suspension is made so far down the bed that the suspending cord will no longer be perpendicular to the bed, but form such an acute angle as will increase the traction on the lower fragment, and even, when we require it, raise the buttock off the bed, sufficient to pass the hand under it. This being done, we next apply a roller from the toes up to the groin, and so effect a thorough diffusion of the resisting force offered to such a position of the whole limb. To maintain the limb in that position, I will now show you that the

movable weight of seven bricks is required; that is, over thirty pounds. You can, therefore, no longer think that there are no forces at work keeping up extension and counter-extension at the seat of fracture in such a case, when suspension is being used. This I wish to discuss with you still more accurately in relation to the principles of mechanics involved in it, and for that purpose I will first consider those involved in the method (Fig. 1) of extension, so called.

If we take C L F K to represent the fractured limb, when in an extended position, and A B the surface of the bed covered by that limb, we have the weight of the limb diffused over that surface, and the weight and resistance are equal; we have the same state for the rest of the body and surface of

bed covered by it. The surface of the bed being horizontal, the centres of gravity for every portion of this man's body and limbs, when at rest, are at right angles to the surface underneath them, and the corresponding points of the bed furnish, in each instance, a resisting force in a vertical direction, and directly opposing them. In this respect both limbs are alike, but where a fracture exists in one a new force comes into play to disturb this state of rest, and which has no such action in the sound limb. I refer to the traction-force produced by the muscles on the front and back part of the thigh, known as its long flexors and extensors. These, by the tilting up and forward of the upper fragment, do not have the firm resistance offered, through the axis of the thigh-bone, to their free contraction, as in the other limb; but, as by their contractions they will approximate the points of their origin and insertion nearer and nearer to each other, a displacement must be effected in the portion of limb below the fracture, if their contractions are capable of moving it on the bed, for such muscles may be paralysed, and then no change of position is brought about, or they may be so weak as not to cause it. Where they are capable of producing shortening, it is evident they draw the limb up the bed; for, acting as a moving force between two movable bodies, they move and approximate, the lesser to the greater in weight. With the axis of the whole limb and the plane of the bed supporting it being still horizontal, the resultant of the action of these two sets of muscles would be in a horizontal line, owing to the lines of their forces forming the same angle with the axis of the thigh at the knee-joint, as seen in E F C and D F C, Fig. 2, provided these muscles were equal in force. A careful study of their relations at the hip-joint will show, however, that, even admitting the power of the muscles to be equal, their mode of application from there must result in other than a horizontal line. Thus D (Fig. 2), which represents the anterior superior spine of the ilium—the origin of the rectus femoris—and E, which represents the tuberosity of the ischium—the origin of the chief part of the ham-string muscles—when connected by a line, are found to bear a singular relation to C—the centre of the acetabulum and the fulcrum on

other, of the muscles, would appear, from the figure (2), to be about equal, but this is when the limb is extended at the knee-joint. When we flex that joint a different state exists, owing to both these sets of muscles being inserted into the leg-bones below the knee, and which revolve round the segment of the circle formed by the condyles of the femur. Hence when the knee-joint is bent to a right angle, the distance from E, the origin of the hamstring muscles, to their insertion, is absolutely diminished an inch and a half, and the tension brought to bear on the rectus femoris in that position is fully counterbalanced by the flexion of the thigh to the line of twenty or thirty degrees from the plane of the bed. Hence, in that position of the limb, elevated and flexed at the knee and hip-joint, the muscular power to resist the adjustment of the fracture, either where the manipulation of setting, as in the treatment by extension, or the application of the suspended splint, is reduced to a minimum. The advantage being decidedly for the latter method, as in it the reduction is made more gradual, and the same force which accomplished it is steadily kept up in the line in which it is most efficient, whereas, in the former, new forces have to be brought into play, and they in a line at great disadvantage. When we find, in a day or more, that the adjustment has been accomplished, that is, sufficient force has been exerted to overcome the displacing power of the muscles, we can readily relax or diminish it by lowering, so that the buttock rests well on the bed. Whereas, if at that time shortening is still evident, we can shorten the suspending cord of our splint, and so elevate the leg and lower fragment, and make the weight of the buttock an extending or traction force. Here the suspended limb resembles very accurately the arms of a quadrant balance, the leg representing the long loaded arm, and the lower fragment of the os femoris the short arm, to which is attached the weight to be balanced or drawn on. All above what is required to raise the knee up after the heel has ceased to rest on the bed must then be what is necessary to counterbalance such weight, or indicate the traction made on it. To carry the knee, in this instance, through twenty degrees, we found we had to use a force represented by three additional bricks, or over thirteen pounds, and to raise it ten degrees further we had to add another brick; making in all seven bricks to maintain the limb in the position of suspension which we desired. Setting three of these off for the weight of the limb below the fracture, we have had a traction-force of the balance, or eighteen pounds, constantly acting, and that without inconvenience to the patient, to overcome the shortening. I think I may, therefore, claim advantage for my favourite method of treatment, both as to the quantity of force and the direction in which we can use it, all demonstrable in accordance with the strict rules of mechanics.

BINET ON IDIOCY AND CONSANGUINITY.

Is consanguinity in itself a cause of degeneration, or does it favour such, or is it without influence? In the case where the related parents are so healthy as to produce sound, strong, and intelligent children, would they, if unhealthy, have produced pernicious results?

These, said Dr. Binet (*Annal. Méd.-Psycholog.*, Nov. 1874) are still debated questions, and opinions differ. In a certain department was a family, where

the parents were sound in mind and body, but their three children were idiots. Inquiries as to their antecedents elicited that the parents' grandmothers were sisters. They were married to men who were in no way related to themselves nor to each other. The elder of these two sisters had two boys and five girls, the younger two boys and two girls. One son of the younger married a daughter of the first (his first cousin), the other son married a woman in no way related to him. From these two brothers descended the parents of these idiots (thus related in the second degree). On the father's side are two blood-marriages, one after the other, on the mother's side one. In the families spoken of, there have been up to now, no hereditary failings such as insanity, epilepsy, idiocy, scrofula, etc. The direct and collateral ancestors were healthy in all respects, lived in the country, and were of mature age. The father of the idiots had no brothers or sisters, the mother had brothers and sisters who married, but whose children bore no signs of idiocy. The father was twenty-six years old when he married and the mother thirty; they lived regular and sober lives, and were in good circumstances.

The eldest of these three children was born twenty-seven months after marriage, at the full period. Up to the fifth month of pregnancy the mother had suffered from vomiting, loss of appetite, loathing of food, and was very thin. The birth was easy, and the mother made a quick recovery. The child was strong, suckled without difficulty, and seemed healthy. After five weeks it began to vomit, grew thin, and squinted; a slight amelioration followed, but the symptoms appeared off and on until death. The first tooth was cut at fifteen months, and only three came afterwards. There was a hernia; and the bowels were, as a rule, confined. It could not stand; it neither laughed, nor recognised anybody, even its mother, and only wept when it had pain in the bowels or was hungry. When twenty months old, it died in a state of marasmus.

The second child was a girl, born twenty-six months after the first. Born miserable, it yet took the breast well, and was given to a healthy wet-nurse. When five weeks old it began to vomit, squint, and was constipated; it never stood up, and for one year all development seemed arrested. There was no spinal curvature nor distortion of the bones. It had five incisor teeth, two above and three below, the first appearing at the eighteenth month. Like its brother, it preferred a dorsal posture, with the head bent backwards. Sensation was blunt, and it scarcely tried to drag away a limb when pinched, nor did it flinch when touched with a cold object. It never tried to talk, and in want of intelligence and power of recognition exactly resembled its brother.

The third child was also a girl, born easily, and reared by the mother. Vomiting, squinting, and emaciation came on at the fifth month. In face it resembled its sister, and was equally devoid of intelligence. At the end of one year it had no teeth, nor any muscular power. We see here three children whose intra-uterine and extra-uterine life was quite alike, in whom, during life, the same diseased appearances were seen, whose constitution was very weak, who in face and conduct bore the stamp of idiocy, and all in such a way that they could scarcely be distinguished. The parents were quite healthy, sober, and in easy circumstances, besides being free from hereditary or acquired defects. What conclusion can

be otherwise formed, than that the cause of the degeneration in the children lay in the consanguinity, which, at first without influence, finally asserted itself owing to repeated blood-marriages?

T. CLAYE SHAW, M.D.

LUSSANA AND ALBERTONI ON THE ACTION OF ALCOHOL, ALDEHYDE, AND THE VINIC ETHERS.

The last three monthly numbers of *Lo Sperimentale* for 1874, contain an elaborate article by Drs. Felice Lussana and Pietro Albertoni on the action of alcohol, aldehyde, and the ethers of wine. To this article was awarded the prize of 500 lire (20*l.*), annually offered by the editorial staff of that journal for the best article published in its pages during the year. It occupies in all 136 pages, and contains the details of 129 experiments on alcohol, 74 on aldehyde, and 14 on vinic ethers, carried out in the physiological laboratory at Padua.

The authors treat of the subject under the following heads:—1. Comparative and pathological action of alcohol in various animals; 2. Absorption of alcohol; 3. Elimination of alcohol; 4. Action of alcohol on the blood; 5. Action of alcohol on the nervous system; 6. Action of alcohol on the circulation; 7. Action of alcohol on animal temperature; 8. Modifications of alcohol in the organism; 9. The thermo-dynamogenic effect of alcohol; 10. Aldehyde; 11. The vinic ethers.

The subjoined summary is taken from the *Giornale Veneto delle Scienze Mediche* for March, 1875.

In their first article, after having studied and demonstrated the analogy of the effects of alcohol on animals with those on man, the authors point out how, among the phenomena of acute alcoholism, disturbance of the intellect prevails in man, while in dogs, and still more in birds, the phenomena of muscular disturbance are most prominent. This is compared with the anatomical fact, that in man the development of the nervous centres of intellect surpasses that of the motor centres, while the reverse is the case in dogs and birds. The centres of intelligence (cerebral hemispheres) bear the following proportions to those of motion (the mesencephalon and cerebellum): in man, 7·7 to 1; in dogs, 5·1 to 1; in birds, 2·8 to 1.

From this the conclusion is drawn, that the action of alcohol on the nervous system is in proportion to the relative development of the nervous centres. And this would appear to be in conformity with the general principle, that the action of a drug on various animals is in direct relation to the greater or less development of the organs on which it specially exerts its influence (Filippo Lussana). The truth of this being admitted, it may be argued that a substance will act in a smaller dose in proportion to the perfection of the organ on which it exerts its elective action. This appears to be proved by the following observations.

1. In man, alcohol affects the intellect when taken in a dose of 0·4 per 1,000 parts of body-weight; but to produce disturbance of the motor function, about 2·40 parts in 1,000 are required. 2. In dogs, alcohol only begins to produce its effects when the dose is in the proportion of 1·5 gramme to 1,000 of body-weight; and the phenomena are referable to the motor functions. 3. In birds also, the symptoms are those of motor disturbance, and are not produced by less than 3 parts in 1,000.

After some general remarks on the action of alcohol on various animal organisms, the authors treat of the ways in which it is absorbed. It appears from their experiments that its absorption is subordinate to its degree of concentration. If this be great, alcohol exerts a strong local irritant action, but a feeble general action; inasmuch as the part congested, deprived of its normal conditions, has its capability for ready and complete absorption impaired. In this way are explained the chronic catarrh of the stomach, and the alterations in the tongue and fauces, which are rather more frequent in liqueur-drinkers than in those addicted to wine. Alcohol of 38° Beaumé burdens digestion if not commenced, and suspends it if it be begun; while small quantities exert a beneficial effect on the digestive process.

The authors give proof of the fact which had already been stated but not demonstrated, that, besides being absorbed by the stomach, especially by the veins, alcohol is also absorbed by the large and small intestines, but in smaller proportions; and they offer a plausible anatomical explanation of this fact, in the presence in the stomach of a layer of epithelium, which renews itself much more rapidly, and which protects the subjacent absorbent layer of capillaries from the irritant action of the alcohol. When mixed with water in the proportion of 12 per cent., alcohol produces local effects on the rectum (hemorrhagic erosions), while it does not affect the stomach when taken in the proportion of 20 parts to 100 of water. From this arise practical deductions as to the most convenient way of administering alcohol in enemata.

If sufficiently diluted, it is absorbed hypodermically more readily and with greater effect than when given by the mouth. It is absorbed by the serous membranes; and still more readily, when properly diluted, by the air-passages.

The study of the absorption of alcohol is followed by that of its elimination. With others, the authors find that alcohol is exhaled in extremely minute quantities by the lungs. The smallest amount of elimination perhaps takes place through the skin; but more probably other products of its transformation, such as acetic acid, are eliminated in this way. The experiments performed by many had shown that very little or no unchanged alcohol escapes with the urine. But experiments continued for several days had not been made; the authors found alcohol in the urine collected for several consecutive days, from two men who had taken it, one in the proportion of 120 grammes, the other of 750 grammes daily. Small quantities only were found. It was found that alcohol did not pass off with the bile, thus showing the groundlessness of the hypothesis that alcohol is capable of dissolving biliary calculi.

The authors conclude that alcohol is eliminated from the system in very small quantities in the unchanged state. On the other hand, according to the experiments of Schulinus and others, much unchanged alcohol is still found in the blood and in the organs four hours after its absorption. The conclusion is therefore of necessity arrived at, that the greater part of the alcohol must undergo transformation within the organism.

As regards the action of alcohol on the blood, the authors regard as exaggerated the opinions of those who consider that it produces much change in the plasma or on the corpuscles. Microscopic examination showed only those changes which might be

attributed to any medium more or less concentrated. They regard changes produced in the blood by alcohol as indirect, that is to say, consequent on the changes in the blood-making organs, but not immediate.

With regard to the action of alcohol on the nervous system, the phenomena of intoxication are examined in their relation to the disturbances of intellect, motion, etc. The action of alcohol on sensation is especially studied. Contrary to the opinion held by many, the authors are led by numerous experiments to consider that, even when marked cerebral phenomena of alcoholism have appeared, sensation is often fairly well preserved. According to them, etherism, or the condition induced by anæsthetics, is to be distinguished from alcoholic inebriation.

In the sixth chapter of their memoir, the authors give a clear description of the action of alcohol on the circulation. Numerous sphygmographic tracings uniformly show how, under the use of alcohol, the line of ascent becomes higher, while in the line of descent there appears a very manifest dicrotism, or even a series of small dicrotisms. This increase of the line of ascent, according to Marey's laws, is to be solely ascribed to diminished blood-pressure; increased impulse of the heart, according to this distinguished physiologist, having nothing to do with it. This conclusion, adopted by Marvaud, Zimmerberger, and others, is not confirmed by Lussana and Albertoni; for, while the said increase of the line of ascent can be without doubt produced by a diminution of pressure, especially by a more ready flow of blood into the dilated capillaries, it cannot, on the other hand, be denied that the line of ascent may be increased by an augmented action of the heart. And in the case of alcohol, say the authors, we have both the one thing and the other; that is to say, there is dilatation of the capillaries, as shown by the redness of skin, sweat, and increased temperature, and there is an increase in the energy of the contractions of the heart; and, perhaps, the dilatation of the capillaries is only a consequence of the additional work on the part of the heart. A computation of the effect produced may be made by examining with the hand the impulse of the heart before and after the ingestion of alcohol, and observing the sphygmographic tracings made in like circumstances; and also, besides the subjective sensations, by comparing the traces obtained under the use of digitalis in a healthy man. Dicrotism is produced when the arterial tension is diminished (through dilatation of the capillaries) and when the ventricular systole is rather strong.

From numerous experiments on the action of alcohol on the temperature, made on dogs, birds, and man, the following conclusions are deduced. 1. In a healthy man, alcohol in a physiological dose does not produce a constant modification of the heat-making process; in the greater number of cases the temperature is lowered, in others it is raised, and in others again it is unchanged. The oscillations, whether upwards or downwards, amount only to a few tenths of a degree (centigrade). 2. In animals (dogs, guinea-pigs, birds) alcohol always lowers the temperature to several degrees below the average, according to the dose.

In order to clearly understand these results, it is necessary, the authors observe, to divide the effects of alcohol into, 1. those which it produces so far as it remains unchanged in the organism; 2. those which may arise from its transformation within the or-

ganism. When alcohol comes unchanged into contact with the tissues, it acts on them in a double manner; that is to say, as a nervine and through its physico-chemical properties. As a nervine it is very powerful, and excites the muscular nerves; and by its physical and chemical properties, it limits the process of organic decomposition, just as it does outside the organism. On the other hand, alcohol, in whatever way it is oxidised, develops caloric and tends to produce an increase of temperature, whether perceptible by the thermometer or dispersed by the cutaneous and pulmonary exhalation.

Alcohol, when absorbed, must be in great part transformed in the animal organism. But what are the modifications which it undergoes? According to Liebig, alcohol is oxidised in the system, carbonic acid and water being produced; he thus represented it to be a calorific material *par excellence*. But to this doctrine the two following facts are opposed. 1. The quantity of carbonic acid in the expired air is diminished after the ingestion of alcohol (Vierordt, Prout, Lehmann, Boecker, and Hammond). 2. The animal heat is generally diminished. On the other hand, the authors observe that, if the combustion of glucose gives equal parts of carbonic acid and water, that of alcohol should give one and a half of water, and one of carbonic acid. The heat developed by the oxidation of alcohol is expressed not only in the temperature of the animal, but also in that which is largely dispersed by the cutaneous and pulmonary transudations.

It is shown to be probable that in one of the phases of its transformation alcohol may furnish acetic acid. On the other hand, the authors exclude the formation of oxalic and formic acids, which may be produced by chemical processes by the oxidation of alcohol.

The next subject treated of is the transformation of alcohol into aldehyde; a view supported by Duchek, but opposed by Lallemand, Perrin, and Duroy. These last named observers showed that aldehyde was not found in the blood of animals in a state of alcoholic intoxication. Aldehyde, however, is a substance capable of producing the phenomena of inebriety when given in a very small dose (0.06 gramme in 1,000 of body-weight). On injecting into the veins of dogs apparently toxic doses of aldehyde, such as are certainly not produced in man, its presence could not be ascertained either in the blood or in the organs, or in the expired air. It was necessary to raise the dose to the proportion of more than a gramme in 1,000 of body-weight. On the other hand, the chemical possibility of an oxidation of alcohol in the blood, and the special phenomena of the first stage of aldehydic intoxication, which have all the characters of alcoholic intoxication, induce the authors to regard as probable the partial transformation of alcohol into aldehyde, in small proportions, and especially in certain cases. Certain experiments, from which it would appear that alcohol injected into the meseraic vein produces more effect than when injected into the jugular, producing the phenomena of anæsthesia, would lead to the suspicion that the seat of transformation of alcohol into aldehyde is the liver.

According to common opinion, alcohol increases the production of mechanical force. But it would seem that alcohol, while it excites the muscular and cardiac forces, also reduces the consumption of material and the organic waste; for the ex-

pired air contains less carbonic acid and there is less urea in the urine. Such a diminution of urea was found in the author's experiments; but they regard it as only apparent and temporary, inasmuch as the degenerations and alterations of the tissues and the atrophy of the organs ultimately show the loss which the organism has undergone.

In the production of mechanical force, alcohol, besides its calorific properties, has a great importance and superiority over similar aliments. With a smaller amount of combustible matter and in less time it produces more force.

Lastly, the authors notice and answer all the objections which have been urged against the opinion that alcohol is an aliment; that is to say, a powerful thermo-dynamogenic, not a plastic aliment. They do not regard as valid the objection that alcohol remains unchanged in the blood and the tissues; or that it passes unchanged, and that traces of its decomposition are not found in the blood and in the secretions: circumstances which are not met with in the case of true aliments. Fat and glucose are good aliments, and yet may remain unchanged in the organism, and pass in part unchanged in the urine, just as albuminose itself may pass. Nor do they recognise the objections, that alcohol produces the phenomena of poisonous but not alimentary substances; that it does not nourish, and does not enter into the composition of the tissues; and that it shows its presence by special effects, while food does not show any appreciable effect on the functions of the organs and on the various apparatus. Alcohol acts not only as a thermo-dynamogenous aliment, but also as a nervine aliment, so far as it remains unchanged.

But it is not enough that alimentation gives a stimulus to labour; it must also furnish material for the nutrition and repair of the tissues. And this is what alcohol does not do. Hence, without a proper supply of nitrogenous food, the muscles and the heart undergo degeneration. Herein lies the explanation of the good and the bad effects attributed to alcohol.

In order to elucidate the question of the transformation of alcohol into aldehyde, the authors studied in detail the action of this substance. After some general remarks on its chemical properties, they show that aldehyde has a preservative action on albuminoid substances, even when diluted with water (3 per 100.) Aldehyde is a substance possessing very powerful action; when given in a dose of six centigrammes for each 1,000 grammes of body weight, it produces marked phenomena in dogs. When injected into the veins, it gives rise to great pain, indicated by cries. This is succeeded, according to the dose, by a stage of excitement, of intoxication, or of anæsthesia, terminating in asphyxia. The state produced presents a great analogy to etherism. The stage of intoxication resembles alcoholic intoxication; but sensibility is more diminished. During this stage the animal breathes quietly, while in a state of coma with abolished sensibility. Beyond this, the animal falls into a state of asphyxia, in which reflex action and respiration are suppressed; the heart, however, continues to beat strongly. The animal may remain in this state for some minutes, and then perfectly recover. But if the asphyxia be prolonged beyond a certain time, death follows.

Aldehyde acts through the stomach much less than through the veins; it has a very powerful irritant and caustic local action, like a caustic alkali. It is

but slightly capable of hypodermic absorption; on the other hand, when inhaled like ether, it readily produces anæsthesia.

The effects of aldehyde on respiration are the following. 1. In a small dose, it at once increases the frequency of respiration. 2. In a large dose, it at first completely suspends respiration (stage of asphyxia); the breathing then returns, but at rare intervals (three or four respirations in the minute); it then becomes more frequent, and regular; and at last is accelerated, being as much as sixty in the minute.

The action of aldehyde on the circulation is very interesting and presents some notable peculiarities, which are illustrated by kymographic tracings taken from dogs under its action, in the stages of excitement, of simple anæsthesia, and of asphyxia. The experiments lead to the following conclusions. 1. In the stage of excitement, there is increase of the blood-pressure, slight alteration in the number of the beats of the heart, great increase of the impulse, and enormous acceleration of respiration. 2. In the stage of asphyxia the blood-pressure is perhaps increased, always so, from the beginning even, in cases where the asphyxia ends in death. 3. The fact which, beyond all others, attracts attention, is the great regularity of the cardiac pulsations in the stage of asphyxia, indicating plainly that the heart beats after the manner of a chronometer, when all disturbing nervous influence is removed. But it is known that the rhythm of the cardiac pulsations in dogs is physiologically irregular. Aldehyde renders it regular and uniform, just as section of the two vagi nerves does in the same animals. From the authors' experiments on this point, the following results are deduced. 1. During the stage of asphyxia and anæsthesia, when the rhythm of the cardiac pulsations is regular, as long as the respiration is suspended galvanism has no effect on the heart. 2. The influence of galvanism of the vagus on the heart reappears at the same time with the re-establishment of the respiratory function; it increases in proportion as the animal recovers from the stage of asphyxia and as the respiration becomes more active. 3. As long as the animal remains under the action of aldehyde, galvanism of the vagus is incapable of completely suspending the cardiac pulsations. Even when the respiration is very frequent, galvanism does not altogether suspend the beats of the heart, but reduces their strength and frequency in dogs, in which, in their normal state, it produced complete arrest of the heart's action. The galvanism of the vagus in animals under the influence of aldehyde always produces a lowering of the blood-pressure.

From these facts, the authors are led to believe that aldehyde acts by reducing and extinguishing the excitability of the vagus nerves, especially their cardiac fibres. In fact, the heart remains insensible to their galvanisation during the stage of complete asphyxia, that is to say, when the respiratory function of these nerves is also suspended; and as respiration is gradually re-established, galvanism of the nerves exerts a greater action on the heart.

With regard to the action of aldehyde on temperature, the following are the conclusions. 1. The effects on temperature are absent, slight, and of short duration, if the aldehyde produce only transient intoxication. 2. Aldehyde lowers the temperature if the intoxication be considerable.

The authors regard aldehyde as a rapid and potent

anæsthetic, well-borne by the organism, but difficult of appreciation in practice.

Finally, the action of the vinic ethers is studied, with the view of distinguishing the effects of alcohol from those produced by the other substances with which it is combined in wine. It is shown that acetic and butyric ethers do not possess any special action, and that cœnanthic ether may assist digestion and stimulate the circulation. A. HENRY, M.D.

MOXON ON INSULAR SCLEROSIS.

The recognition of this disease by English physicians, Dr. Moxon observes (*Guy's Hospital Reports*, vol. xx. Third Series, 1875), will appear singularly slow when its characters shall become more generally known. It will then appear strange that this singular and definite disease has not yet been admitted by the profession in this country, although it has not only constant and characteristic symptoms, but also a peculiar and remarkable morbid anatomy. Of eight cases related by Dr. Moxon, two have been verified by *post mortem* examinations. These are the only two instances on record in which, on this side of the channel, the diagnosis has been made sure by inspection after death.

The symptoms of insular sclerosis* are various in different cases, but still they can be recognised in all cases. Dr. Moxon puts the question: 'When a case comes before one with cerebro-spinal symptoms, are these due to round patches of grey degeneration in the nervous centres, or are they not?' 'This is a question,' he adds, 'which can be answered with certainty, yet the disease is not even alluded to in the nosological list of the Royal College of Physicians, and no English author as yet has given any attention to it.'

The diagnostic characters of insular sclerosis are: (1) A peculiar trembling of the head and limbs during movements, ceasing when the parts are supported; (2) paralytic weakness of the extremities without numbness; (3) rigidity or contractions of the lower extremities; (4) nystagmus (twitching of the eyeballs); (5) little disturbance of power over the excretions; (6) normal electro-excitability; (7) a peculiar affection of the speech, so that syllables are uttered with morbid distinctness of accent; (8) the intellect and control of emotions ultimately somewhat impaired without morbid delusions or morbid moral aberration.

The peculiar trembling is difficult to describe. 'When at rest in bed the patient gives no sign of his malady, but on attempting to rise, when the hands are extended to grasp some object for help, they oscillate with a quickish waving or wagging movement, generally pretty regularly, almost rhythmically indeed. The most evident movement is usually that of flexion and extension at the wrist, as the hand is stretched out prone or semi-prone; but the agitation implicates the whole limb to a less degree.' The legs are involved in this tremulous movement, in the early stages, but ultimately fall into a state of paralysis and stiffness.

These jogging movements, although in the de-

scription they may seem to resemble other nervous tremblings, yet require only to be seen for their differences to be recognised.

The paralytic weakness is more pronounced in the lower extremities, which may ultimately become completely palsied. Constipation occurs from weakness of the abdominal muscles.

The cutaneous sensibility is not diminished beyond an occasional subjective slight numbness. The contractions and rigidity of the limbs are observed chiefly in the lower extremities, and bear a direct proportion to the paralysis. The twitching of the eyeballs is absent during rest, *i.e.*, when the gaze is straightforward and passive.

The affection of the speech is one of the principal features of the disease. The words are pronounced a syllable at a time, slowly and distinctly. This does not arise from paralysis of the tongue. There is no very marked enfeeblement of mind, but there are bursts of unmeaning laughter, or of weeping, out of relation to its proper causes. The impulses are beyond control. There are hopefulness at one time and depression at another, without corresponding variation in the course of the complaint. Ultimately the patient becomes inattentive even to the involuntary passing of the evacuations.

These symptoms are constant in their occurrence, although there may be distinguished three principal varieties, namely cerebral, spinal, and cerebro-spinal.

The morbid anatomy of insular sclerosis shows patches of this grey degeneration scattered broadcast throughout the nervous centres, so evidently distributed indifferently to the structural composition of the nervous mass, that it is at once a cause of natural surprise that there should be any describable exact set of symptoms attached to a change so variously placed. The variation of symptoms is doubtless due to the large number of locations of the sclerotic change. The minute anatomy is evidently that of chronic inflammation; the details of this condition are revealed by the microscope with the greatest clearness.

The elementary items of the morbid change seen in recent specimens are granule-cells, amyloid corpuscles, adventitious fibrous and fibroid substances with nuclei; also disintegrating nerve-fibres or nerve-cells, which latter, however, are always much less affected than the fibres.

In hardened and coloured sections of the spinal cord, cleared with oil of cloves, the changes may be followed with great exactness. The incipient sclerotic patch shows as a thickening and extension of the medullary rays of connective tissue [inter-columnar septa?—*Rep.*] which progressively become largely invaded. This change is rendered visible by its deep red carmine tint among the comparatively uncoloured medullary matter. As the lesion extends the nerve-tubes and their axis cylinders disappear, and the more deeply tinted, altered connective tissue, takes their places. This altered nucleated tissue becomes more and more fibrous.

With this change Dr. Moxon finds an analogy in the subacute arteritis, which he has called 'inflammatory mollities.' The same change, he observes, which renders the aortic coats softer, renders the brain harder. In the one case the new fibrous substance displaces an elastic firm tissue, in the other it displaces a soft medullary structure. Further, Dr. Moxon traces an analogy in this disease to 'cystoid disease' of the bones, as described by Froriep and

* The term 'insular' is here employed as having a more definite meaning than 'disseminated,' and as expressing well the islet-like appearance of *sclérose en plaques*. [It further distinguishes this lesion from what has come to be known as 'miliary sclerosis,' which lesion, however, from its want of structure, would be more correctly designated 'miliary degeneration.'—*Rep.*]

Engel. One common relationship the 'author finds among all these forms of disease, viz., that there is reason to regard these disorders as eruptive. 'Eruptions are not only to be expected in the skin; in small-pox, the inward reflections of the integument show the characteristic eruptions. In syphilis the same kind of action is found in the muscles, bones, etc., in the form of gumma. I believe an essentially eruptive nature belongs to such maladies as I have mentioned with insular sclerosis. By an essentially eruptive nature I mean that the local disease is set up by some agency which is of a specific kind, and is not native in the part in which the change is seen.'

The results of the treatment used in these cases have been most unsatisfactory, no approach to a cure having been made. The details of the eight cases given by Dr. Moxon record the employment, without any benefit, of arsenic, iodide of potassium, bichloride of mercury, nitrate of silver, and electricity.

The drawings which accompany this paper, admirably illustrate and explain the text. This is more particularly true of plate 2, which give details of the changes in the connective tissue of the cord.

W. B. KESTEVEN, M.D.

A LOST ART OF MEDICINE. BY S. D. GROSS, M.D.

An Address delivered before the American Medical Association.*

[We here reproduce in full, with the exception of some preliminary opening matter, the address of Professor Gross before the American Medical Association. After contrasting the present disuse of venesection with the universal employment of it in his boyhood, and asserting that bleeding is emphatically one of the lost arts, the venerable Professor continued as follows.]

How this extraordinary change in sentiment and practice was brought about, by what influence, agency, authority, philosophy, logic, or mode of reasoning, is a matter worthy of brief inquiry. The causes, so far as they are patent to my mind, are mainly four: First, the influence or tyranny of authority, soon passing into more or less extensive fashion; secondly, the indiscriminate employment of the lancet in the days of what has been termed, not inappropriately, the Sangrado practice; thirdly, a more accurate knowledge of the nature and seat of diseases; and, lastly, the use of certain remedies unknown a third of a century ago, but now of general, if not universal resort, in the treatment of inflammatory affections.

I. The influence of authority annually slays millions of human beings. Its pernicious effects upon human life, in its individual and collective relations, are felt in every direction; in the construction of our dwellings, in our habits and occupations, in our dress, in our social entertainments, in our amusements, in our food and drink, and in a thousand other ways. Of its malign influence in our profession examples daily fall under our observation, as the result of pernicious doctrines and practices. Superstition and fanaticism have kept the world in a state of intellectual bondage from the earliest records of society down to the present moment. The spiritualism of the present day has its counterpart in the witchcraft of three centuries ago, fortunately without the hang-

man's halter. Every age has its peculiar absurdities, characteristic of the minds of some of its people. Mesmerism deluded thousands of persons. The metallic tractors of Perkins enjoyed for a time a world-wide notoriety. Homœopathy is still at work in deluding the world. Clairvoyance has many devout adherents. Berkeley, in the middle of the last century, effected many wonderful cures with the aid of his tar-water. For upwards of one hundred years the lancet enjoyed unlimited sway. Everybody was bled. Surgeons, during the last dozen years, have had carbolic acid on the brain as a dressing in wounds and other injuries. Broussais, Cookeism, and the blue pill of Abernethy, each had a reign of at least a quarter of a century. For an equally long period the medical mind of Italy was agitated by the tartar-emetic treatment of Rasori and his followers. Thompsonianism, or the lobelia and cayenne-pepper treatment, is not yet entirely extinct on this continent, although its days were numbered long ago. For nearly a third of a century the doctrine of a change of type in disease has tyrannised over the minds of medical men, and exerted a controlling influence upon their practice. Of all these delusions, the latter, often called Toddism, after Dr. Todd, its author, has exercised the most pervasive and baneful effects upon civilised society. Ensnconing itself behind a false position, it has literally enslaved the medical world, entrapping alike the wise and the foolish, and sweeping over human life with a force equal to that of the fiercest and most destructive hurricane. Unlike the doctrine of sthenic and asthenic diseases of Dr. John Brown, who in the latter part of the last century enjoyed such a wide celebrity as a medical reformer, it assumes that all maladies are of a low type, imperatively demanding the use of stimulants for their successful management. It countenances no half-way measures. The patient must be upheld by stimulants or he must die. Now and then, perhaps, a few leeches may be tolerated, but only in very exceptional cases, where there is not too much depression of the vital powers. Who and what Dr. Todd, the author of this system of medicine, was, it would be needless to inquire. Everybody knows that he was one of the ablest writers and clinical teachers whom this century has produced; but that he was a profound thinker I doubt, and it is well to bear in mind that the class of patients at King's College Hospital, London, of which he had charge, were persons in the lower walks of life, broken down by overwork, privation, and various forms of intemperance, and therefore unable to bear depletory remedies. Such patients as Dr. Todd had are to be found in the wards of every eleemosynary institution in Europe and in this country. It was from a study of this class of cases that this famous man, in an evil hour, deduced the absurd doctrine of a change of type in disease. I say absurd, for if there ever was anything absurd this doctrine most assuredly deserves that name. Who that has any knowledge of the human constitution as it is daily met with in our intercourse with our fellow-citizens, in the various pursuits of life, will lend credence to such an idea; I had almost said to such a slander? I assert, without the fear of successful contradiction, that man's power of endurance in health and disease is not one particle less than it was fifty years ago, when depletory measures of every form were the order of the day; when, in fact, it would have been deemed derogatory to a phy-

* From the *Philadelphia Medical Times*, May 22.

sician's character to let a patient die without the aid of such remedies. The exploits performed during our late terrible war alone are sufficient to settle this question. Never, since man battled with man for national supremacy, were there so many rapid, laborious, and brilliant marches executed in so short a time as there were on both sides of the line. The exploits of the soldiers of Alexander, Hannibal, Cæsar, and Bonaparte fade into comparative insignificance by the side of those of some of our generals. Our labourers, farmers, miners, hewers of wood, carriers of water, mechanics, artisans, and professional men, evince no evidence of decline in muscular power or mental endurance. Our sailors are as hardy a race of men as they were in the days of Sir Francis Drake or Captain Cook.

If we look at the habits and modes of life of the people of the present day, it will be found, if I do not greatly err, that they do not differ in any essential manner, from those of a third of a century ago. The different classes of men and women, in city and in country, live very much as they did in my boyhood, using the same kind of food and drink, pursuing similar occupations and amusements, and exercising as much control over their appetites and passions generally as their fathers and mothers. If there be any differences in any of these particulars, they are certainly not well marked, nor so radical in their character as to diminish, in any material degree, the power of endurance of our people in health and disease. On the other hand, owing to the more extensive cultivation of our soil, the destruction of our forests, the draining of our marshes, and a greater attention paid to the study of hygiene, our people, especially those in the rural districts, are much more exempt from the diseases caused by the noxious exhalations from the earth's surface, so prevalent in newly settled countries, and so pernicious in their effects upon the constitution, than they were in the early days of my white and bald-headed contemporaries.

Do not men during accidents and surgical operations, and women during parturition, often lose enormous quantities of blood, and yet frequently make excellent recoveries? In epistaxis, hæmoptysis, and hæmatemesis, this fluid is often largely poured out, and yet it is seldom that we hear of a person dying from the effects of its loss.

In the face of such facts as these, and a hundred others that might be adduced if time permitted, the doctrine of a change of type in disease must fall to the ground as utterly untenable.

The influence of fashion is not limited to our profession. We all recollect how the crinoline of the French empress, invented to conceal a condition of which most ladies are proud, enslaved the female mind, until every woman, married and single, considered it as an indispensable article of dress. A sofa, however spacious, was hardly long enough for a woman thus arrayed to sit upon. How the fashion has changed within the last six or eight years is familiar to everybody. Now the dress is so narrow as to show the outline of the person, and compel the greatest care in progressing lest the fair wearer should trip and tear her garments. Even diseases occasionally become fashionable. When it became known that Louis XIV. was labouring under anal fistula, the disgusting malady became at once the fashionable ailment of his debauched court. The use of enemata was cultivated as one of the fine arts in France in the time of Molière, who lashed

the faculty without mercy for its follies and extravagancies.

2. The indiscriminate employment of the lancet in former days did much to bring blood-letting into discredit, not only with the better thinking class of physicians, but the public at large. 'We cure the sick,' says Gui Patin, a professor in the Royal College of France, 'when over eighty years old, by blood-letting, and also infants of not more than two or three months, with as much success and as little inconvenience.' Rush, the great champion of this operation on this side of the Atlantic, bled indiscriminately and remorselessly at all periods of life, the young, the middle-aged, and the old; in all kinds of diseases, in the eruptive fevers, in fever and ague, in puerperal fever, in inflammations, in injuries, in hæmorrhages, and even in anæmia, often taking immense quantities of blood, and repeating the operation six, eight, or even a dozen times in the same patient. In short, he and his followers used to bleed in every possible disorder until, in many cases, no more blood would flow, because there was none left. That such a practice would at length work out its own destruction is what might reasonably have been expected. It rang its own knell.

3. That we are much better acquainted with the nature and treatment of disease than our fathers were, is a fact so universally accepted as to require no argument in its support. Our progress in this respect, during the last forty years, has simply been marvellous; and to nothing are we so much indebted for these improvements as to the study of pathological anatomy and histology, and the astounding developments of chemical science.

4. That the treatment of disease has been greatly simplified within the period above specified is familiar to every member of the profession. Homœopathy, by the absurdities of its doctrines and primitive practices, long ago demonstrated to the world that most of its cures are effected spontaneously, through nature's restorative powers alone, while the patient's mind is medicated with the decillionth part of a drop or a grain of medicine; and in comparatively recent years two eminent medical philosophers, Professor Bigelow, of Boston, and Sir John Forbes, of London, showed us, by a series of admirably conducted observations, that certain diseases, as small-pox, scarlatina, measles, typhus and typhoid fevers, are self-limited in character, and therefore not to be materially if at all abridged in their course by any plan or means of medication whatever. A third of a century ago the only so-called depressants, aside from the use of the lancet, were tartar emetic, calomel, and digitalis, the latter of doubtful efficacy in any case, and the first often exhibited without due discrimination. Of aconite and veratrum viride, now so universally employed as antiphlogistic agents, we were totally ignorant. These two medicines, as I shall endeavour to prove by-and-by, although frequently of immense service in the treatment of inflammatory affections, are far, far inferior to blood-letting.

Believing that these are the principal, if not the only, reasons which have led to the abandonment of blood-letting as a therapeutic agent, I propose now to speak of the operation itself, and to point out, first, the classes of diseases to which it is more especially applicable; secondly, the period at which it should be performed to yield the greatest amount of good; and, lastly, its mode of action.

1. Blood may be abstracted in different ways, as,

first, by venesection; secondly, by leeches and cups; thirdly, by incision, scarification, or puncture; and, fourthly, by arteriotomy. The latter operation is so difficult of performance, that few practitioners are willing to attempt it. There are cases, as in violent inflammation of the brain, eye, and ear, in which it is supposed to exercise a peculiarly beneficial influence; but, generally speaking, it is quite certain that venesection, if properly executed, answers every purpose, even in the affections here specified. Similar remarks are applicable to bleeding at the jugular vein, also usually a difficult, and sometimes even a dangerous operation.

The diseases to which blood-letting is more particularly applicable are the different inflammations, acute and chronic; general bleeding being best adapted to the former, and local to the latter. Hippocrates and his immediate followers bled largely in pneumonia and pleurisy; and Sydenham, Rush, Louis, Drake, and many others often took immense quantities of blood in the treatment of these maladies. In acute inflammation of the eye, in robust subjects, bleeding is often indispensably necessary to save the affected organ. Who would hesitate to draw blood largely, under similar circumstances, in acute inflammation of the brain and its envelope, in acute pericarditis or endocarditis, in hepatitis, splenitis, gastritis, enteritis, peritonitis, cystitis, metritis, or orchitis? Stricture of the urethra would be much less frequent if young men labouring under severe gonorrhoea were freely bled at the beginning of the attack. In traumatic affections of the joints, untended with loss of blood or severe shock, the abstraction of blood would often prevent ankylosis, so common under the present system of treatment. The spasm which is so often present in recent fractures, especially in those of the leg and thigh, is more readily controlled by venesection, followed by a hypodermic injection of morphia, than by any other agent I have ever tried.

In chronic inflammation, blood-letting is often an indispensable remedy. Even the most ultra advocate of the stimulant method of treatment will hesitate to employ it when destructive action is gradually but surely undermining structure and function. The abstraction of five, eight, or even ten ounces of blood in chronic pneumonia and pleurisy, especially when associated with severe pain and obstructed respiration, often acts like a charm, relieving suffering and promoting the beneficial action of other measures. In chronic ophthalmia, a few leeches applied to the fore part of the temple, on a line with the commissure of the lids, frequently produce the happiest results. But I will not consume your time by an enumeration of the different cases of chronic inflammation in which blood-letting might be advantageous. What I have said respecting the lungs, pleurae, and eye is equally applicable to other structures, and needs no further elucidation here.

It requires no laboured argument to show that general bleeding can be successfully practised only at the beginning of an acute disease, or during its earlier and gravescent stages. Performed at a later period, when the morbid action is fully established and the affected tissues are inundated with inflammatory deposits, it cannot fail to do harm by robbing the system of the strength so much needed to carry on its vital processes. A copious bleeding at the outset of a violent inflammatory disease is gold; but at its height, lead; or, to express myself more clearly, life in the one case, death in the other.

2. To draw blood to the greatest possible advantage, the quantity should be measured, not by ounces, but by the impression it makes upon the system, as denoted by the pallor of the countenance, the reduction of the heart's action, the softened state of the pulse and skin, the abatement of pain and of other symptoms, as headache, thirst, and restlessness, so universally present in all severe inflammatory attacks. To insure this result in the most speedy and decided manner, the blood should be drawn from a large orifice in a large vein at the rate of two and a half to three ounces in the minute, while the patient is in the erect or semi-erect posture. If the body be recumbent during the operation, a much larger quantity of blood will be required to be drawn to produce the desired effect than when the reverse is the case. While, therefore, the bleeding should be spoliative, care should be taken not to waste the fluid unnecessarily.

To prevent undue reaction after the operation, the bleeding should not be carried to complete syncope, but merely to an approach to this condition, the effect of the operation being carefully watched by a reference to the countenance and the pulse, lest it should exceed the proper limits, and thus do harm instead of good. Violent reaction, however, in any case, after the abstraction of blood, may generally be effectually prevented by a full dose of some diaphoretic anodyne, as ten grains of Dover's powder with one-fourth of a grain of morphia, given immediately after the operation.

Respecting the repetition of the operation, every case must, so to speak, make its own rules. If, after a very copious bleeding, the symptoms rapidly reappear in all or nearly all their former intensity, the operation should at once be repeated, either by reopening the original orifice or by selecting another vein. In urgent cases, as in violent pneumonia, pleurisy, peritonitis, cerebritis, or endocarditis, the operation may often be repeated several times in rapid succession. Under such circumstances the practitioner must, like a wary general, make forced marches, and follow up his successes, not waiting until the enemy has intrenched himself behind his works, but striking heavy blows while he has the opportunity.

But I shall be told that such heroic treatment must inevitably induce serious debility. I grant it will; but in turn I ask, will the disease, if neglected, or permitted to progress, not also cause debility? Debility, perhaps of the very worst kind; debility from over-action of the heart, imperfect supply of nerve-fluid, deranged circulation, impaired function of vital organs, and, above all, from disordered structure from inflammatory deposits? The enlightened practitioner bleeds to save tissue, and to prevent the morbid action from running riot. He repairs strength, when the time for it arrives, by making blood with nutritious food and drink, and thus speedily sets the machinery of life again in motion. The timid, hesitating practitioner, the opponent of bleeding, on the contrary, although he may employ the same restoratives, uses them inopportunistically, and thus allows the debility caused by his treatment to linger for an indefinite time, provided the patient is so fortunate as to survive the first onslaught of his disease.

3. Before I proceed to speak of local bleeding, let us briefly inquire into the mode of action of venesection, or, in other words, how the removal of blood from the system affords relief in inflammatory affections.

This question can be easily answered. In the first place, the abstraction acts spoliatively, diminishing, as the name implies, the quantity of blood, both in the part and system. Secondly, it weakens the power of the heart, and thereby prevents it from sending the blood with the same force and velocity into the suffering structures. Thirdly, it unlocks all the emunctories, and thus promotes secretion. Fourthly, it disorgs the vessels at the seat of the disease, restores the circulation, and places the absorbent vessels in a better condition for the removal of effused matter. And, last, but not least, it favours the action of other remedies, as purgatives, diaphoretics, diuretics, and anodynes.

But it will be said that all these effects may and can readily be induced by the agency of other remedies, as aconite, veratrum viride, digitalis, mercury, and tartar emetic, and that, too, at much less cost to the system. That these articles are powerful depressants, lowering the heart's action and promoting secretion, no one at all acquainted with their virtues will question; but I deny that they exercise the same beneficial impression upon the vessels at the seat of the inflammation. When blood is drawn freely from a large vein at the bend of the arm, from a large orifice, to an approach to syncope, the vessels at the seat of the morbid action are unloaded, often to such an extent that the affected structures do not exhibit any marked difference in colour from those in their immediate vicinity. Thus, for example, in violent conjunctivitis the mucous membrane, the seat of the disease, always, under such circumstances, presents a perfectly blanched appearance, however red and engorged it may have been the moment before. Now, what occurs in the eye, in such a case, may reasonably be supposed to take place in any other part of the body when a patient is bled to a similar extent. In pleurisy, one of the immediate effects of the copious abstraction of blood is a mitigation of the torturing pain which forms so prominent a symptom in this disease, due, evidently, to the diminished calibre of the vessels in the pleura, previously in a state of complete repletion. Has any one ever witnessed such an effect from the exhibition of aconite, digitalis, veratrum viride, or tartar emetic? Never. No matter how these articles may be administered, whether singly or variously combined, they are simply depressants, not depressants and evacuants, as the abstraction of blood from a vein or an artery; there is no blanching of tissue from their use, no unloading of distended and crippled vessels,—indeed, no direct appreciable effect of any kind.

The more recent researches in pathological histology furnish a hint not easily to be mistaken as to the most salient treatment of inflammation in its earlier stages. The leading indication is to restore the paralysed capillaries to their normal tonicity, so as to prevent structural changes in their walls, and facilitate the outward passage of the white globules with which they are choked. It is now well known that in every inflamed area there is marked hyperæmic distension of the blood-vessels, which are often crowded to their utmost capacity with leucocytes, which emigrate through the vascular walls, and, in conjunction with the effused blood-liquor, constitute the most important elements in inflammatory deposits. Hence the object of treatment should be to restore the capillaries to their normal calibre through the artificial induction of contraction of their walls—an effect which can be

brought about, as is daily witnessed in many of the external inflammations, by cold applications, which, as is well ascertained, produce reflex contraction of the vessels. In inflammation of the more deeply-seated organs and tissues, however, this object can only be attained by spoliative bleeding, whereby the affected capillaries are relieved of their contents. In this way only can their tonicity be restored, the further effusion or migration of cell-elements restrained, and the absorption of existing deposits favoured.

Another effect of bleeding, not to be overlooked in this discussion, is the diminution which it causes in the quantity of fibrine and white globules, so remarkably augmented in inflammatory affections. This change, of which I have witnessed many examples, was beautifully illustrated in the case of a young man, nineteen years of age, whom I attended along with the late Dr. Charles Woodward, of Cincinnati, on account of a severe attack of pleurisy. Blood was drawn on three consecutive days, the first bleeding being performed about thirty-six hours from the commencement of the attack. The fluid, amounting to nearly a quart, was not only greatly buffed, but cupped on both sides of the crassamentum, as is shown in the specimen which is still in my possession. At the second operation the fluid was buffed, but not cupped; and at the third it was merely a little sizzly, all pain and active inflammation having by this time disappeared. If such effects follow the use of the articles above mentioned, I am uninformed of the fact.

In leeching and cupping, blood may be taken directly from the affected structures, or indirectly, as when they are practised at a distance from the seat of the inflammation. In the latter case the effect, if carried to a great extent, is similar to that produced in venesection, but generally much more tardy, and therefore, in the main, not so efficacious. When the tissues are divided, as in incisions, scarification, or puncture, the vessels are directly drained of their contents, an operation often followed by great, if not permanent, relief. Illustrations of the efficacy of this mode of depletion are daily witnessed in tonsillitis, in erysipelas, ulcers of the extremities, inflammation of the uterus, and in impending mortification, not to mention other affections.

I have said that general bleeding can be successfully practised only at the beginning of an inflammatory attack, a fact which, I repeat it, is not to be lost sight of in weighing the propriety of such a procedure. Let it be borne in mind also that bleeding is not to be practised indiscriminately, but judiciously, and with proper regard to the condition of the system. Our fathers grievously erred, because they bled in every stage of disease, and in all states of the system, the plethoric and the anæmic, the strong and the weak. Of course there were exceptions, but as a rule this was the practice; the harm, hence, as a natural consequence of the abuse, the abandonment of the treatment. It is within the recollection of all the older members of this Association when the practice of medicine in this country and in Great Britain was limited to the lancet, calomel, digitalis, opiates, and tartar emetic, with gruel and chicken-broth as the chief diet during sickness. I well remember the time when the use of cold water was interdicted as highly improper, especially in the treatment of the so-called eruptive fevers, and when ventilation of a sick man's chamber was considered as fraught with danger. Bleeding

will again come into fashion; history constantly repeats itself, and knowledge runs in a circle. No sensible man can fail to read the signs of the times; but it will not be indiscriminate bleeding, but bleeding performed for a reason, early, and, if need be, freely, to save tissue and promote resolution; in the robust and plethoric, in the young and middle aged, not in the weak, the anæmic, the intemperate, the broken-down, and the decrepit. Practitioners, during the last third of a century, have laboured under a delusion and a dream, from which they are gradually emerging to a sense of their duty; and, although I am not a prophet or the son of a prophet, I venture to predict that the day is near at hand, if, indeed, it has not already arrived, when this important element of treatment, so long and so shamefully neglected, will again become a recognised therapeutic agent, and will thus be instrumental in saving many lives, many an eye, many a lung, many a joint, and many a limb.

But bleeding should not be restricted to the treatment of inflammatory diseases. There are other affections in which it may often be practised with the greatest benefit. In puerperal convulsions, attended with a plethoric condition of the system, copious venesection, promptly followed by the administration of a full anodyne, either alone or in union with chloral and bromide of ammonium, and the application of leeches to the temples and cold to the head, is the sheet-anchor of our hopes, a positive *sine qua non* to success. An experienced and learned member of this Association, Dr. J. Fordyce Barker, recently called attention to this subject in a paper characterised by strong sense and great practical acumen, worthy of his high position as an accomplished gynæcologist. I believe, indeed, that the practice thus set down is the one now generally, if not universally, adopted in the treatment of this dangerous disease, as it was in the time of Dewees and his more enlightened contemporaries. In certain forms of apoplexy the judicious employment of the lancet cannot be too strongly insisted upon, especially in comparatively young and vigorous subjects. Blood in this disease is often taken with leeches when it ought to be taken with the lancet. In asthma, bleeding is frequently of inestimable value, in relieving engorgement and spasm of the lungs, the causes of the terrible dyspnoea so often present in the more aggravated forms of the disease. I recall to mind the case of a lady who was the subject of asthma from the age of fourteen up to that of eighty-six, when she died of pneumonia, whom I repeatedly bled with the greatest advantage in attacks of this kind, which nothing else could relieve. In another case, that of a tall slender gentleman of this city, nearly eighty years of age, in which a severe attack of asthma was complicated with great congestion and slight inflammation of the lungs, the abstraction of less than ten ounces of blood by the lancet led to a speedy convalescence and a complete cure. I verily believe that if this gentleman had not been bled he would have died. In certain forms of phthisis, venesection, judiciously employed, is frequently productive of great benefit. I allude more particularly to the chronic variety of the disease, kept for years in abeyance by great care and a properly regulated regimen. I remember the case of the late Mr. Benjamin Drake, of Cincinnati, a brother of the great professor, who laboured for many years under disease of the lungs, associated with tubercular deposits, the more urgent symptoms

of which were always promptly relieved by the loss of eight to sixteen ounces of blood by venesection. I have always felt satisfied that his life was materially prolonged by this treatment. Dr. Rush was in the habit, as Sydenham had been before him, of bleeding in every case of phthisis attended with a hard pulse, or a pulse rendered weak by the laborious transmission of blood through the lungs. In one of his cases he bled eighteen times in two weeks, and in another, fifteen times in six weeks, with the happiest effect. I do not cite these instances as examples for our imitation, but simply to show that a system borne down by disease may react favourably under what to us of the present day appears as a most heroic measure.

Forty years ago it was customary in protracted labour, dependent upon rigidity of the uterus and the perinæum, to bleed in order to relax the parts and expedite the expulsion of the child. Dewees, in such cases, often took large quantities of blood, especially in young, robust, primiparous women, and occasionally even repeated the bleeding. I well remember that this was the general practice for a number of years after I entered the profession. Why it has fallen into desuetude it would be difficult to tell. The abstraction of blood under such circumstances was always followed by the exhibition of a large anodyne, under the influence of which the labour usually progressed rapidly to a favourable issue, without subjecting the poor woman to undue torture, the danger of lacerating the perinæum, or the necessity of applying the forceps, the use of which is now so common among all classes of accoucheurs.

The plethoric condition of the system so frequently met with in young, robust, pregnant women is generally promptly relieved by the abstraction of twelve to fifteen ounces of blood, and certainly there is no more rational remedy in such circumstances, especially when the redundancy of blood is accompanied by dizziness, vertigo, or headache. Thirty years ago there were few women that were not bled once or twice during uterogestation on account of these symptoms, and I do not know that I ever heard of one that was injured by the practice.

Certain forms of hysteria and epileptic convulsions, dependent upon congestion of the nervous centres and a redundancy of blood in the system, are generally materially benefited by venesection. The relief in the former affection is often prompt and permanent, as I can testify from personal experience.

In the convulsions of infants blood-letting is frequently of signal service. In that form of the disease which follows upon the more severe attacks of cholera, so rife in our hot summer months, and which are manifestly due to over-excitement of the brain, as is shown by the excessive heat of the head, the flushed condition of the countenance, the suffused eye, the intense thirst, the incessant restlessness, the intolerance of light and noise, and the twitching of the muscles, the abstraction of two to two ounces and a half of blood from the arm, in a child from one to two years of age, not only, in many cases, promptly arrests the vomiting and other distressing symptoms, but protects the brain from more serious mischief, and thus places the system in a condition for speedy convalescence.

In what is called hay-fever, a good bleeding sometimes affords immediate alleviation of all the disagreeable suffering incident to that complaint, as dyspnoea, violent sneezing, nasal catarrh, tightness

in the frontal sinuses, headache, and horripilations, or chilly sensations along the course of the spine. I recollect one case which came under my observation many years ago, in a clerical gentleman, thirty-three years of age, who, on being largely bled one Sunday soon after the close of his religious services, was completely cured for that season; and, although the malady recurred during several consecutive summers afterwards, the attacks were always comparatively light.

Cases have been related of great benefit afforded by bleeding in uræmic coma, attended with unconsciousness, dilated and fixed pupils, convulsions, a highly albuminous condition of the urine, and excessive prostration of the system. The blood at first issued feebly, but gradually the stream increased in volume, the blood assumed a brighter hue, the pulse rose, the convulsions ceased, consciousness returned, and the patient finally made an excellent recovery. Several such examples will be found recorded in the *London Medical Times and Gazette* for September, 1874, by Dr. Benjamin W. Richardson, in an article on 'Blood-letting as a Point of Scientific Practice,' and are worthy of special study.

This spring twelve months ago I was requested to visit a lady, a stout, muscular person, in robust health, upwards of forty years of age, who for several years past had suffered much from attacks of headache, attended with dizziness, and occasionally, also, with vertigo. She had tried various remedies without benefit. I suggested bleeding, to which she at once assented, and I drew fully three half pints of blood, with immediate and permanent relief.

Surgeons the world over draw blood after severe reaction in concussion of the brain, to prevent inflammation of that organ and of its membranes. The more plethoric the patient, the greater the necessity for such interference; but the operation should by no means be restricted to this condition, as it is often of great value, if timeously performed, in the comparatively anæmic subjects. It was a case of concussion of the brain that gave rise to the never-to-be-forgotten conversation between John Hunter and his pupil, Dr. Physick, at the time resident physician at St. George's Hospital, London. A man labouring under concussion of the brain from a fall from a scaffold was brought into the surgical ward in a state of utter unconsciousness. 'What shall I do?' said the pupil to his master. 'Shall I bleed him?' 'Bleed him? Bleed him, sir? No, sir! You would kill him outright. Wait, sir, until he reacts, and then bleed him,—bleed him to death, sir.' (Dr. Charles D. Meigs, in *Pennsylvania Hospital Reports*, vol. i. p. 27, 1868). In compression of the brain from fracture, with depression of bone and compression from extravasation of blood, the abstraction of blood by the lancet and leeches is frequently resorted to for the purpose of securing cerebral accommodation, and the practice, as is well known, is often followed by the most gratifying results.

We all have, at some period or other of our lives, experienced the torturing racking pains in the back and limbs, so common in bilious, remittent, and intermittent fevers, as if the body was about to be broken in two, causing us to turn and toss about almost incessantly in search of ease; the head generally at the same time terribly distressed, the skin hot and dry, the thirst intense, and the heart in wild tumultuous motion. Who that has ever been freely bled in such a condition of the system does not re-

member with grateful feelings the prompt alleviation afforded by the operation? The application of a dozen wet cups to the aching back has often speedily transported the poor patient, as it were, from torment into elysium. In gout and rheumatism the abstraction of blood is frequently of immense benefit, if not as a direct curative agent, as a means of relieving pain and paving the way for the more successful action of other remedies. The passage of renal and biliary calculi is often greatly expedited and the suffering caused by it much alleviated by a copious bleeding, especially in stout plethoric subjects.

But I must stop, for my remarks have already been extended far beyond my original design, which was simply to point out a few of the more prominent diseases in which, in my humble opinion, this much-neglected but most valuable therapeutic agent may be advantageously employed.

The fate of blood-letting teaches us an important lesson, not at all calculated to elevate our pride as men intrusted with the preservation of the health and lives of our fellow-beings. It shows what little faith there is to be placed in human judgment, and how sadly we are influenced by authority and fashion in a matter pertaining to the dearest interests of society. If I wished to be satirical, I should say that there are in our profession, as there are, indeed, in every other, two distinct classes of men,—the thinking and the non-thinking. The former, whose number is exceedingly limited, accept every novelty, or great and sudden change, with suspicion, wisely concluding that the one ought not to be adopted until it has been fairly tested by well-conducted observation and experiment, and that the other should not be rejected without sufficient cause. The non-thinking man, on the contrary, eagerly lays hold of every novelty, and seldom stops to seek a reason for his new faith. He adopts it simply because his neighbour adopts it. Especially is this the case when the novelty, whatever it may be, has a distinguished parentage, as when it has received the sanction of a great name, or, perchance, if it had a transatlantic origin. Jones, Robinson, or Brown, in Europe, is always a great man, far greater than his namesake on this side of the water. This non-thinking man confounds progress with improvement. He does not weigh the pros and cons of a question; he takes a shorter route; sees things in a distorted light; assumes for granted what he cannot comprehend, and jumps at conclusions. As the sheep follows the wether, so he follows his master, looks through his spectacles, believes in his infallibility, and swears by his authority. The more the assertion borders on the marvellous, the more greedily does he gulp it, so much easier is it to assume the truth of a proposition or statement than to prove it by sound logical argument and inductive reasoning. I think I am not guilty of exaggeration in what I say. It really seems to me as if we were bereft of our senses. No sooner is a new remedy, an operation, or a method of treatment introduced to notice, than it is puffed into gigantic proportions and endowed with virtues as foreign to it as any other folly under heaven. Certain it is, there never was any greater need for deliberation and reflection than there is at the present time; greater need of asking ourselves, 'Watchman, what of the night?'

SUTTON ON THE RELATION OF ACUTE TO CHRONIC DISEASE.

In an extremely interesting report (*The Pathologists' Report to the House Committee of the London Hospital*, 1875), Dr. Sutton discusses, from the data afforded at that important institution, the relation of the acute to the more chronic changes.

The relation of the acute to the more chronic changes is shown by an examination of the individual cases; this reveals that acute pleurisy had been mostly preceded by chronic or subacute phthisis, by fibroid, emphysematous, or by pyæmic changes in the lungs; by chronic disease in the kidneys, heart, or other parts. Acute peritonitis, preceded by more or less chronic disease in or about uterus, liver, stomach, or other abdominal organs. Acute pericarditis, preceded by rheumatism, by chronic changes in the heart, kidneys, or other organs. And even with respect to the fifty-two cases in which acute pneumonia occurred, the records show that in twenty-four of these, this acute pulmonary change had been preceded in eleven by more or less chronic phthisical alteration in the lung; in six by emphysema; and in seven by fibroid changes in the lung; in three other cases heart-disease preceded the pneumonia; in three, dilated heart and granular kidney, etc.; in three, epithelial cancer of gullet; in seven the pneumonia was preceded by renal disease; in four by atrophy of brain; in one by syphilis; in one by gout; in one by disease of cæcum; one by fatty liver; one by diabetes.

In only three cases was pneumonia the sole appreciable morbid change; and these were in children under the age of five years. And of the forty-eight cases in which acute bronchitis was the immediate cause of death, there was evidence showing that chronic lung, heart, kidney, or other disease, had preceded the bronchitis, or that erysipelas, typhoid fever, or other zymotic disease, had determined it.

These particulars further show, what is already recognised by pathologists, that acute pneumonia rarely kills adults who are free from chronic diseased changes, but in children under five years of age it is often fatal.

In three cases acute nephritis, without appreciable chronic disease, caused death, one case in a child, and two in adults—some of these may have been scarlatinal.

Dr. Wilks years ago pointed out that acute morbid changes are the outcome of chronic ones; and the *post mortem* examinations in your hospital have shown that such is the case, with very few exceptions. The above particulars teach that, excluding cases of mechanical injury and zymotic disease, it is proportionately very rare for an adult, free from chronic morbid changes, to die of acute inflammatory affections. And other data might be taken from the records, showing that this rule holds good, not only with inflammatory, but with almost all, if not all, acute changes in the body, excluding poisoning and violence.

If the records be further examined, they show that some of the persons killed by acute changes were at the time of seizure doing their work or going about as usual—thought to be well, or ailing little—when some incident common to ordinary life occurred, and this, it was thought, produced the disease which, in a few days, or in less time, destroyed life.

For instance, a man, aged sixty, had seemingly gone about as usual, until one day, whilst coming down the stairs of his house, he fell; he was lifted up, and it was then, for the first time, noticed that he could not stand—it was evident he had lost the use of his legs. His friends naturally concluded that the fall had caused the injury, and they brought him to the hospital. He was admitted into one of the surgical wards, and his legs and his bladder were found to be paralysed; acute changes followed rapidly in his urinary organs, and in a few days he died. The coroner's court held an inquiry, and were satisfied that the patient had not been knocked down; and there was apparently nothing showing that he fell because the stairs were in a dangerous condition. It therefore seemed clear that he had not been thrown down by any external cause, but by some destructive change within his own body; and it remained for the pathologist to show why he fell. The *post mortem* examination clearly revealed that long antecedent to the fall the patient had disease in several organs of his body, and although the spinal cord looked healthy to the naked eye, microscopic examination showed that it was very much diseased; chronic changes had greatly altered its texture, and doubtless impaired its function, until at last an ordinary act of life was sufficient to bring about some rapid alteration in this organ, which paralysed the lower extremities.

I may mention another case in illustration. A man was admitted with fractured pelvis. His friends said he was hanging out a clothes line from a window when he fell, and injured himself very much. Consequently they brought him to the hospital. Forty-eight hours after admission he died. The question arose, why did this man fall from the window? The examination of the body showed great atrophy, that is, chronic wasting change, in the brain-convolutions. The remainder of his body seemed healthy. The investigation, therefore, established that slow diseased changes in the brain had preceded the fall. And knowing that persons with such diseased brains are very liable to sudden changes—either apoplecticiform, epileptiform or paralytic, or to other sudden seizures, such as giddiness, violent bursts of passion or impulse, the pathologist was led to conclude that this man had probably been seized with apoplexy, or, at all events, with some disorderly action in his brain at the moment of hanging out the line, and that he fell in consequence—that sudden changes, supervening on chronic, had brought about his destruction. The witnesses subsequently examined before the coroner's court, said that this man intentionally threw himself from the window—that he committed suicide.

I have given the particulars of the above cases, because they illustrate the direction in which the pathologist has to work; and they, together with the details of very many other cases, might be brought forward to establish that persons with more or less chronic disease, yet going about as usual, have been attacked by some acute illness (not fever or violent injury); and such details would, I have no doubt, further establish that even physicians and surgeons, in some instances, have failed during life to find any indications of disease preceding such acute seizure; and, what is still more instructive, pathologists themselves, with the body and all its organs exposed before them, sometimes cannot, by the naked eye alone, discover any morbid change to account for the sudden change, or even the death.

But whilst recognising such facts as undeniable, pathologists know that increasing and better means of investigation are every year more and more lessening the number of these exceptional cases, and convincingly revealing that persons at the time of sudden seizure are not really, but only apparently, well.

If, instead of examining this question of the relation of acute to chronic disease, as above, it be studied deductively, it is known that the body is formed slowly by the external conditions acting on the internal structures. These external agents are the atmosphere, the food, etc.; and the internal are the cells and organs of the body. The external afford the materials, and the internal are the builders; and inasmuch as both act slowly and gradually in constructing man's body, it would seem unreasonable to conclude that they can, whilst unaltered, act otherwise than slowly in disordering and destroying it.

If, however, either the external or the internal agents be not of the ordinary, but exceptional kind, that is, not the average—for instance, the air unusually cold and moist, or hot and moist, the motions in the air too exciting or otherwise, the food not appropriate—then these external conditions, coming into action quickly and abruptly, might, and probably in some persons must, of necessity, produce exceptional, abrupt, more or less rapid, internal changes; and the amount of effect, so to speak, will vary according to the intensity of the cause, and to the self-conservative, healthy resistance within the body itself. Consequently, the disturbance in the body would be great according to the force of the cause, and the degree of departure from health in the sufferer.

And such exceptional external actions do commonly produce rapid catarrhal, diarrhoeal, and other changes, which disturb, inconvenience, or even temporarily incapacitate but do not long disable, much less destroy, healthy persons. The effects, however, become more disabling in proportion as the sufferer is low in health. This variability in effect is, however, in many persons presumable rather than demonstrable.

But if the body be as yet only imperfectly developed, as in infancy, it would seem only reasonable to conclude, what experience confirms, that like any other fabric partly built, its incompleteness will offer less resistance; or if it be decaying, as in old age or in disease, then abrupt changes outside may bring about rapid changes within, and the effects will correspond to the degree of feebleness of resistance. Hence infants, very young children, and aged or diseased persons, commonly die of diarrhoea, bronchitis, and broncho-pneumonia, and other acute affections, but not healthy adults.

It may be thought unnecessary for a pathologist to enter thus elaborately into the relation of acute to chronic disease; nevertheless it may be conceded that the relationship shown above is not generally sufficiently recognised, and yet it ought to be known as a fundamental basis for both the prevention and cure of disorder* and disease.

For prevention, it should be known that not only, as already said, are inflammatory but also abrupt and rapid actions, such as apoplexy, cerebral hæmorrhage, epilepsy, sudden stoppage of heart, rapid

failure of the renal or other organic function, always preceded by more or less slow morbid change in their respective organs; and very many facts might be adduced in evidence tending to show that even outbursts of drunkenness, of crime, and many other disorderly acts common to life, generally are, if not always, preceded by slowly acting deteriorating changes in the body.

Medical men, whose minds are specially trained to follow the co-relation in the consecutive symptomatic phenomena, are able, in many cases, to trace the disorder and the remote causes which have preceded the acute outbursts; but daily observation shows that many minds, not specially trained, generally look for and only recognise the proximate cause. They learn that sudden and great changes in weather, or exposure to wet and cold, commonly produce catarrhal and other bodily disturbance; the facilities and temptations of the public house, or agreeable companionship, lead to drunkenness, or the sight of gold prompts to theft. They may know that great exertion, passion, or fright may be followed by, and seemingly cause apoplexy, epilepsy, or even sudden death; that some exciting social or political event leads to, and seemingly causes, madness, murder, suicide, etc. They may be, to some extent, sensible of the disorder immediately before the outburst; in the same way as they see the storm-cloud in the sky, and subsequently witness its outpour, and trace its devastating effects, but they are unable to track the invisible changes which have slowly collected the storm-forces from afar. But the sudden rapid outpour from the cloud is a part only, in fact often the end only, of the storm. Its immediate fall is determined by some common prominent object or condition; yet the same determining condition may be constantly present, but it only excites the outburst when the remote actions have gathered the cloud.

And this is the case, as every pathologist well knows, not only with atmospheric outbursts, but with those of the human body also; and as long as there are no slow actions deranging it, the various conditions of life, apart from violence, poison, etc., it would seem, do not excite severe attacks of acute disease or destructive outbursts of any kind.

When, however, the body has been deranged by slower changes, many common incidents may excite acute seizures, inflammatory, paralytic, emotional, drunken, suicidal, or other.

Those who are satisfied as to the truth of such conclusions will at once see that, although these acute seizures of all kinds may be to some extent prevented by efforts to remove or counteract the influence of the immediate determining causes, yet, inasmuch as these causes are often common to, and, in fact, seemingly at present inseparable from, ordinary life, the counter efforts must, in the face of the remote causes and chronic deteriorations, of necessity often, perhaps generally, fail.

From many quarters data might be collected supporting the inference that there are always, and must always be, slower, although perhaps, at present, inappreciable changes, leading up to the rapid ones, teaching that incidents, though sudden in time, that is in man's estimate, are not so in reality; pathologists would, however, at once admit that they cannot at present, not even imperfectly in many cases, trace the disposing, intercurrent, remote conditions, which excite and produce rapid injurious changes in the body—but the effect is the foot-print of the cause;

* By disorder is here meant a minor deviation from the normal condition, which in its later and more developed form, is known as disease.

the cast must have a more or less distinct impression and likeness of the mould, the hand can only trace its own movements, and even the storm can only force the wreck and leave it in the form and direction in which it is travelling. The pathologist, therefore, by *post mortem* examinations, endeavours to discover the form of the cause from the shape of the effect. Whilst endeavouring to do this he has to keep in mind that the morbid changes visible to the naked eye, be they in the form of tumours, dilatation of heart, atrophy of brain, or other, are only the gross aggregate morbid products; the cells, fibres, vessels, nerves, etc., with their abnormal changes, seen only by the aid of the microscope, and sometimes only by very high power, are bound up together, and form the diseased mass. It is the alteration in these cells, fibres, vessels, etc., which impair and arrest the function of the diseased organs; therefore, microscopical examinations of the minute constituents are indispensable for the ascertainment of the changes which destroy life. And microscopic, chemical, and other minute examinations have already shown that these minute changes are sometimes present when the part looks healthy to the naked eye; thereby not only indicating that the minute alterations are the primary ones, but enabling us to understand why the chronic changes are for awhile very insidious or even latent, because the changes at the outset, being very minute, cause little or no disorder in the action of the organ affected, and still less in the working of the body generally.

When, however, the diseased changes have become much more widely disseminated and the organ largely involved, its function becomes greatly impaired, and then it becomes manifest that there is organic disease.

The pathologist knows what an enormous aggregation of altered microscopic parts make up an atrophied brain, a diseased liver, or a contracted lung, etc.; consequently he is well aware that the eye must be long trained, by microscopic and other aids rightly to appreciate these changes and trace their relations.

Reason, too, must be long trained to track the morbid changes back to their origin, and make known the successive transformations which have produced the abnormal conditions, and diseased structures.

If this be done, the knowledge gained will frequently indicate what measures should be adopted to prevent the occurrence of disease.

If the cure of disease be next considered, it is to be kept in mind that the pathologist, whilst tracing the cause from the effect, or *vice versa*, tracing the disease downward from the cause, endeavours to ascertain what are the actions within the body as well as outside, which produce and constitute disease. And in doing this he learns what should be done to prevent the morbid changes. He, moreover, estimates what changes must take place within and without the body to restore it to health; or if cure be impossible, owing to the nature of the disease, what changes should be promoted to counteract and retard the progress of the disease, relieve suffering, and delay death. The following abstract from Cullen defines clearly the position and application of pathology in the cure of disease.

'From pathology,' he says, 'you know the deviations from a healthy state which the body is capable of; that from a comparison of physiology and pathology you know the several changes that are necessary to be made for restoring the body from a morbid to

a healthy state; that is, the several indications, as they are called; and, lastly, that from the knowledge of the powers which act upon the human body you know the means by which disease may be avoided, and health restored when it is wanting.' [Vol. I., p. 444, *Works of Wm. Cullen*, 1827.]

It is therefore evident that the cure of disease must necessarily be promoted by the ascertainment of its cause. For centuries this has been recognised, in proof of which I may be allowed to give the words of one renowned for his great learning and research, whose work itself evidences that his statements are the expression of the teaching of ages. Burton (*Anatomy of Melancholy*, p. 52, vol. i.) says:

'It is in vain to speak of cures or think of remedies, until such time as we have considered of the causes; so Galen prescribes, and the common experience of others confirms, that those cures must be imperfect, lame, and to no purpose, wherein the causes have not first been searched, as Prosper Calennius well observes in his tract, *De Atrâ Bile*, to Cardinal Cæsius, insomuch that Fernelius puts a kind of necessity in the knowledge of the causes, and without which it is impossible to cure or prevent any manner of disease. Empiricks may ease, and sometimes help, but not thoroughly root out; *sublatâ causâ, tollitur effectus*, as the saying is; if the cause be removed, the effect is likewise vanquished.'

Not only is this the teaching of the past, but also of the present age; in evidence of which I may be allowed again to quote the words of a standard work, on the *Science and Practice of Medicine*, by Dr. Aitken, vol. i. p. 4, which says:

'Pathology dictates the maxims of rational practice. It is in the nature of the science of pathology that it always ought to be in advance of our certain knowledge regarding the treatment of disease. It is the basis of rational medicine; for it is rational to know the nature of a disease in order, 1. To enable us to prevent it; 2. to understand the principles which ought to guide us in the management of it.'

In concluding this report, it may be well to mention the history of medicine shows that for two thousand years there have been two methods employed for the study of physic, the dogmatic, or pathological, and the empirical. The advantages of both have been much discussed, and physicians have been divided on their respective merits. But both having been continued for centuries is demonstrative of their utility, and it is now fully recognised that pathological investigation and reasoning indicate the principles for the treatment of the sick, whilst the physicians and surgeons test their worth empirically, *i.e.* by practice.

ANATOMY AND PHYSIOLOGY.

CAULET ON THE EFFECT OF LIME AND MAGNESIA ON THE ALKALINITY OF THE BLOOD AND URINE.—The known power of mineral waters, holding the bicarbonates of lime and magnesia in solution, to render the urine alkaline, formed the starting-point of the present investigation (*Bulletin Général de Thérapeutique*, April 30, 1875.) From the fact that the urine of patients taking such waters may be deprived of its earthy salts by boiling and filtration without thereby losing its alkalinity, the author concludes that the latter must be due to soda and not to the alkaline earths. The small proportion of carbonate of soda which is present in those waters

has been experimentally shown to be inadequate to give an alkaline reaction to urine which was previously acid. The effect must therefore be attributed to the earthy salts themselves. How is it brought about? Artificial calcareous waters were prepared by dissolving known quantities of lime and magnesia in water saturated with carbonic acid under pressure. These solutions were administered to four healthy individuals, and were found invariably to render their urine alkaline; the alkalinity persisting after the urine was boiled and filtered. It was further ascertained that the proportion of earthy salts in the secretion was not increased by prolonged use of the waters; thus furnishing another proof that its alkalinity was not due to the elimination of the earthy compounds through the kidneys. The question which next presented itself for solution was this: granting that the alkaline reaction of the urine is due to excess of soda, is this excess absolute or relative? In other words, is there a positive increase in the proportion of soda eliminated, or a diminution in the free acids of the urine? The answer to this question is an indirect one. Increased alkalinity of the blood must precede alkalinity of urine. How do the carbonates of lime and magnesia produce the former result? Are they absorbed into the blood? The author concludes that they are not; or, if they be, it is in proportions so minute as not appreciably to modify the alkalinity of the circulating fluid. This conclusion rests upon the following experimental basis. The vegetable salts of the alkali-metals are converted into carbonates in the blood, and eliminated as such, rendering the urine alkaline. Now considerable doses of acetate and lactate of lime, citrate and lactate of magnesia, were found to exert no influence at all on that secretion; whence M. Caulet concludes that they were not absorbed. Accordingly he argues that if the earths do not increase the alkalinity of the blood directly by being absorbed, they must do so indirectly, by increasing the acid juices poured into the stomach; and this must be regarded as the remote cause of the 'sodic alkalisation' of the urine during the employment of calcic and magnesian waters. In conclusion, he directs attention to some differences of clinical effect between the carbonates of the alkaline earths and those of the alkalis.

1. Owing to the very indirect way in which the former operate, their effect on the urine is less constant and certain than that of the latter.
2. The alkalinity caused by the former makes its appearance more slowly, and lasts much longer, than that produced by the latter.
3. The former probably exercise an alternative action analogous to that demonstrated by Dr. Parkes in the case of liquor potassæ.
4. There is every reason to believe that the former are superior to the latter in the treatment of gravel, calculus, and other troubles incidental to the uric acid diathesis.

STEINER ON THE ACTION OF CURARE.—J. Steiner (*Reichert and Du Bois-Reymond's Archiv*, 1875, Heft 2, p. 145), during his residence at Naples has investigated the action of curare upon some of the lower animals. His results may be summed up thus.

1. In fishes curare paralyses—*a*, the central organ of voluntary movement; *b*, the respiratory centre; *c*, the motor nerves.
2. This action varies with the time, and corresponds to the letters *a*, *b* and *c*, where *a* represents the earliest effect.
3. Paralysis of the motor nerves occurs much later than in the highly organised amphibians, birds and mammals;

still the passage to the fishes is not abrupt, but occurs gradually through animal species on both sides.

4. The late occurrence of the paralysis of the motor nerves increases with the size of the fish in spite of a larger dose.
5. In the electric rays the paralysis of the electrical nerves occurs much later than that of the motor nerves.
6. The other rays and hag-fish are affected in the same way by the poison as the freshwater fish.
7. The cause of the phenomena of 3 and 4 is quite unknown.
8. Paralysis also takes place in crabs, which, however, occurs relatively later than in the fish.
9. In snails, starfish, and holothuria, only paralysis of the central organ of voluntary movement occurs.
10. In the medusæ it appears, from very few observations however, that the poison exerts no influence.

W. STIRLING, D.Sc., M.B.

BOWDITCH ON THE VASO-MOTOR NERVES.—Dr. H. P. Bowditch (*Boston Medical and Surgical Journal*, January 21, 1875), presents the following as the most probable explanation of the demonstrated facts respecting the functions of the vaso-motor nerves.

The smooth muscles of the blood-vessels are kept in a state of moderate tonic contraction under the influence of a plexus of nerve-fibres and ganglion-cells, closely surrounding and imbedded in the vascular walls. This tonic contraction is increased by an impulse coming from the central nervous system through the 'vaso-constrictor' nerves. That these 'vaso-constrictor' nerves are in a state of constant activity is evident from the fact that vascular dilatation follows their section. This vascular dilatation is, however, not permanent. After ten days or a fortnight, the vessels assume their original dimensions. To explain this, we must assume that after separation from the central nervous system, the nervous plexus surrounding the vessels gradually acquires a higher degree of activity than it before possessed. The 'vaso-dilator' nerves act by inhibiting the activity of the ganglion-cells in the nervous plexus around the vessels, thus causing a diminution of the vascular tonicity. These nerves are not in a state of continual activity, as is proved by the failure of the vessels to contract when the nerves are divided. They are therefore to be regarded, not as constant, but occasional antagonists of the vaso-dilator nerves.

DAMMANN ON INJECTIONS OF WATER INTO THE ALIMENTARY CANAL OF DOMESTIC ANIMALS. After relating the well-known observations of Dr. Gustav Simon and Alfred Hegar on the human being, Professor Dammann (*Deutsche Zeitschrift für Thierheilkunde, etc.*), details various experiments in which he injected water by the rectum which led him to the following conclusions.

1. In dogs, water may be sent *per rectum* through the great intestine nearly half way into the small intestine.
2. In swine, water may be sent through the whole of the great but only a small amount into the small intestine.
3. In horses, water may pass into the colon, and also into the great cæcum, but never into the small intestine. He points out the value of these facts in the treatment of obstruction and diseases of the lower bowel.

PATHOLOGY.

SUMMERS ON THE NATURE OF DIPHTHERITIC MEMBRANES.—Dr. T. O. Summers (*Nashville Medical Journal*, April, 1875) from original observations, arrives at the following conclusions.

The membrane of true diphtheria is fibro-cellular. The fibres are well-marked, and deposited from organisable lymph. The cells are more or less modified; intermingling with and feeding on these is found the fungoid vegetation.

There are two kinds of exudation—one in which the fibrinous nidus and the fungoid vegetation are seen in the membrane as soon as it is deposited upon the mucous membrane of the fauces; another in which the fungoid vegetation appears first without any fibrinous nidus, and then dies out of itself, or, upon the subsequent appearance of the fibrinous deposit, goes on proliferating with it, as in the first kind of exudation.

The *contagium vivum* is communicated to healthy individuals through the introduction of the germs of the fungi by inoculation.

In all cases in which the *contagium vivum* is communicated to healthy individuals, the exudation is of the second variety, in which the fungoid vegetation first appears.

The virulence of the disease is indicated by the character of the exudation. If only the fungoid vegetation appear, the disease is perfectly tractable, and yields promptly to treatment. But when the poison has entered the system, and so impressed itself upon the elements of the blood as to cause fibrinous exudation, then comes the tug of war. The fibrinous nidus may form on any inflamed or congested surface, and the fungoid growth be elaborated at a fearful rate.

COURJON ON PARAPLEGIA IN POTT'S DISEASE.—Paraplegia in Pott's disease is by no means always due to the pressure exercised by the displaced vertebrae on the medulla. On the one hand, the displacement may be considerable without there being any paraplegia; and on the other, paraplegia may exist without any deformity. Paralysis is most often to be explained by an inflammation of the medullary meninges, as numerous researches have shown, amongst which those of MM. Charcot and Michaud must be quoted. This pachymeningitis takes its rise in the dura mater which covers the diseased bones. The exudations first gain the nerve-pairs on their exit from the vertebral foramina, and in this way those violent pains without paralysis, which are often observed in patients attacked by vertebral lesions, are explained. At a later period the medulla itself is attacked, and the lesions of the funiculi are the cause of the different troubles which arise with regard to motility, sensibility, and the nutrition of the limbs. M. Courjon has thoroughly studied in his thesis (*Thèses de Paris*) the progress and varieties of paralysis in Pott's disease, and has in its course taken note of the principal points of this disease, considered as to its causes, symptoms, diagnosis, and treatment. While for the most part the deformities produced by the displacement of the vertebral bodies are absolutely incurable, it is not so with the medullary lesions, of which the progress may be impeded, and in some fortunate cases the principal symptoms removed.

MEDICINE.

MAHOMED ON SCARLATINAL CONVALESCENCE.—In the *Practitioner* of July, Mr. Mahomed contributes a paper on scarlatinal convalescence, from which we extract his remarks on albuminuria in this condition.

During the second week, in favourable cases, the frequency of the pulse becomes reduced, and the character assumed is that of the normal, soft, and full type. In some cases, however—and these require great care and close watching during their convalescence, they occur most frequently in children—the pulse, instead of becoming diminished in frequency at the end of the second week, continues rapid; the other symptoms may be apparently favourable, the temperature having fallen to 99° or even lower; the child, however, will frequently look pale, and not be very bright, and his stools are not unfrequently green and offensive. These indications are of the greatest value practically, for they foreshadow coming danger, which may be guarded against by warmth, milk-diet, and gentle purgatives. Constipation or chill would now produce the most disastrous consequences. If such a case as this go on in the usual way, it will be found that about the eighteenth to the twenty-second day his pulse will suddenly fall in frequency and become perhaps abnormally slow, often as low as 40 per minute, having previously been stationary at 110 or 120 for some days. The physician will probably hail this alteration with delight, and possibly report a great improvement to the friends; but his confidence will be misplaced if he rely on it as a sign of improvement, and he will be doomed to disappointment. The sudden fall in rapidity of the pulse at this crisis means sudden increase of arterial tension, and of this it is the surest sign; the pulse will be felt at the same time to become hard and full, the vessel remaining distended during diastole, the expansion being slow and sustained, and the artery assuming a whipcord or rigid character, so that it can be rolled under the finger. At the same time it may become somewhat irregular, a phenomenon which always occurs coincidently with a change of pressure

in the arterial system. This condition requires no sphygmograph to detect it, although it was first recognised by its aid, but reveals itself to the educated touch of any careful observer.

If now the urine be examined, it will be found to be either albuminous or about to become so, the condition of pre-albuminuria existing. Before proceeding to describe this condition, it may be noted that this period of the disease, namely, from the eighteenth to the twenty-second day, is the time when albuminuria or some inflammatory lesion is most likely to occur.

The writer has shown elsewhere (*Trans. R. Med. Chi. Soc.* 1874), in a paper on the etiology of Bright's disease, that the presence of a poison in the blood, such as scarlatina, erysipelas, gout, lead, and many other conditions, or imperfect assimilation of food, as in functional derangement of the liver, or increased effete material in the blood, as in pregnancy, all give a tendency to albuminuria by altering the relation between blood and tissue, and producing high tension in the arterial system; in all of these conditions the excretory system is overtaxed, and if either the skin or the bowels be prevented from performing their excretory function by either chill or constipation, the condition is intensified, increased work is thrown on the kidneys, and albuminuria is produced. To these predisposing conditions may be added two others which have also been mentioned as causes of albuminuria; the one, damage to a large portion of cutaneous surface, as from a burn or acute eczema, a cause which is present to an extreme degree in scarlatina; the other, cold to the surface, a cause which very readily operates on scarlatinal patients on account of the delicate condition of their new skin. We have then in scarlatinal convalescents four important conditions, each or all of which may produce albuminuria; first, a derangement of the liver; second, destruction of cutaneous surface; third, a tendency to chill; fourth, the presence of a specific blood-poison.

It is impossible in a paper of this description to enter fully into a discussion of the forms and causes of albuminuria following scarlet fever; a short reference to each may, however, be attempted. They are presented here in a tabular form, and the actual cause of the albuminuria, the condition of urine, the state of arterial tension, and their etiology also indicated.

ALBUMINURIA.

FORM	CAUSE	CONDITION OF URINE	ARTERIAL TENSION	ETIOLOGY
ARTERIAL	Transudation from Malpighian tufts.	Quantity diminished. Paraglobuline. Albumen, blood.	Always high.	Blood-poisons. Constipation.
VENOUS.	Transudation from tubular plexus.	Quantity normal. Albumen. No paraglobuline or blood.	May be low. Usually high.	Chill. Intense fever. Heart or pulmonary disease, etc.
ARTERIO- VENOUS	Transudation from dilatation of capillary vessels.	Quantity increasing. Albumen. Often blood.	Diminishing towards recovery.	Chronic condition of either preceding causes.

Albuminuria may be regarded as the symptom of certain conditions which, if allowed to continue,

would produce disease of the kidney and other excretory organs, but the disease does not in the first instance arise in those organs. Before describing these conditions, it will be as well first to explain two indications that will frequently be referred to. The sphygmographic signs of high tension are as follows: a sharp point at the apex of the tracing, representing an increase in the percussion element of the pulse; a prolonged sustension of the tidal wave, indicating a prolonged and laboured systole of the heart; a slow collapse of the artery, and the ability of the pulse to overcome considerable pressure, as shown by its power to raise the lever of the sphygmograph when a pressure much greater than usual is employed.

Under certain conditions, the writer has shown that a constituent of the blood may be present in the urine when no albumen or any other abnormal element can be detected; no reaction is obtainable with the nitric acid test when most delicately applied; no blood-cells can be discovered by the microscope; no colouring matter of the blood can be seen by the eye or detected by the spectroscope. Its presence is invariably associated with high tension in the pulse; it usually precedes, accompanies, or persists after arterial albuminuria. It is detected by the use of the guaiacum test for blood, which is employed as follows: a few drops of urine are placed in a small test-tube, a drop of tincture of guaiacum is added, and then a few drops of ozonic ether; after agitation the ether rises to the top, and if the abnormal element which is believed to be paraglobuline be present, a blue colour is produced, which is extracted from the mixture by the ether, and forms a brilliant blue upper stratum.

By the assistance of these indications we are able to classify albuminuria into three distinct forms, which have the following clinical histories.

The mildest form of *arterial albuminuria* will be found to occur almost without any constitutional symptoms about the end of the third week. Most frequently the patient may have been a little constipated (one day passed without an action of the bowels is usually sufficient to produce it), and it will be found that his pulse is harder than normal; if a tracing be taken, well-marked signs of high tension will be found; he will have slight subconjunctival oedema, the first sound of the heart will be a little prolonged and perhaps reduplicated. On examining the urine, a blue reaction more or less intense will be obtained with the guaiacum test; no albumen may be present if the case be taken sufficiently early, but on the following day it will appear. If the urine have been measured and the quantitative analysis for urea be performed throughout the illness, both will now be found somewhat decreased. Beyond these symptoms, however, there will be none; the patient will express himself as feeling quite well, and there will be neither nausea, vomiting, headache, pain in the loins, nor increase of temperature. A sharp purgative administered in this stage will almost invariably remove all the symptoms; the paraglobuline, the albumen, and the high tension will all disappear in a few hours.

This, however, is a sketch of the most favourable form; a form which is due almost entirely to constipation, and can be easily overcome. The first cases observed by the writer were all of this mild nature, and they gave the impression that albuminuria could be checked immediately if taken early enough; but during the recent epidemic it was

soon found necessary to modify this opinion. The variability of the disease at different periods and during different epidemics has always been a matter of common remark. The albuminuria which now prevailed was of a much more severe type, but it nevertheless proved amenable to treatment, and out of a large number of cases observed at the Fever Hospital, not a single death occurred; all except one, who was a gouty subject and a hard drinker, entirely recovered before leaving the hospital, and only one went on to dropsy, and this only existed for two or three days.

This more severe form appears to be due to a larger dose of poison; constipation has little or nothing to do with its production, the bowels being often relaxed at the time of the attack. Such cases partake more of an 'inflammatory' nature, and begin with rigors, a rise of temperature up to 102° or higher, and the urine becomes distinctly bloody almost on the first day, and is greatly reduced in quantity. These patients frequently have vomiting and not seldom diarrhoea; they look puffy in the face, and have a good deal of constitutional disturbance; in fact, they all have the well-known symptoms of acute nephritis. The urine will frequently continue bloody for several weeks, and at the same time more or less scanty; the secretion gradually increasing in quantity, and arterial tension coincidentally diminishing as the condition improves. With milk-diet, sweating in hot packs, purgatives, and flannel next the skin, they all recover sooner or later. These cases, like the others, all exhibit high arterial tension from the commencement, and the desired object is to reduce it.

Venous albuminuria also occurs at this period; it is due to a chill of the skin. This occasionally might be the exciting cause of the inflammatory form just mentioned, but such cases come under the head of arterial albuminuria. More frequently chill or exposure to cold gives rise to a much milder form, undistinguishable from the first set of cases, except that, while the urine may be highly albuminous, it never gives any reaction with the guaiacum test or contains blood in any form. The tension of the pulse is increased, but not so markedly so, and sometimes not at all; no complaint is made of any constitutional symptoms. Such cases as these are frequently curable, if detected at their commencement, in an hour or so by the hot pack; the urine passed immediately before the patient is placed in the pack being albuminous, while immediately afterwards it is normal; the arterial tension at the same time being rapidly reduced. Other cases, again, are of longer duration, especially if the condition have become well established before treatment is commenced. So susceptible are scarlatinal convalescents to chill, that two cases came under the observation of the writer in which albuminous urine was secreted immediately the patients left their beds, the secretion becoming normal as soon as they returned to them, the change being instantaneous; the experiment could be repeated several times in one day. In these cases the pulse-tension was hardly perceptibly increased, and no reaction with the guaiacum test could ever be obtained with their urine.

Exactly similar results have been obtained from observations made on the effect of cold bathing in the healthy subject. In these cases temporary albuminuria resulted after ten or fifteen minutes' immersion, although actively engaged in swimming; a similar

result to those previously reported by Dr. Johnson. The urine in these cases gave no reaction with the guaiacum test, and the arterial tension was not increased; the arteries becoming contracted, the pulse smaller and varying with respiration, showing congestion of the right heart; the veins were turgid, albuminuria evidently resulting from transudation from the venous capillaries; slight cough and increased bronchial secretion indicated also slight temporary congestion of the lungs.

The same characteristics occur in the pulse and urine when albuminuria occurs in the course of a severe fever, or is secondary to heart-disease or bronchitis. In these cases it is undoubtedly due to venous congestion; blood only appears in the urine in very severe examples of these conditions, and then owing to rupture of venous capillaries from pressure.

The last form has been designated *arterio-venous albuminuria*. It is not due to any active congestion, but to chronic dilatation of the renal capillaries after acute congestion, from their inability to recover their normal tone, thus permitting a prolonged drain of albumen from them; blood may or may not be present. The cause may have been removed, and the arterial tension having been gradually reduced may have become normal, the urine being increased in quantity and being sometimes excessive, although albumen is still present.

There is a peculiar characteristic of the urine which frequently occurs in connection with this state; it is found after the disappearance of chronic albuminuria, where the patient is anæmic, or in other cases in which anæmia has occurred after scarlet fever, but without albumen being present in the urine, although the patient looks 'puffy,' and from his general condition albuminuria would be suspected. In these conditions, after adding nitric acid as before described to form a lower stratum in the test-tube, a violet or purple ring is found almost immediately above the acid. If to a specimen of this urine an equal quantity of strong hydrochloric acid be added, the whole agitated and allowed to stand for some hours, a deep blue colour is produced with a deposit of indican. This symptom is frequently found in idiopathic anæmia, peritonitis, and other conditions attended by anæmia and exhaustions. It has also been described as resulting from diseases of the spinal cord. It has been stated to be due to disintegration of blood-corpuscles, but its pathological significance has not yet been definitely determined.

HALL ON THE TREATMENT OF CHOLERA.—In the *Practitioner* of July, Surgeon A. R. Hall, of the Army Medical Department, gives an account of the success that has attended the treatment of the cold stage of cholera by the hypodermic injection of chloral-hydrate. He says: 'The fact, that the Government of India attach so much importance to the matter as to have published letters from Mr. Higginson, the civil surgeon of Kheri, in Oudh, and myself, concerning it, in their official gazette of Feb. 14, 1874, is also very satisfactory. These reports were published in a letter in the *Times* of August 15, 1874.

'During a continuous service of upwards of eleven years in Bengal, I have seen a good deal of cholera. I have suffered from it myself; and I think it may be of interest to describe, as tending to throw some light on the pathology of the disease, what particularly struck me in my own symptoms, and the conclusions I have drawn from them and from the writings of various authors.

'While doing duty with troops who were suffering from an epidemic, in April, 1864, I had a severe attack. The first thing that I specially noticed was the entire absence of all griping, colic, or straining, while the purging was going on. The stools seemed to be expelled by the contraction of all the muscular fibres of the intestines themselves, without any assistance from the abdominal muscles. I noticed that my pulse was hard and then small before it ceased to be felt at the wrist. But what struck me as curious, was the fact that my heart was beating forcibly all the time! The absence of pulse, therefore, did not seem to me to be caused by exhaustion of the heart's power, or a tendency to syncope.

'The cramps in my arms and legs were very torturing. There was total suppression of urine for about twenty-four hours. My voice at first was rather shrill and squeaky, before it became what is called sepulchral. The rice-water evacuations were ejected at frequent intervals, and the vomiting was almost incessant. I craved for liquids, and drank cold water and soda-water for a time, only to expel them with a spasmodic rush. I did not experience any nausea; when the fluid reached the stomach it seemed to be expelled by the rapid contraction of the muscular coats of that organ. I am thankful to say no stimulants were given to me, and I lived through the attack. I retained my consciousness the whole time, and recovered without much secondary fever.

'After this experience, I naturally took more interest than ever in studying the disease. The writings of Dr. Brown-Séquard seemed to me to lead to the conclusion that irritation of the vaso-motor portions of the sympathetic nervous system would account for many, if not all, the symptoms of the collapse of cholera. When I read Dr. George Johnson's 'Notes on Cholera,' I felt convinced that the asphyxia produced by the contraction of the pulmonary arterioles was apparently the chief condition to be overcome.

'We have then, apparently, to deal with some morbid influence which acts with fearful violence for a time. It often kills rapidly, but if the patient do not succumb, he gets well pretty quickly. The question is—What state is he actually in, and what can be done to keep him alive?

'Dr. Brown-Séquard sums up the result of his well-known experiments by asserting that the parts supplied by the sympathetic, when that nerve is divided (or paralysed), show: (1) Dilatation of blood-vessels; (2) Afflux of blood; and (3) Increase of vital properties; while galvanisation of the nerve is followed by (1) Contraction of blood-vessels; (2) Diminution of blood; and (3) Decrease of vital properties. It seemed to me therefore to be more probable that the sympathetic nerve is in an irritated state, rather than paralysed.

'I think that the different symptoms of the collapse of cholera lead to the conclusion that the morbid influence (whatever it may be) exercises a stimulating action on the vaso-motor portion of the sympathetic nervous system, producing increased heart-action, contraction of the muscular walls of the arteries, and, at first, augmented blood-pressure. The increase of arterial tension is first shown by a hard pulse. This afterwards becomes small, because there is a very little blood in the artery. I am sorry that I have not been able to obtain sphygmographic tracings of the pulse as yet. Dr. Parkes has pointed out the frequency of copious micturition of limpid urine at this early period. This flow has been shown

by Traube to be intimately related to high arterial pressure; but when the state of muscular activity passes on into cramp-like spasm, there is a total suppression of urine. This is probably due to complete closure of the renal arterioles.

'A sensation of burning heat at the epigastrium is often experienced in collapse. This may be due to a hyperæmic condition of the solar plexus. The condition of irritability of the sympathetic produces, through its vaso-motor nerves, spasm of the muscular coats of all the arteries of the body. The heart contracts forcibly, but cannot dilate normally, its muscular walls being spasmodically affected. This is a point that I wish to bring prominently forward. I believe that the irritation and hyperactivity of the vaso-motor portion of the sympathetic is so great, that the inhibitory or dilating action of the vagus on the heart is not able to control it.

'We have then, I presume, the following conditions: At first, increased blood-pressure, caused by the heart beating strongly, forcing the blood through contracted arteries. As the disease advances, the heart, though contracting forcibly, gets very little blood from the lungs, and therefore has only that little to send into the arteries. The systemic veins are gorged with blood, which occasions the blue colour of the face and surface of the body.

'The peculiar choleraic voice is one of the first symptoms that attracts attention in this disease. One thing seems evident, that this peculiar voice does not depend on deficiency of air entering and leaving the lungs. If a cholera patient be desired to take a deep breath, he can generally do so. A considerable quantity of air is heard rushing into the thorax, and if one's hand be put to the mouth, the breath can be felt coming out pretty strongly, only very cold. I cannot help thinking that we must attempt to explain the existence of this voice by the effect produced on the larynx by the abnormal condition of the nerves which supply its muscles.

'Violent cramps in the voluntary muscles are felt in most cases, which occasion the real pain in collapse. Dr. C. B. Radcliffe, in *The Dynamics of Nerve and Muscle*, says that contraction of muscle is a temporary death. It is, in fact, an imperfect *rigor mortis*, which condition is seen strongly marked in persons who die in collapse. The cramps in cholera may therefore be caused by the cutting off of the blood-supply to portions of the muscles by the contracted state of their arterioles.

'The vomiting is apparently due to spasm of the coats of the stomach caused by the hyperactivity of its nerve supply; and the evacuations from the bowels may be the result of exudation from the distended venous radicles of the portal system, which partake of the general venous engorgement; for Niemeyer has shown that when the arteries are contracted there is venous distension. I am aware that many facts have been observed, which go to prove that the rice-water fluid is the result of secretion and not of transudation. The celebrated experiments of Moreau bear particularly on the point. Lately, in this country, Dr. Lauder Brunton has been carrying out a series of experiments on the nerves supplying the intestines, some of which he was kind enough to allow me to witness, for which I take this opportunity of thanking him. But time will not permit me to go into this question here, and I beg, for the present, to leave it an open one. It is clinically interesting to know that the purging is not accompanied by any of that pain known to us as

colic. The intestinal activity of cholera is absolutely painless. The packed condition of the intestines (in which they are seen drawn back to the spine, and occupying much less space than usual in the abdomen), described by Sir William Gull and Dr. Baly, is probably produced by great contraction of all the longitudinal as well as the circular fibres. But I look upon the vomiting and purging as of secondary importance. The worst cases, those of so-called cholera sicca, appear to die of asphyxia before much fluid can be thrown out by the stomach and intestines; for though rice-water fluid is found in the intestines in these cases after death, there is nothing like the quantity that is often expelled during life in other and less severe cases. According to my idea, the morbid influence is expending its force most fatally on the heart and lungs, through the vaso-motor centres, and to these our whole attention must be directed.

It is also a matter of clinical fact that in the worst cases there is absolute suppression of secretion of bile and urine. These facts point to the spasmodic condition of the arterioles of the liver and kidney. The blood is shut off from the liver-cells and Malpighian tufts. The gall-bladder, however, is usually found full, or half full, after death. The general condition of spasm of the involuntary muscular system has probably involved the circular fibres of the bile-duct and so prevented the bile (which had been secreted since solid food was last taken, and before the state of spasm had set in) from being poured into the intestines. The urinary bladder is generally contracted to the "size of a walnut," as has been remarked.

It has also been observed that abortions frequently occur in pregnant women when attacked by cholera, and that the foetus has been often expelled alive, proving that the miscarriage was not caused by the death of the embryo. Of course, the contracted state of the mother's blood-vessels may cause the death of the child in time by stopping the utero-placental circulation; but I fancy that the uterus often contracts before this is brought about.

One of the chief peculiarities about this disease is, that while such fearful disturbance is going on in the body, the intellect is generally unaffected. If there were really a tendency to syncope, we should probably oftener see loss of consciousness.

I now beg to bring forward what I consider to be the right principle on which to treat collapse of cholera. Presuming the morbid state against which we have to contend to be one of asphyxia, caused by spasms of involuntary muscular fibres, due to a condition of hyperactivity of the sympathetic nervous system, the logical inference distinctly points to the exhibition of a remedy calculated to neutralise this condition. Such remedies are to be found in the class of agents which directly depress the activity of the muscular fibres of the circulatory apparatus.

In a previous paper, I have pointed out that it is of no use to give medicines by the mouth, as they are generally immediately rejected. I suggested the hypodermic injection of pure sedatives, which, if given in sufficient quantities, actually do produce syncope by their palsyng action on the heart. When I wrote that paper, chloral-hydrate had only recently been discovered. At that time I had never seen chloral-hydrate, and did not know what its real therapeutic action was.

Surgeon-Major Collis (of "The Buffs") and myself

performed a number of experiments on bull-frogs (about $1\frac{1}{2}$ lbs. in weight, and twelve inches in length) with digitalis and other drugs, which produce an effect on the circulation through the nervous system. We found that chloral-hydrate caused the death of the frogs, with the heart in the most complete diastole, thereby proving that it is one of the most powerful vascular sedatives that we possess.

It so happened that I had not an opportunity of trying the hypodermic injection of a pure sedative till August, 1873. I then had a soldier in collapse under my care. I dissolved ten grains of chloral-hydrate in 100 minims of water, and injected this quantity under the skin of the arms in four different places. The record of this case will be found in the *Indian Medical Gazette* for November, 1873. Reaction was established in about five hours, and the patient made an excellent recovery, without any inconvenience from the punctures.

In September, 1873, Mr. Higginson, the civil surgeon of Kheri, in Oudh, treated nineteen cases on this plan, and only two died (one of whom might probably have been saved if the native doctor left in charge had carried out his instructions). The letters preceding this paper refer to seventeen of these cases. These results speak for themselves. Of course a great many more cases will be required to prove the efficacy of this treatment, but at all events it is a good beginning.

I attach great importance to the strength of the solution used; one part of chloral-hydrate to ten of water. If it be stronger than this it will probably not be absorbed into the blood, and only cause ulceration, or perhaps sloughing. Mr. M'Reddie, the civil surgeon of Hurdni, in Oudh, reported unfavourably on the hypodermic method, in the *Indian Medical Gazette* for December, 1872; but he dissolved twenty grains of chloral in sixty minims of water, which was much too strong.

I cannot here go into the subject of the secondary fever. I believe this to be a condition closely allied to heat apoplexy, and will only say that it would appear probable that the activity of the muscular walls of the blood-vessels is followed by a period of relaxation. This really is a partial paralysis, the result of exhaustion. In this dilated condition of the systemic arterioles, I have found quinine and a combination of stimulants and tonics to be the best treatment.

J. MILNER FOTHERGILL, M.D.

PEPPER ON LATENT CIRRHOSIS OF THE KIDNEY.—At the Pathological Society of Philadelphia, March 25 (*Philadelphia Medical Times*, June 5,) Dr. William Pepper presented the heart and kidneys from a case of latent Bright's disease. The patient was a young woman, aged twenty-seven years, whose appearance always indicated full health, with some tendency to plethora. It was not known that she ever had scarlatina, and no symptoms had ever attracted attention to the kidneys. For some years past, occasional dyspnoea had been noticed, which grew much more severe last autumn, when it became constant, and much increased on exertion. She also had occasional violent paroxysms of orthopnoea, resembling attacks of spasmodic asthma, and usually at night, and, on several occasions, hæmoptysis occurred. The secretion of urine was abundant, of light colour, and rather low specific gravity; it was carefully examined several times, but no albumen or tube-casts were found. The breathing was very frequent, and there were frequently signs of marked

pulmonary congestion. The action of the heart was habitually rapid, but was readily kept under control by moderate doses of digitalis. Physical examination showed a considerable degree of hypertrophy, chiefly of left ventricle. While under treatment, several severe nocturnal paroxysms occurred; and, finally, after having enjoyed an unusual degree of comfort for several weeks continuously, she was seized with symptoms of intense dyspnoea soon after retiring one evening, followed in a few minutes by insensibility, purplish suffusion of face, and death.

At the necropsy, extreme cirrhosis of both kidneys was found; the organs being reduced to about one-third their normal size. There was intense venous congestion of all the abdominal organs. The lungs were deeply congested, but no apoplectic clots were found. The heart was much hypertrophied, the walls of the left ventricle being especially affected. The valves were competent, but the leaflets of the mitral were thickened and somewhat too rigid. The right ventricle was not much enlarged, and its full expansion seemed checked by a delicate band, which passed from about the middle of the septum to the outer wall. There were traces of old pericarditis.

Dr. J. H. Hutchinson remarked that some years ago he had exhibited two kidneys, which had undergone even greater contraction than had taken place in those just presented by Dr. Pepper, the smaller weighing only seven drachms. The patient, an unmarried woman of about thirty years of age, was admitted into his ward at the Pennsylvania Hospital for a slight disease of the skin. Shortly afterwards, most distressing dyspnoea set in, and continued until the occurrence of death, in less than twenty-four hours after the seizure. Owing to an oversight, the urine was not examined during life, but that which was removed from the bladder after death was found to be highly albuminous. Dr. Hutchinson afterwards learned, from the gentlemen in whose house she had lived for some time as a servant, that she had apparently always enjoyed good health, and that she had at no time presented symptoms which could be referred to disease of the kidneys. He had known of other cases in which distressing dyspnoea appeared to be dependent upon cirrhosis of these organs and was almost its only manifestation.

Dr. De F. Willard said, with regard to the absence of albumen from the urine, he was called last summer to a girl who had not passed urine for thirty-one hours, and was suffering from uræmic convulsions. He removed a small quantity by the catheter, but found, on examination, that it was non-albuminous, and without tube-casts. The girl died in three hours. He made a *post mortem* examination, and found both kidneys extremely contracted, both smaller than those presented by Dr. Pepper. He re-examined the urine drawn by the catheter very carefully, and found neither albumen nor casts. He could learn little of her previous history (she was a prostitute), but it was said that she had Bright's disease. He had previously seen specimens of urine in which a single examination had failed to point out the presence of albumen, which was subsequently found present.

Dr. James Tyson remarked that the cases just quoted illustrated the form of Bright's disease, in which it was well known that albumen is present in minimum amount, and, according to some excellent authorities, sometimes altogether absent.

HYDATIDS OF THE LUNGS IN AUSTRALIA.—In the *Melbourne Medical Record* of March 6 is an unsigned article, which says: In no country, with the exception of Iceland, is hydatid disease so frequently met with as in Australia. Prior to 1861, when Dr. Hudson, now of Ballarat, drew attention to it, little was known concerning it. In 1861, when this gentleman published a paper on the subject, but few cases had been met with in the hospital. Since then it has become one of the most common diseases of the colony. It was, however, common on the sheep stations up the country amongst the blacks, partly from eating raw or underdone mutton and drinking unboiled water from water-holes frequented by sheep-dogs and other animals. Great numbers fell victims to this disease in the early days of the colony. Drinking the water of pools containing hydatids, and eating hydatid meat, are not the only sources of disease. The animal may be seen attached in some ponds to the plants growing in them. I have seen them on the common water-cress. Eating this vegetable when it grows in ponds or ditches frequented by sheep, pigs, or dogs, is always attended with risk.

Few patients can trace the period when they first took the hydatid into their systems. In one case the patient, six months before he began to suffer from pain, followed by swelling, had drank, after walking a long distance, from a pool in which the body of a sheep which had died of hydatids was rotting. He had two companions with him; but although they drank quite as freely of the water as himself, neither suffered. In a girl aged twelve years, eighteen months before seen she had, at a school treat, drank water from a paddock where sheep were grazing. The swelling had existed six months when she came under notice. Most of the cases of hydatids occurring among children living in Melbourne can be traced to drinking water from ponds; girls seem to be much more liable to hydatids than boys, although the reverse might be expected, from the latter being about more than the former; later in life males are more liable than females. It is, then, nearly invariably met with among men who as shepherds, stock-riders, etc., are liable to drink water containing hydatids. Whether it takes six months or more for the hydatid to increase to such a size as to produce troublesome symptoms, I am unable to say. The growth will depend very much on whether the patient is living in a damp situation or a dry one; cold and wet seem invariably to cause it to increase more rapidly than a dry atmosphere. Placing the patient in a warm bath will cause the hydatid to increase in size, while a hot-air bath, by causing copious perspiration, will reduce it, if the patient abstain from drinking. The lungs stand next in liability to the liver. Taking a hundred cases, the relative liability would stand thus: liver, seventy; lungs, twelve.

RAWLINS ON TUBERCULAR DISEASES IN THE NEGRO.—In the *Medical and Surgical Reporter* for May 29, Dr. James T. Rawlins writes as follows. As the fatality of diseases affecting the coloured race is alarmingly upon the increase, I think a few remarks upon this subject not inappropriate. Of all diseases, the great scourge is pulmonary tuberculosis. Until within the last decade, tubercular affections were not more frequent in the coloured than in the white race; indeed, the amount of white blood seemed to be the predisposing element, the African enjoying a certain

degree of immunity. But within my observation, the contrary seems now to prevail; especially is this the case in the acute type of disease. I have never seen a case of acute miliary tuberculosis in a white; with the mulatto the type is generally more rapid than with the white, galloping consumption, as it is frequently called. But in the black we encounter the acute miliary type, *sui generis*.

Contrary to Niemeyer's rule, that this disease generally follows old caseous deposits, it appears to result from any depressing cause, and in many cases the patient has never been known to have had any organic disease. Especially is this the case with young females, about the age of puberty. The eruption of the tubercle appears to be essentially a neoplasm.

The physician is generally consulted in these cases for some trivial derangement, as the attention is seldom early attracted to the lungs. I have found neither cough nor hæmoptysis among the first symptoms, and have seen patients die without having had either. It is a hard thing for the laity to understand, that a person can die of consumption without cough or hæmorrhage. The early symptoms are sometimes obscure, and the general appearance of the patient has much to do in the formation of a diagnosis. The two characteristic symptoms, the most striking and disproportionate to all the rest, are the rapidity of pulse and frequency of respiration. From the general diffusion of tubercles, percussion often fails to elicit an observable dullness. You find, upon auscultation, a suppression of the vesicular murmur; with small, dry, crackling râles throughout the lungs. In several cases I have failed to observe any increase of temperature until near the termination of the disease, which appears to be from asphyxia, due to the general obstructive diffusion of tubercles.

J. MILNER FOTHERGILL, M.D.

DALLY ON THE METHODICAL TREATMENT OF HYPOTROPHY AND ATROPHY.—Dr. Dally in his recently published pamphlet on this subject (Masson, Paris) endeavours to show the existence of a rational physical therapeia as well as of a biological therapeia. He writes: 'In the same way as the physical properties of organised bodies hold a considerable place in biology, the agents of the same order should hold a corresponding place in therapeutics.' The author endeavours to establish the following propositions concerning the diminution of the trophic properties of the tissues. In practice it is important, in the first instance, to distinguish the trophic troubles, and specially the hypotrophies, which are dependent on a primary acute or chronic change in the nerve-centres; and then those which have their starting-point in the primary and direct lesion of the peripheric organs. The first are generally incurable; but they may become much lessened when their seat is primarily cerebral, or when they take on in the medulla a rapid acute progress which can be modified, especially if located near the outset of the symptoms. The hypotrophies of peripheric origin, traumatic, rheumatismal, professional, anæmic, etc., are, on the contrary, generally curable. In the treatment of hypotrophies, the physical agents—manipulations, heat, electricity—may be successfully applied whenever they reach the primitive lesions. They act by creating local intermediary conditions, favourable to the internal processes of nutrition, and not by artificially stimulating the special nerves which set the circulatory and secretory apparatus to work. If even this

action be real, it soon exhausts itself and remains sterile. Chemical agents do not appear to have any other action than to modify the digestion favourably when necessary. Biological agents, such as kinesis and gymnastics, bring on, when possible, natural functional synergias; the struggle between innervation and of the peculiar function of the elements which seem necessary to the trophic actions, or at least favour them. The systematic and combined employment of these different agents give the physician a powerful influence in directing the functions of nutrition.

RINTELN ON RECOVERY FROM INTUSSUSCEPTION AFTER SEPARATION AND VOIDANCE OF FOUR INCHES OF SMALL INTESTINE.—Dr. Rinteln, of Oeynhausen, reports the following interesting case under the heading of 'Gleanings from Practice,' in the *Berliner Klinische Wochenschrift* for May 24, 1875. The patient, a delicate and spare woman, aged sixty, actually lived ten years after her recovery, and enjoyed fair health. The attack was preceded by diarrhoea and colicky pains. Then came symptoms of obstruction of the bowels, and vomiting of fecal matters, some of which were in lumps, which leads Dr. Rinteln to infer that they were formed in the small intestine. After ten days rather active medication, under which she grew worse, resort was had to opiates, and absolute rest to the bowels. At the end of three weeks her life was despaired of. On the twenty-fifth day, however, she greatly improved. On the preceding night there were five or six feculent stools, mixed at first with blood and mucus. In one of these about four inches of dark gangrenous small intestine were found. From this time her recovery was rapid, and it must have been complete, since she never afterwards had the least difficulty in passing motions. [Similar cases in younger subjects have several times been noted. By the courtesy of Mr. Hutchinson, the reporter saw one such in the practice of Dr. Stutter, of Sydenham, in which a boy passed nearly a foot of small intestine, and recovered. Rinteln's case is, however, interesting on account of the patient's age.—*Rep.*]

SURGERY.

ANNANDALE ON KNOCK-KNEE.—In the *Edinburgh Medical Journal*, July, Mr. Annandale describes a new operation for the cure of knock-knee as follows. On the 3rd of March last, a little girl aged six, was brought to me from Glasgow, on account of a serious deformity of her right leg. Mechanical means had been employed for two years with the object of relieving the condition, but without success, and the deformity was steadily increasing in severity.

A careful examination determined an aggravated form of knock-knee, and it was found impossible, in any position of the limb, to bring the leg into a straight line with the thigh, the head of the tibia forming a considerable angle with the condyles of the femur. The femur had a distinct bend inwards and forwards about the junction of its lower and middle thirds, and the condyles of this bone were much more oblique in their direction than in the natural condition.

The adductor muscles were somewhat contracted, and the distortion was such that the patient walked with difficulty. The left limb was well developed and natural in position. A study of the case convinced me that the oblique position of the condyles, the result apparently of the bending of the shaft of the femur, was the principal obstacle which was preventing the tibia and leg being brought into a line with the thigh, and it therefore seemed to me, that if this obliquity could be removed, the deformity might be cured or very much relieved.

Two ways of removing this obliquity suggested themselves. The first was to divide the shaft of the femur at the point where bent; the second to remove an oblique slice of the condyles. The latter operation would be attended with more risk than the former, because it necessitated the incision of the knee-joint. But some little observation decided me to adopt the latter proceeding, for I felt sure that it would be more effectual than the former, and I trusted that the risks of opening into the joint would be counteracted by the careful use of the antiseptic treatment.

The consent of the child's parents having been obtained, I operated on March 16 in the following way.

An incision, about five inches in length, was made along the inner aspect of the knee-joint, the articulation opened into, the internal lateral ligament cut across, and the patella and its ligament being drawn outwards, the crucial and external lateral ligaments were also divided. An oblique slice was then sawn off from the condyles of the femur, the tibia not being interfered with. After the removal of this slice of bone the leg was readily brought into a straight line with the thigh; and a drainage tube being inserted into the cavity of the joint, a few sutures were applied, and the limb placed on a wire splint, in the straight position. The whole operation was performed under the antiseptic spray, and the usual antiseptic dressing was applied to the wound.

Some suppuration of the wound followed the opera-

tion, but this gradually ceased, and on March 24 the discharge was so slight that the dressing was changed only once in two days. On April 25 the wound was quite superficial, and on the 29th of this month the wound was soundly healed. On May 6 the patient was allowed to get out of bed, the joint being supported by lateral splints, which were removed daily to permit of passive movements of the joint being made. On May 30 the splints were entirely removed and the patient allowed to bear weight on the limb. At this date the limb was perfectly straight, and of equal length with the opposite one. The lateral mobility of the joint was very slight, and very much as in the natural condition. Flexion and extension were very limited.

On June 5 I placed the patient under chloroform, and forcibly bent the knee to rather more than a right angle, and I also moved the joint freely, so as to break down the adhesions which had resulted from the operation. No bad consequences followed this forcible bending of the knee; and two days after, the patient was again going about the ward with the help of crutches, and able to bear weight upon the limb, the mobility of the joint being decidedly improved.

Remarks.—I am not aware that this or any similar operation has been before practised in cases of knock-knee, but the successful result obtained in the case reported encourages me to recommend this method of operating in certain aggravated cases of the deformity which have resisted the division of the biceps, tendons, or other tense structures, and carefully-applied mechanical treatment.

The employment of the antiseptic treatment in this and similar operations I consider most valuable, and I must confess that it was my confidence in this treatment which led me to freely incise so important a joint, and to carry out the proceeding described.

J. MILNER FOTHERGILL, M.D

MARTIN ON THE TREATMENT OF SOME OF THE COMPLICATIONS OF STRICTURE OF THE URETHRA.—In a clinical study of the subject, M. Martin arranges his remarks (*Archives Générales de Médecine*, April, 1875) under three heads.

1. Strictures impassable, or difficult to overcome.
2. Strictures complicated with infiltration of urine, or with urinary abscess.
3. Strictures complicated with urinary fistulæ.

Under the first head he states what he means by an 'impassable' stricture, one through which it is impossible by any means to pass an instrument into the bladder. He divides the treatment of this first group of cases into two modes, gentle and forcible, quoting Dupuytren in favour of trying gentle means before resorting to force.

He reviews the subject of bougies, and quotes Civiale and Guyon, who recommend that the ends of bougies (gum elastic) should not be too tapering, but that on the contrary, the bougie should offer resistance sufficient to straighten it when bent back with the finger. It should accommodate itself to the course of the stricture, and not double back. He mentions an ingenious plan of M. Curtis, of collodionising the end of the filiform bougie. He dips the end in collodion to give it resistance, and to preserve any curve given to it. M. Guyon makes great use of bougies, and gives various directions to the ends.

The rigid instruments (metallic or whalebone) employed in England (?) and America, the author says are likely to cause false passages.

M. Guyon employs wax bougies, and claims two advantages for them. First, at the moment of withdrawing the bougie, a patient suffering from retention will often pass urine more easily than before. Secondly, immediately on withdrawing the wax bougie the surgeon may pass the stricture with a fine bougie.

Of the influence of pressure made by a wax bougie against a stricture, he states that M. Guyon says the pressure of the urine from behind, which was powerless alone to separate the sides of the stricture, succeeds when anterior pressure has been made in addition.

M. Guyon also thinks that wax bougies are more capable than any other instruments of moulding themselves on all the points of the anterior aspect of the stricture, and even of penetrating into its anterior orifice, and thus of modifying the form of its antechamber. This mechanical action of the wax bougie is only applicable to cases in which the bougie is pressed against the anterior aspect of an impassable stricture.

On the subject of the length to which sittings should be carried, he says M. Guyon seldom prolongs a sitting over a quarter of an hour, or half an hour at most. He proceeds very gently and slowly, stopping directly the canal bleeds. He repeats the sitting daily, or every other day, according to the sensitiveness of the patient, and always preceding the filiform bougie by the wax bougie.

When the bougie has entered the stricture, and cannot be advanced, Messrs. Voilemier and Guyon agree in advising that no force be used, that the instrument should be withdrawn in three or four hours, or as soon as it causes pain.

Under the head of 'Results of Treatment' the author states that, out of nearly 400 cases of stricture treated at the Necker Hospital by M. Guyon, only three cases required external urethrotomy without a conductor. He again lays stress upon the superiority of gentle over the forcible treatment of stricture.

In speaking of accidents and complications of treatment, the author admits that now and then the collodionised bougie enters a fistula or an old false passage, but that without any other accident than slight pain or a little fever.

The indications of the treatment of stricture, complicated with infiltration of urine are, to give exit to infiltrated fluids, and to re-establish urination.

The author thinks that Dr. Caron, a pupil of M. Flaubert of Rouen, is the only author who has satisfactorily laid down rules for making the incisions of urinary abscess and infiltration of urine; and he describes deep median incisions carried well backwards to avoid burrowing.

In speaking of the re-establishment of urination, the author reviews various opinions, and states that M. Guyon is in favour of waiting fifteen days, or even three weeks, before trying catheterism. He advises that during this time the surgeon should attend only to the treatment of the infiltration, and not till the incisions have nearly healed should attempts be made to pass an instrument.

When M. Guyon has determined to make trial of an instrument, he methodically explores the urethra and ascertains the number and direction of the strictures, and then passes in a bougie, and leaves it in. In the numerous cases of old dense strictures, intolerant of dilatation, M. Guyon performs internal urethrotomy, with M. Maisonneuve's instruments.

Omitting penile fistulæ, M. Martin divides perineo-scrotal fistulæ into three groups:

1. Simple fistulæ without much induration;
2. Fistulæ with considerable induration;
3. Numerous old and hard fistulæ resisting milder methods of treatment.

The author states that the first group may be cured by the simple restoration of the calibre of the canal; yet he has not seen any of these cases cured at the Necker Hospital by dilatation *pur et simple*. Commonly it was necessary to follow up dilatation with the *sonde à demeure* or by caustics. In other cases the toughness and length of the strictures compelled resort to other means, and above all to internal urethrotomy with Maisonneuve's apparatus. He has several times seen this operation followed by excellent results.

In the second group of cases it is necessary to divert the course of the urine to accomplish cicatrisation of the fistulæ.

The treatment consists in either leaving an instrument in the bladder or repeated catheterism or cauterisation of fistulæ.

Fistulæ belonging to the third group may be cured (1) by incision of the fistulous track with or without cauterisation; (2) by external urethrotomy; or (3) by excision. By this last operation is meant excision of the fistulous track and its surrounding callosities. M. Voilemier's ten successful cases are referred to; and then M. Martin writes that during the year M. Guyon performed a rather different operation for three such cases (old cartilaginous callosities not possessing any tendency to contract or cicatrise). Having freely excised the indurated portions, he performed internal urethrotomy along the inferior wall of the canal. In two, no complication occurred, and complete cures resulted. In the third patient, infiltration of urine took place, and the case ended fatally.

Under similar circumstances, M. Guyon would now prefer to incise the upper wall of the urethra, and to excise the fistula at a second operation.

VACHER ON THE TREATMENT OF SIMPLE FRACTURE OF THE SHAFT OF THE CLAVICLE.—In an article reported from the *Liverpool and Manchester Medical and Surgical Reports*, after a preliminary review of the different methods of treating this fracture, Mr. Vacher states that in 1872 he had constructed for use in dealing with this injury, two sheet-iron shoulder-pieces or caps. They were carefully shaped to fit the parts they were intended to grasp, and were connected together behind by straps and buckles. A cross-strap was added in front to prevent the caps from tilting. Each cap measured five inches across the top, and the pair weighed, inclusive of straps, padding, etc., just twenty-four ounces. He had used this apparatus on several muscular subjects, and asserts that 'if it be skillfully employed it will place and retain the acromial half of a broken collar-bone in a position very closely approaching its position before fracture, without galling the patient's skin, compressing the axillary contents, or interfering with the free action of the chest.' JOHN CROFT.

KEYES ON THE INJECTION OF BLADDER.—Dr. Keyes, of New York, in a paper published in the *American Journal of Medical Sciences*, April, 1875, states that an efficient and easy method of injecting the bladder with warm water by the patient himself alone can meet the requirements of many cases of chronic cystitis.

To wash the bladder thoroughly it must be some-

what distended. The apparatus, advocated by the author, consists of a soft rubber catheter, a two-way stop-cock, and a fountain-syringe.

About eight ounces of fluid should be first prepared, and warmed to about 110° Fahr. The bag containing this fluid is to be suspended about six feet from the floor. Air is to be ejected from the stop-cock. The catheter is to be next introduced; and, when urine begins to flow, the coupling is made with the stop-cock. Urine then flows out through the discharge part of the two-way stop-cock. As soon as the urine has escaped, the bladder is to be refilled by turning the stop-cock that only the injecting fluid from the bag can flow in. In this way the bladder can be repeatedly washed out.

The advantages over the piston syringe and injecting-bag are—(1) simplicity of structure; (2) absence of valves and piston liable to get out of order; (3) a steady stream; (4) capability of furnishing repeated successive injections without being refilled, without reapplication of the instrument, or the risk of imparting any motion to the catheter.

The author gives an illustration of the apparatus.

JOHN CROFT.

CLARK ON FRACTURE OF THE SPINE: COMPRESSION OF THE CORD: REMOVAL OF THE DEPRESSED BONE.—In the transactions of the Cincinnati Academy of Medicine, May 31 (*Clinic*, June 5), Dr. H. A. Clark reported the following case, the operation upon which he had witnessed by invitation of Drs. Stemen and Sherrick, of Van Wert, Ohio, who had it in charge.

Mr. W. P. W—, an artisan, aged twenty-nine, married and in good health, while engaged in a gravel bank, was injured in the spine by the falling in of a mass of earth. An examination of the injury showed fracture of the eleventh dorsal vertebra with depression of the arch; considerable inflammation with swelling of the back, even up to the neck, followed the injury. But little more is known of the immediate results of the accident, as the early history of the case was not accessible. About a month ago (nine months after the injury) the case came into the care of Drs. Stemen and Sherrick, of Van Wert, by whom the speaker was invited to witness the operation. Their examination elicited the following. There was depression over the site of the eleventh dorsal vertebra, the tip of the spinous process of which was detached, and from the symptoms presented Dr. Stemen surmised fracture of the laminae and compression of the spinal cord (which proved correct), and did not deem it safe to push the physical examination further than to ascertain that there was then present no sign of inflammation in the parts involved. The pressure had produced complete paralysis of all the parts below the seat of injury; no motion whatever could be effected by volition in the palsied muscles, and hardly sufficient sensation could be perceived in the lower limbs to determine which one was being sharply pinched. There was no control whatever over the sphincters of the anus and bladder. The bowels generally constipated. Ten months after the receipt of the injury, Drs. Stemen and Sherrick operated for the purpose of removing the compression on the spinal cord. A linear incision was made in the median line over the seat of injury, and the vertebræ exposed by dissecting off the adjacent soft parts. Fracture of both laminae was now discovered as had been anticipated; on the left side the lamina was completely fractured

with depression; on the right side was a partial fracture of the lamina or bending, so as to permit the left end of the fragment to be depressed. This fragment, which included the spinous process, was firmly fixed in the position described. Both laminae were cut nearly through with Hey's saw at the seat of fracture, and an effort made to remove the fragment by firmly seizing the spinous process, but it could not be removed by any force that seemed justifiable. The spinous process was then removed with a bone-forceps. This made room for the application of the trephine, by means of which the left or depressed end of the fragment was removed almost entire and the arch restored to its normal contour. On removing the cap of bone isolated by the trephine the meninges of the cord pressed backwards and bulged into the opening. The wound was dressed by a few interrupted sutures, a piece of wet lint, and a wet sponge as an elastic compress, held by a body bandage. No marked disturbance followed the operation. The pulse was never over 90. The wound healed by first intention, except at the point where the fragment of bone was removed. The wound seemed hardly to produce inflammation, as no perceptible swelling followed; hardly any increase of temperature was perceptible. The night after the operation the patient slept well, the next day he ate as usual, and stated that he felt more comfortable than before. There was a slight soreness in the back with occasionally a prickling sensation, also now and then sharp pains running through the bladder and legs, which he described as telegraph operations. Sensation was improved so that he could tell what exact toe was touched, but no motion. On the third day after the operation, there was every reason to anticipate a speedy recovery from the operation, and Drs. Stemen and Sherrick had high hopes of some relief from his previous condition, though to what extent is of course a matter of the merest conjecture. This operation has been performed in all thirty-eight times, the case now reported making the thirty-ninth; of these twenty-nine died. It was twice performed by Dr. Blackman. Dr. Stemen's makes the third in Ohio.

Dr. Clark had just received a letter from Dr. Stemen to the effect that the patient was still improving; sensation was returning to the palsied extremities, and he was regaining some control of the sphincters. The wound was healing kindly and with but little suppuration. Pulse and temperature were not above normal. The treatment by hypodermic injections of morphia was continued. This letter was dated five days after the operation.

MATERIA MEDICA AND THERAPEUTICS.

LEONARD ON KOUMISS AS A REMEDIAL AGENT. In the *Chicago Medical Journal* for May, Dr. R. L. Leonard says: It has been my fortune to have an early experience in the use of koumiss (fermented mare's milk), and the effect of its use has been such that I deem it proper to call the attention of the profession to a few cases which have been materially benefited by its use.

The first patient was P., a babe, born at full term, and apparently healthy, weighing eight pounds. The mother's breasts secreted little or no milk, and from its birth the child was obliged to subsist upon cow's milk. For a few days it seemed to thrive, but the fifth day it vomited a good deal; an occasional ten-grain powder of the subnitrate of bismuth was ordered. I called on the ninth day, and found that there was little or no vomiting; but on the tenth day the vomiting had increased considerably, and there was a very loose condition of the bowels. Subnitrate of bismuth was ordered in ten-grain doses every four hours, and for a day or two the child was better; but on the fourteen day, when I called, it was reported much worse. The bismuth, which had been discontinued partially, in view of the marked improvement noticeable at my last visit, was now resumed, and the dose increased to fifteen grains; but, in spite of treatment, on the fifteenth day the babe retained but little of either milk or medicine, and its extreme emaciation induced me to obtain its weight, which I found to be seven pounds. On the eighteenth day the mother reported that it had vomited everything (milk and medicine) for forty-eight hours, and it seemed about dying from actual starvation. In this extremity it occurred to me to try koumiss. Acting upon this idea, I obtained a quart bottle of medium koumiss, and, returning, had the nursing-bottle filled with two-thirds koumiss and one-third hot water, and gave it to the starving babe; to my utter astonishment it took the koumiss with an evident relish, emptied the bottle, and equally astonishing to me was the fact that it was retained. I ordered the mother to give all the babe would take, if retained; and, on calling the next day, found that it had used the entire quart, and the bowels were moving at intervals of about six hours. On the third day after commencing the use of koumiss in this case, a slight diarrhoea manifested itself, which disappeared in twenty-four hours without treatment. The babe had all the koumiss it would take from the first, improvement continued to be rapid, and at the time of writing the child has used twenty-four gallons of koumiss, or an average of about three pints per day, is fat and healthy as a child can be at the age of fourteen weeks.

The second patient, Mrs. B., a lady of American birth, aged thirty-six years, had been debilitated by typhoid fever. Her stomach was irritable; and although the disease had a week previous passed its acme, still but little nourishment could be given on account of this excessive irritability. Koumiss was ordered in its purity, and was acceptable to the stomach; the recovery of strength was rapid, and the koumiss was discontinued in two weeks.

The third patient, Mrs. O., an American lady, aged forty-three, had been afflicted with dyspepsia for

many years, for the past ten of which her diet had been confined almost exclusively to oatmeal and her drink to very weak tea, as these were the only things that would remain unvomited. I had used koumiss in these other cases of irritable stomach and extreme emaciation, and thought it advisable to try it in her case, so I ordered it to be taken gradually for a day or two, then all she could take, to the exclusion of other food and drink. In two weeks she was much improved, so much so that she was not only able to sit up, but to take a broom and sweep the house, an exercise for which she had been totally incapacitated during the whole of the last seventeen years. After three weeks she was able to go for her own koumiss, walking a distance of one and a half miles on that mission every few days; and at present, after two months' use of the remedy, she has so far regained her digestive power that she requires but little koumiss, and can eat beefsteak and partake of the usual diet of her family table.

The fourth case, J., is a babe, aged six weeks at the time of my first visit, which was depending upon the bottle, the mother having no milk in the breasts. When I called, the babe, a little puny thing, seemed as if it were gasping for its last breath; it was extremely emaciated, and for twenty-four hours up to that time had been unable to take the bottle, and had received an occasional drachm of milk from a teaspoon; the bowels were moving every hour, and it had retained scarcely anything for a day or two. A spoonful was put into its mouth which was with difficulty swallowed; soon it was followed by another, and so on at short intervals for four hours, at the expiration of which time it took the koumiss from the bottle, and from the very moment of the administration of the first spoonful to the present time, a period of nearly two weeks, its improvement has been exceedingly rapid, and it is now quite strong and apparently healthy.

I might mention another case, in which Mrs. S., a lady aged about twenty-five years, was debilitated by a miscarriage which was accompanied by excessive hæmorrhage and succeeded by a three months' illness which left her in an extremely anæmic condition, which refused to yield to quinine, iron, strychnia and other tonics. Upon the introduction of koumiss to the treatment of the case, she improved rapidly, and in three weeks so far recovered as to be discharged cured.

It is my candid belief that in koumiss the profession has a valuable acquisition to the list of remedies; and while I have dwelt in detail upon the report of these cases, selected from my experience during the last three months with about fifty gallons of medium koumiss, I am satisfied that my success is not that kind which is attainable only in the hands of the writer, but may be duplicated by my professional brethren who have cases of extreme debility or emaciation to deal with, particularly where the stomach is in an irritable condition without active organic disease.

DAWSON ON ARTIFICIAL DIET.—In the *New York Medical Record*, June 5, is a report of a communication made by Dr. B. F. Dawson to the New York Medical Association, in which occur the following remarks on diet.

If this be judiciously selected, there is no reason why a child should not thrive as well upon artificial food as when its support is derived from the mother's breast. No food is capable of properly nourishing

an infant unless it possesses heat and fat-producing properties. Any nourishment which does not come up to the requirements of a liquid food having the proper quality will produce intestinal troubles. What nourishment are we to give? Is there any one kind of nourishment which uniformly and perfectly supplies the place of breast-milk? The article which most perfectly answers all the requirements, and can be trusted to furnish all the elements of nutrition in the most digestible form, is milk from some animal. The milk of various animals varies to a certain extent in the properties of its different constituents; but the milk of the cow is the one which should ordinarily be used, and when properly prepared may answer all purposes. In its natural state it is not a fit article of food, and some article must be added which will effect a proper dilution. Water is the article commonly added; but by far the greater number of cases suffer in consequence of its addition. The addition of water alone does not improve the digestibility of the casein, for it does not dilute it; and when milk is introduced into the stomach, diluted with water, the water is soon taken up and the casein is left as undiluted and unchanged as before the food was given. Nor does the addition of sugar make the coagula any more easy of digestion; nor does skimming the milk act beneficially, but, on the contrary, deprives it of one of its most important constituents. Inasmuch as the mother's milk contains proportionately more fat than other milk, may it not be true that the finer coagula which is formed, when the mother's milk is introduced into the stomach, is due to the presence of this fat? and would it not be better to use the milk as an article of food, from which casein has been removed, rather than use the milk which has been deprived of its cream? It had been his experience that this was the more proper course to pursue. The admixture of farinaceous articles with the milk also leads to disastrous consequences. There is one article, however, which contains such small quantities of starch that it can be used with very great success for effecting a proper dilution of cow's milk, and that is barley-water. Good cow's milk diluted from one-third to one-half with barley-water forms one of the best articles of food that can be used for infants when it is necessary to bring them up artificially. If barley cannot be obtained, oatmeal may be substituted, and answers nearly as good purpose. This article produces a real dilution of casein, and renders the coagula much finer and more nearly like the coagula which is found in milk from the mother's breast.

LIDD ON GLYCERINE AS A THERAPEUTIC AGENT.—In the *Detroit Review* for May, Dr. C. H. Lidd writes: In cases of deafness from deficiency, accumulation, or hardness of the cerumen, and attended with dryness of the meatus, glycerine is one of the best agents we possess, introduced into the canal by means of raw cotton saturated with it; but the profession at large are too well acquainted with this use of the agent to justify my entering into a detailed account of its uses in cases of this class. There is one other use of glycerine, of which I would like to speak at this point. I refer to its use in the food of children that are being raised by hand; children thus raised can be kept comparatively free from many of the ills to which they are prone, by the substitution of from four to six drachms of glycerine daily, for the amount of sugar that is usually added to the cream, milk, or water constituting their diet. In all irritable conditions of the bowels in children,

sugar should be excluded from the food and medicine prescribed, and glycerine substituted, for the simple reason that the latter is at once bland and nutritious, furnishing not only the requisite sweetness, but considerable nutrition, while absolutely resisting fermentation, and, above all, it allays the irritability through its exosmotic properties by being brought into actual contact with the bowels, thus serving, as will be readily observed, a triple purpose.

The exosmotic properties of glycerine surpass those of any agent at our command; it possesses the power of withdrawing the watery elements from any tissue to which it is continuously applied. Marion Sims long ago demonstrated the fact that a ball of lint, saturated with glycerine and applied to a freely suppurating surface, would arrest the secretion; Furst and M. Eberhurd each states that he has been successful in applying the glycerine plug in cases of fluor albus. These two writers are the only ones that I can find that even mention the use of this agent, in this way, in any of the journals that I have at command, and these only casually mention the fact of having used it with success. My attention was first called to this property of the drug some three years ago, since which time I have constantly employed it in such cases as I deemed it necessary, and in every instance I have been highly gratified with the results obtained.

J. MILNER FOTHERGILL, M.D.

REEVES ON THE UTILITY OF GUM ARABIC CAKES IN DIABETES.—In the *Melbourne Medical Record* (March 27), Dr. Reeves writes: I have been informed that diabetes is more common in New South Wales than in Victoria; but as I have not had an opportunity of seeing the returns of the number of deaths in the former colony, I am unable to state whether this is true or not. In this colony the deaths in thirteen years amounted to 38—22 males to 16 females. In analysing the number of deaths and the relative liability of the sexes, from 1861 to 1865, a period of five years, two males and seven females died; from 1866 to 1870, twelve males died and five females; and from 1871 to 1873, eight males and two females.

In the first of the cases treated by the gum arabic bread, and the best observed, the husband of the lady being fully alive to the importance of a carefully regulated diet in the disease, the patient was forty-seven years of age, a native of New South Wales, and about two years in this colony. She was not reduced in flesh, but she was weak, and very little exertion fatigued her. Her menstrual discharge was still regular, and of a good colour. She had had seven children; her family were healthy, and both her parents were living. She thought that the disease had existed two years and a half, as she had not observed any sediment in her urine since that time. The cause she considered to have been great and continued mental anxiety, but a few months before the disease was noticed she had suffered from an attack of lead-poisoning. This occurred when living in Sydney. Her urine, she states, was then sweet. Mental anxiety always increases the quantity and the sweetness of the urine. For the last four months she has been losing both flesh and strength, and pain across the loins has set in. She passes urine about three-quarters of an hour after food, and three or four times in the course of the night. Her skin is dry, the temperature both of it and the breath is lower than natural. She is passing from ten to thirteen or fourteen pints of urine in the twenty-four hours. Its

specific gravity is 1.040 or ninety-three grains of solids in the pint.

Ordered gum arabic bread, meat, with buttermilk for diet. Phosphoric acid, sedative solution of opium and biphosphate of copper one-sixth of a grain in a pill three times a day.

7th day.—The quantity of urine was reduced to six pints in the twenty-four hours, and the specific gravity from 1.040 to 1.030, or sixty-nine grains of solids in the pint.

14th day.—The quantity of urine was reduced to five pints in the twenty-four hours, and the specific gravity to 1.028. The urine was tasteless and free from sugar.

From this time there was no sugar; a week later the specific gravity of the urine had sunk to 1.025, and still later to 1.020, and not more than four to four and a half and five pints were passed in the twenty-four hours. She steadily gained flesh and strength from the first.

About six weeks later I was again requested to see her. From exposure to cold and wet, and living in a damp house, bronchitis set in of a peculiar character. The mucous membrane ulcerated, without any implication of the substance of the lungs; the expectoration was heavy and purulent, without any air-cells in it. The urine had undergone no alteration either in the quantity passed or the specific gravity. She had adhered strictly to the diet. This attack reduced her strength so much that she sank.

The second case was a man employed in a beer store. He thought the disease was excited by drinking large quantities of beer. The amount of urine passed, as in the former case, ranged from ten to fourteen pints in the twenty-four hours; the specific gravity was (after food) 1.032, and before food (no food or drink having been taken for three or four hours) 1.035. This patient had only been suffering for twelve months. His recovery was rapid. I have not seen him for more than twelve months. He had suffered severely from crop after crop of boils, and was doing so when seen. With the disappearance of the sugar the boils ceased to return.

In the third case, a female aged twenty, the treatment was equally successful. Chlorosis had existed before the urine was noticed to be passed in large quantities. It was difficult to determine when the diabetes had appeared. She has since married, and had two children.

The fourth case was not successful; the patient, a publican, aged forty, could not refrain from eating and drinking whatever his appetite tempted him to take. When he confined himself to the diet, which he did with great reluctance, he improved; the urine lessened in quantity, and the specific gravity diminished. He died from diarrhoea of a watery character, about three years from the commencement of the diabetes.

The value of any system can only be tested by a rigid investigation, which can only be carried on in a public institution, where patients can be carefully watched that they do not get everything their appetites crave for. I do not profess to say that gum arabic made into bread is a specific for diabetes; but it is, I think, worthy of a trial.

The gum arabic powder is easily made into small cakes with the aid of one-fourth of baked flour. Care should be taken, as some of the powdered gum sold contains large quantities of starch.

GERRARD ON THE ALKALOID OF JABORANDI.—After experimenting very laboriously and skilfully with both bark and leaves of jaborandi, Mr. A. W. Gerrard, of University College Hospital, has completely succeeded, not only in separating the alkaloid of that plant, wherein its great power seems to lie, but has also recently produced crystals of the nitrate and hydrochlorate salts of this alkaloid, which he terms pilocarpine. The following is a brief digest of Mr. Gerrard's process for preparing the alkaloid, published in the *Chemist and Druggist* of June 15.

Prepare a soft extract either of leaf or bark with 50 per cent. alcohol. Digest this with water, filter and wash. Evaporate the filtrate to a soft extract, cautiously add ammonia in slight excess, shake well with chloroform, separate the chloroform solution and allow it to evaporate; the residue is the alkaloid pilocarpine with probably a small amount of impurity.

Besides the alkaloid, jaborandi contains an acrid resin, tannic acid, volatile oil, and chlorophyll. The acrid resin is soluble in ether, and possesses properties which indicate it to be the substance by which the effects of its external application are produced.

Forty-five grains of pilocarpine, produced as above described, were prepared. To this distilled water was added and sulphuric acid drop by drop until the alkaloid was nearly dissolved, and the solution was neutral. After setting aside for ten days for slow evaporation, and no definite crystals resulting, Mr. Gerrard made other experiments, employing nitric and hydrochloric acids. With these he has completely succeeded, and has produced nitrate and hydrochlorate of pilocarpine in a crystalline condition, which it is likely will be the future form in which this remarkable medicine will be administered. Mr. Jameson, Dr. Sydney Ringer's assistant, reports that half a grain of the nitrate produced the usual therapeutic effects of a full dose of jaborandi on a patient within an hour; while one drop of solution of the nitrate (gr. 1 to 3j.) put into the eye of a patient caused the pupil to contract to about the size of an ordinary pin's head.

BARABAN ON THE TOXIC EFFECTS OF TARTAR EMETIC.—Dr. Leon Baraban, in his inaugural thesis, (Nancy, 1st series, no 15) gives the results of his experiments on tartar emetic. He has convinced himself that the effects of tartar emetic are not so simple as generally believed. With regard to its toxic qualities, the smallest dose of tartar emetic, capable of killing when introduced into the blood, ranges between one and two centigrammes to every kilogramme of the weight of the body (one or two parts in 100,000). Every dose above two centigrammes to the kilogramme produces death more or less rapidly, by destroying the functions of the nervous system. Prostration is further favoured in smaller doses, by the considerable lowering of the temperature and by copious serous losses. Every dose above one centigramme to the kilogramme does not kill of itself, but, if repeated a certain number of times, produces a biliary hypersecretion, which, on the one hand, brings on diarrhoea, and on the other the absorption of the principles of the bile. The blood then undergoes all the alterations which can be produced by the sodic salts of the biliary acids, and the animal finally dies of hæmorrhage. Tartar emetic possesses an alterative action on the blood-corpuscles, but that action is not enough to bring on death; that is produced by the rapid depression of

the nervous system by strong doses, and by the action of the biliary salts in small ones.

SCHMIEDEBERG ON THE PRINCIPLES CONTAINED IN DIGITALIS PURPUREA.—The *Bulletin de Thérapeutique*, contains a brief account of Schmiedeberg's researches on this subject. He distinguishes four principles which may be separated, by appropriate methods, from commercial digitalin.

1. *Digitonin*, identical with Nativelle's digitin, is an amorphous product, soluble in water, insoluble in cold absolute alcohol, benzine, ether, and chloroform. It resembles saponine in forming a lather; its empirical formula is $C_{62}H_{52}O_{34}$, not very unlike that assigned to saponin by Bochleder, viz. $C_{64}H_{54}O_{18}$. It is reddened by sulphuric acid, and furnishes at least four derivative compounds by its decomposition, viz., digitoresin, digitonein, digitogenin, paradigitogenin. The last-mentioned product is crystallisable.

2. *Digitalin*, $C_{10}H_8O_4$.—Soluble in alcohol, in a mixture of alcohol and chloroform, and in dilute acetic acid; very sparingly soluble in ether and chloroform. It forms the chief constituent of the amorphous digitalin of Homolle and Quevenne and of the digitalatin of Walz. It is not coloured by cold concentrated sulphuric acid; when heated with it, it turns yellow or greenish-yellow (like commercial digitalin). A crystal of potassic bromide, dropped into the yellow solution, turns it red, with the formation of digitaliresin and sugar. Digitalin produces the characteristic effect of digitalis on the frog's heart.

3. *Digitalein*.—Yellowish, amorphous, forming a lather with water, sparingly soluble in chloroform. Ebullition with dilute acids splits it up into digitaliresin and sugar. It is said by Görz to exhibit the specific cardiac effects of digitalis.

4. *Digitoxin*.—Absolutely insoluble in water and benzine, freely soluble in absolute alcohol and chloroform. Crystallisable in needles or tablets. Not a glucoside. Formula $C_{42}H_{33}O_{14}$. Its alcoholic solution, heated with dilute hydrochloric acid, furnishes toxiresin, but no sugar. The author believes digitoxin to be the active ingredient in the crystalline digitalin of Nativelle; the latter also containing paradigitogenin.

PATHAULT ON THE MONOBROMIDE OF CAMPHOR.—In a pamphlet containing a limited number of original observations on the physiological action and remedial uses of the drug, together with an abstract of the literature bearing on the subject; the author finds that the monobromide of camphor exerts a decided hypnotic influence on guinea-pigs and rabbits; that it lessens the frequency of the pulse and the number of respiratory movements; and that it causes a marked fall of temperature. It is eliminated in the urine. Occasionally, twitching of the hind legs was observed in rodents submitted to its influence, and true epileptiform convulsions in the cat. It has been administered with good effect in delirium tremens, hysteria, chorea, simple sleeplessness, and pain in the neck of the bladder. Perhaps the most satisfactory results put on record are those obtained at the Salpêtrière by M. Bourneville; he found that the prolonged administration of the remedy to epileptics exerted a very marked influence on the number of paroxysms of epileptic vertigo, without any corresponding dimi-

nution in the number of convulsive attacks. The monobromide of camphor is best given in capsules, each of which contains three grains of the remedy; from two to twenty of these capsules may be given for a dose.

CRAIG ON THE ACTION OF 'CHANGED ALOIN' AND THE 'RESIN OF ALOES'.—According to Mr. Craig (*Pharmaceutical Journal*, April 17, 1875) the most important constituents of aloes are—a *volatile oil*, present in very minute quantity, to which the drug owes its peculiar odour; crystalline aloin (about 25 per cent.); and resin of aloes. The last-named product is usually regarded as 'changed' or oxidised aloin, notwithstanding the circumstance that the resin yields about 20 per cent. of ash when burned; whereas aloin yields none at all. Mr. Craig's experiments on rabbits and on the human subject led him to the following conclusions.—1. Aloin is an active aperient, and is, in all probability, the active principle of aloes. 2. 'Changed aloin'—aloin oxidised by prolonged exposure to air, possesses very decided purgative properties. 3. The 'resin of aloes,' when thoroughly freed from aloin, has no aperient action, and cannot, therefore, be regarded as identical with 'changed aloin.' 4. The griping which sometimes follows the administration of aloes is not caused by the resin. The last two results coincide with those obtained many years ago by Dr. Garrod and Dr. F. Farre.

OBSTETRICS AND GYNÆCOLOGY.

THOMAS ON THE TREATMENT OF TUBAL PREGNANCY.—In the *New York Medical Journal*, June 1875, Dr. J. G. Thomas communicates a most valuable clinical contribution upon the subject. It is also reprinted in the form of a pamphlet. After alluding to the difficulties besetting the management of extra-uterine foetation by surgical interference, he gives the details of a case of tubal pregnancy.

The patient, a married lady, aged thirty, menstruated last on October 25, 1874; within three weeks from that date the gastric symptoms of pregnancy declared themselves. She had been sterile during the six years of her married life. About January 15,

1875, during the night, the patient, who for some days had experienced some uneasiness in the left iliac fossa, was awakened from sleep by a severe 'cramp' in this region, increasing in severity until it became agonising. Morphia hypodermically, in free and repeated doses, relieved the pain. Soreness and tenderness over the left iliac fossa continued during the next few days.

The severe attacks of pain recurred at intervals of several days, the injection of morphia being necessitated. When first seen by Dr. Thomas, on Feb. 4, fourteen weeks from the date of the last catamenia, the patient was emaciated, the eyes sunken, and her mind greatly disturbed by the fear of the recurrence of what she termed 'the cramp.'

On vaginal examination the uterus was found to be larger and less mobile than normal; a tense, elastic cyst, which filled the whole iliac fossa, dipped into the pelvis and pushed the uterus over to the right side. Ballottement was detected. Dr. Marion Sims also saw the case.

On Feb. 7, the patient, having been etherised, was placed on a table before a window admitting a strong light in the left lateral position, and Sims's speculum was introduced. The uterus was then steadied by a tenaculum in the cervix, and with the platinum knife of the galvano-caustic battery, which was brought to a white heat, the vaginal roof was slowly cut through. 'In six minutes the cyst was opened by the incandescent knife, and a straw coloured, slightly pinkish fluid was thrown out with such force as to fly into my face and over my clothing.' No blood whatever was lost thus far. The index finger was then passed into the cyst, and a fœtus detected lying horizontally. Extraction by the feet, aided by a pair of long-handled placental forceps to deliver the head, was resorted to, and the cord was then cut. Gentle traction and detachment of the placenta was then attempted, but when a little over half had been separated, a very severe hæmorrhage took place. A solution of the persulphate of iron was then injected into the sac, and the flow of blood was instantly checked. A long tent of carbolised cotton, saturated with a solution of persulphate of iron, was then inserted; 'in twenty-eight minutes from the commencement of the operation the patient was put to bed.'

The patient progressed favourably until the fourth day when symptoms of septicæmia showed themselves, but yielded to constantly repeated injections into the sac of carbolised water. On the seventh day after the operation slight hæmorrhage took place from the sac. On the fifteenth day the remaining portion of the placenta came away spontaneously. Six weeks afterwards the vaginal opening had completely closed. Ten weeks after the operation the patient, now perfectly convalescent, could scarcely be identified as the same individual.

[In this brief abstract we have but attempted to give an outline of the case. It is impossible to do full justice to the valuable remarks made by the author on the value of ballottement in forming a positive diagnosis, or to allude even to the various modes of treatment and other clinical suggestions contained in the pamphlet.—*Rep.*]

REPORTS OF FOREIGN SOCIETIES.

ACADEMY OF MEDICINE IN PARIS.

May 18, 1875. *Treatment of Anthrax by Antiseptic Subcutaneous Injection.*—M. Davaine read a report on Dr. Raimbert's memoir, on the treatment of anthrax in the human subject by the subcutaneous injection of antiseptic liquids. In two cases M. Raimbert had used carbolic acid with success; in a third he used iodine, and although the patient who was pregnant, died in premature child-birth, the antecedent anthracoid affection was to all appearance cured. In another case, iodine was successfully employed in the cure of anthracoid œdema. In these four cases cauterisation was employed at the outset, and the injection of the antiseptic liquids was performed when it was found that the progress of the disease had not been arrested, and that nothing more was to be expected from cauterisation. The injections, made to a certain extent *in extremis*, produced a rapid improvement at the points to which they were applied.

A discussion was raised between MM. Davaine, Colin, and Bouley, as to whether in these cases the cauterisation performed before the injection had not produced the effects attributed to injection only.

May 25. *Scurvy.*—MM. Villemin and de Méricourt resumed a discussion on scurvy. M. Villemin differed from M. Le Roy de Méricourt, who attributes scurvy to the want of fresh vegetables exclusively. Without denying the bad influence likely to be exercised by this privation, he does not believe it to be sufficient to produce the disease in question without the intervention of a miasmatic agent; and in support of his opinion quotes a certain number of cases in which scurvy made its appearance, notwithstanding the ingestion of fresh vegetables. He subsequently brought under notice that in cases of scurvy observed at sea, the disease has almost always been arrested by altering unhealthy arrangements of the vessel. The conclusion then arrived at is that bad hygienic influences must be altered, the weakening of the system striven against, and fruits or lime-juice be given; but that it is still more important to avoid overcrowding and the mephitic atmosphere engendered by it, and to ventilate, disinfect, disperse, and, if necessary, isolate.

June 1. *Congenital Polycystic Tumour attached at the symphysis of the lower jaw and the under surface of the tongue; spontaneous premature delivery; removal of the tumour during labour; examination of the specimen.*—The communication was made by M. Verneuil. Microscopic examination showed that here was no question of a fetal inclusion, nor of one of those monstrosities described by Geoffroy St.

Hilaire, under the name of epignathus, nor even of a dermoid cyst; it was purely and simply a neoplasm, which not only adhered to the lower maxillary, but likewise came from that bone itself. In other words it was a fibro-cystic tumour, only differing from those sometimes observed in the adult by its precocious development going back to the embryonic period. It was evident that the morbid product sprang from the symphysis, which explained the circumstance of its containing masses of epithelium with vibratile cilia. As to the cysts, they certainly originated in the dental follicles.

June 8. *Lung-diseases in Copper and Iron Workers.*—M. Tardieu read a report on a memoir by Dr. Proust, on the lung-diseases or pneumoconiosis of copper and iron workers. M. Proust's work gives interesting deductions (1) from the hygienic point of view of the handicraft; (2) from the physiological and pathologico-anatomical point of view; (3) from the nosological aspect. 1. The reforms which have been introduced into the copper-worker's handicraft has greatly diminished the cases of anthracosis amongst this class of workmen, but as this is not the same with iron-casters, who still use coal-dust, it would be advisable to use some other method. 2. The possibility of the direct introduction of coal-dust into the air-passages is demonstrated. 3. The nosological conclusions deduced by M. Proust show the existence of a special kind of phthisis, which might be termed carbonaceous phthisis.

June 15. *Medical Men and Life Assurance Offices.* M. Amédée Latour presented a pamphlet by Dr. Fallard on medical men and life assurance offices. The conclusions arrived at in this pamphlet, which was really the official report of the general meeting of the association of the French medical men on the relation of medical men with life assurance offices, were as follows. 1. To always and absolutely refuse to give a certificate or any attestation whatever as to the health of their usual patients, even when solicited by them, or however satisfactory the certificate might prove to be. 2. To excuse themselves, if as medical referees to a life assurance company they are delegated by the company to examine one of their own clients, and to cause another medical man to be deputed to make the examination. 3. To use their influence with the companies to which they are attached, to obtain the revision and the simplification of the interrogations to which they have to reply. But should this interrogatory be adopted, they should take every pains to answer it in the clearest way, and in that most adapted to give information to the officials whose business it is to accept or refuse the assurance.

Relation of the State of the Lungs to the Phenomena of the Death-Struggle.—M. Piorry read a memoir on the death-struggle caused by bronchial mucus or aphrosic hyperæmia. The conclusions of this work were the following. The crepitant lung which remains voluminous at the time of necropsy is in an eminently pathological state. That state has in these cases caused the death-struggle, and death. To consider it as the type of the physiological condition is a very great error, and one that in diagnosis, therapeutics, and prognosis, would lead to disastrous consequences. By admitting this dangerous error as a truth, the crepitation which causes death would be recognised as the type of the healthy condition; that this would be to ignore the most ordinary causes of death, and consequently to lead to the belief that the medical

world is not up to the proper scientific level, and that the labours of Bichat and his successors are disregarded.

ACADEMY OF SCIENCES IN PARIS.

May 17. *Action of Mancenilla Bark.*—M. Hardy presented a memoir on the action of mancenilla bark. This bark, which the savages use to poison their arrows, comes from the *Erythrophleum guineense*. The most frequent phenomenon produced by the injection of the active substance of this bark consists in the slackening of the heart-beats and its arrest in systole. After this arrest, some respiratory movements are still found to exist in guinea-pigs. Galvanic currents act longer on the muscles of the life of relation than on those of the heart after the death of the animal. However, this action is more rapidly destroyed after poisoning by mancenilla bark than after simple ligature of the heart. Sulphate of atropia does not exercise any antagonistic action.

Glycerine in Diabetes.—M. Garnier communicated a note on the efficaciousness of glycerine taken internally in doses of twenty to fifty grammes in glycosuria. This treatment, recommended by Herr Schulze of Dorpat, seems to have yielded satisfactory results both in his and in M. Garnier's practice.

May 24, 1875. *Dissociation of Violet of Paris.*—A note presented by M. Cornil was intended to show the disassociation of the violet of methylaniline and its separation into two colours under the influence of certain normal and pathological tissues; specially by tissues in a state of amyloid degeneration. This decomposition of the colouring matter into two distinct shades, on those parts to which it is applied, is very useful in investigations in pathological anatomy. Thus, on an organ in a state of amyloid degeneration, the application of the violet of methylaniline gives a pale violet colour on the normal parts, whilst the diseased parts assume a reddish tinge. This process gives more exact results than the examination by iodine and sulphuric acid.

Application of the Graphic Method to the Mechanism of Deglutition.—A note by M. Arloing on the application of the graphic method to the study of the mechanism of deglutition was presented by M. Bouley. The results with regard to the respiratory system with isolated pharyngeal deglutitions were the following. 1. The intervention of the diaphragm has been placed beyond doubt by the direct exploration of the posterior face of this septum, by the aid of an ampulla which was inserted in front of the cæcum of a horse, passing at the back of the eighth rib on the right side. The precise moment when the depression commenced was fixed by the pressures which were felt in the pharyngeal vestibule. The traces demonstrate—(1) that the thoracic depression begins before the glottis is closed; (2) that it continues and ceases whilst the larynx is closed; (3) that the laryngeal vestibule, partly opened when the movement of deglutition commences, closes above and below when the food arrives above it, and remains perfectly closed until the mass has reached the œsophagus. From these facts, MM. Arloing and Bouley conclude that the thoracic depression may (1) at the commencement make its effects felt at the bottom of the pharynx and help in bringing the food there; (2) by stretching the œsophagus, fix the postero-inferior region of the pharynx, while the larynx bears forward and upward, and

helps in dilating the bottom of the back of the throat ; (3) more exactly keep either the parts which form the entrance to the pharynx, or the vocal cords, one against the other.

2. With successive acts of deglutition, the accidents which raise the curves of the respiration (ilium and thorax) during the deglutition of drink do not denote very small complete respiratory movements ; but a succession of simple changes of intrathoracic pressure due to the displacement of the diaphragm, and similar to those which coincide with isolated deglutitions. Consequently, the occlusion of the glottis corresponds with the discordant jerks of the ilium and thorax, and to the intratracheal depression ; and the opening of the glottis allows the circulation of the inspired or expired air. The enlargement of the bottom of the pharynx is one cause which helps the introduction of the ball of food into the œsophagus. By placing an ampulla between the base of the tongue and the lower surface of the palati velum of a horse, MM. Arloing and Bouley perfectly established the existence of the depression pointed out by M. Cartel. It was the perfectly natural consequence of the driving back of the air into the nasal cavities, but this very slight depression was soon lost in the pharyngeal depression already pointed out.

In comparing together the changes which the air in the pharyngeal vestibule undergoes, the investigators have fixed the duration of the three principal phases of deglutition. The pharynx takes less than half a second to shorten itself, drive the ball of food into the œsophagus, and relax itself.

The shock and the electric tetanus of the fleshy layer of the œsophagus resemble the shock and the tetanus of any other striated muscle. It appeared to the experimenters that, in an œsophagus of which the external nerves were dead, the shock did not diffuse itself from above 0.25 to 0.30 mètre, and that in an organ of which the nerves are excitable, the tetanic contraction propagates itself with a rapidity (20 to 21 mètres in the second) similar to that of shock and very near that of the nervous excitations. In the white part of the canal the shocks cease more rapidly ; their diffusion scarcely ever exceeds 0.15 mètre. As to the physiological contraction, MM. Arloing and Bouley have observed the fact pointed out by MM. Chauveau and Wild, that the contraction of the œsophagus produced by a pharyngeal deglutition traverses all the red portion, notwithstanding the exit of the mass. They have also observed that the peristaltic wave is not long in disappearing above the heart, if the mass do not descend as far as the stomach. The rapidity of the peristaltic wave, which should not be confounded with the rapidity of the ball of food, seems to be variable. The investigators have established that, on the average, the peristaltic wave passes over 0.20 mètre per second in the red part and 0.50 mètre in the white part. This result shows that in the horse, the peristaltic wave would take ten seconds to traverse the œsophagus.

The function of the œsophagus is thus distinguished in the two cases. *a.* In isolated deglutition the ball enters the œsophagus, and cannot get back again towards the pharynx, because of the disposition of the muscles of that region which close the œsophagus above the ball, and drive it from above downwards. Its descent is facilitated by the tension the displacement of the larynx and the movements of the diaphragm impart to the œsophagus. The constriction of the œsophagus

is at its maximum when the mass is either very small or very large. *b.* In combined deglutition, an unexpected difference has been observed. 1. Thus, the fleshy coat of the red portion is inert during deglutition of drink in hasty mouthfuls. This part of the duct merely plays the part of an elastic tube ; 2. The white portion of the œsophagus relaxes by degrees as the animal drinks, then gradually contracts when it ceases to drink. The contraction is accompanied by more or less powerful peristaltic contractions, the object of which is to empty the œsophagus from above downward. Consequently, the drink is as it were injected into the œsophagus by the organs of pharyngeal deglutition. The inertness of the red portion and the dilatation of the white portion when this exists, are indispensable to the descent of the drink, otherwise, the swiftness of the œsophageal wave being known, as well as the narrowness of the cardia, the prehension of drink would soon become impossible in a subject making from 80 to 115 deglutitions per minute, each absorbing 150 to 200 grammes of liquid.

M. Cloquet presented a note by M. Wecker on a new method of operating for cataract (extraction by peripheric morsels).

IMPERIAL-ROYAL MEDICAL SOCIETY OF VIENNA.

April 30, 1875. *Scrofula.*—Dr. Rabl, in a paper on scrofula, expressed the opinion that the scrofulous process depends on the formation of granulation-tissue, which assumes two forms. In one form (small-celled tissue) the microscope shows small lymphoid cells with roundish distinctly visible nucleus and nucleolus. The matrix of the tissue is a granular mass, very delicate, and often resembling mucous tissue. The second form (large-celled tissue) is more characteristic of scrofula. Proliferation of the cells, and division of the nuclei and cells, are not unfrequently to be observed, as well as blood-spaces and giant-cells. According to Rabl, these cells are not characteristic of tuberculosis, as Schüppel and Bühl have maintained, but of scrofula. All the preparations examined were taken immediately from the living subject, and most were examined in Müller's fluid. Dr. Rabl defines the scrofulous granulation-tissue as presenting the characters of an inflammatory new formation—an accumulation of lymph-cells and the young elements of various forms of connective tissue. Its specific peculiarity, and the character which distinguishes it from newly formed tissue, is its great weakness and its tendency to be broken up. The product of the breaking up of the granulation tissue has various degrees of consistency. It may be a thick pulpy mass, even cheesy. The flocculent form is seen in scrofulous adenitis in young subjects ; the pulpy in old indolent ulcers in cachectic individuals. According to Dr. Rabl, the formation of the granulation-tissue depends on mechanical and chemical influences acting on the lymph-spaces. To the mechanical influences belongs the stuffing (*Stauung*) of the lymph, through which it is also subjected to chemical modifications. Rabl also thinks it possible that the altered lymph-corpuscles excite the nearest connective tissue-cells to proliferation, and that then the process extends to the neighbouring cells which are not destroyed, but are changed into the tissue of the new formation. Speaking of the clinical characters of scrofula, Dr. Rabl said that the first signs in children are affections of the

skin and respiratory mucous membrane. This is most evident in children who are in unfavourable conditions—*e. g.*, damp dwellings. The irritation of the skin is vicarious with that of the mucous membrane, for which reason Rindfleisch has called eczema a catarrh of the skin. As the scrofulous condition advances, the glands swell, and granulation-tissue is formed in them. Scrofulous periostitis and caries are of special interest. The latter arises in three ways: (1) the inflammation may be communicated from the periosteum to the bone; (2) it may commence in the medulla of the long bones; or (3) in the cancellous bones. Diseases of bone form 50 per cent. of all scrofulous affections, and occur in the following order of frequency—tarsal bones, lower epiphyses of the femur, vertebræ, fingers and toes, bones of the face and skull, epiphyses of the long bones, carpus, ribs, sternum, and ilium.

May 7. *Scrofula*.—Dr. Rabl resumed his communications on scrofula by speaking of the etiological conditions, among which the acute exanthemata and hereditary dispositions were enumerated. He then referred to the relation of tuberculosis to scrofula, and expressed the opinion that the so-called tuberculous infiltration of internal organs are nothing but caseification products (*Verkäsungsprodukte*) of phthisical inflammations: that is, that the inflammatory cell-proliferation has taken place on the free surface of mucous membranes or in the interstitial connective-tissue. Both these homologous processes differ in nothing from scrofulous inflammation of external parts; phthisis is then one of the forms in which scrofulous disease frequently manifests itself.

Examination of the Rectum and Bladder.—Dr. Juriè spoke of Simon's method of examining the rectum by the introduction of the whole hand, and said that he had followed the method with success, although its use was troublesome, and required patience and strength. Professor Dittel commented on the difficulty of introducing the hand into the rectum, when the patient was very muscular. He related two cases in his practice, in one of which there had been obstruction of the bowels for fourteen days in consequence of cancerous stricture. Here the introduction of the hand was followed by laceration of the rectum. In a second case the operation was followed for several days by paralysis of the muscular coat of the rectum. Dr. Juriè said that the introduction of the hand must be performed with extreme slowness and care. The laceration he believed to have been produced by the introduction of the hand into the upper part of the rectum, which is not capable of so much distension.

NEW INVENTIONS.

BED URINAL.

This urinal has been constructed by M. Galante, the well-known French surgical-instrument-maker, on a plan furnished by Dr. Boulomier. It is based on the following principles. 1. The line according to which an individual is recumbent (the decubital line) is a broken line, of which the upper open angle is placed at the level of the nates. 2. There is between a horizontal line passing by the anterior extremity of the penis and the bed, a space large enough to place a reservoir capable of holding from 600 to 900 cubic centimetres, according to the size of the nates and the thigh of the individual. 3. As

a reservoir intended to collect the urine emitted during the decubitus should be found at the point where it flows spontaneously, it should be placed behind a layer which would prolong the direction of the penis.

The principal parts of the apparatus are (1) of a penile portion, P, a cylindrical tube sufficiently large to contain the penis; (2) India-rubber reservoir, R, provided at the back with an evacuating tap.

The parts intended to fix the apparatus are (1) a waist-band, C, fig. 2; (2) three India-rubber straps, two of them uniting by double flat buttons the penile portion, the other the back part of the reservoir to the waist-band, B B', figs. 1 and 2; (3) an India-rubber strap slipping into a slide, inserted directly into the reservoir and intended to fix the apparatus to one of the thighs, B".

The parts intended to insure the penetration of

FIG. 1.

FIG. 2.

the urine into the reservoir, and to prevent its reflux are:—1. A half-disc in very flexible India-rubber placed at the entrance of the penile tube in its lower half only; 2. A thin plate of metal L, intended to assure the persistency of the angle formed by the reservoir and the penile part; 3. A valve S, placed at the end of the penile portion and formed of a simple flat tube arranged like the finger of a glove, and slit bilaterally.

The more or less oblique insertion of the penile tube and the adaptation of a rigid cylinder in a sheath of flexible India-rubber P and p, allow the apparatus to be applied to various conformations. This apparatus differs from those which have been made up to the present time by the situation given to the reservoir, which, placed in the sloping points, can fill itself completely without the liquid leaving the right direction.

HAYEM AND NACHET'S NEW APPARATUS FOR COUNTING THE BLOOD-CORPUSCLES.

Messrs. Hayem and Nachet have lately invented an apparatus for counting the corpuscles of the blood, of which the description is as follows. By its aid they make a mixture of blood and serum as homogeneous as possible; that is to say, in which it may be admitted that there is an equal distribution of the corpuscular elements. But as it is almost impossible to count the elements contained in the entire mass of the mixture, they endeavoured to find a simple and correct means of circumscribing a mathematically determined portion of this mixture without changing the distribution of the corpuscles by the manipulatory part of the operation. The apparatus which MM. Hayem and Nachet have invented for this purpose, is principally composed of a cell formed by a very thin glass plate, perforated in the centre and fixed on a perfectly flat piece of object glass. The

thin perforated glass plate is polished with fine emery on a metal plane, so as only to present a fixed thickness. By superintending this operation by the aid of the spherometer, this thickness may be obtained with certainty. Thus a cavity (Fig. 1) is obtained, of which the depth is mathematically known. By placing a drop of the sanguineous

FIG. 1.

mixture in the centre of this cell, and immediately covering up the drop with a thin plate of very flat glass resting on the edges of the cell, a thin sheet of liquid, with parallel surface and of a known thickness, will be obtained. If care be taken to place properly the drop of liquid to be examined, and not to take one sufficiently large to fill the entire cavity, any elevation of the small glass plate by the liquid will be avoided, and the drop will flatten out without the regular dissemination of the corpuscles being altered. By placing a little viscid liquid, a little saliva, for instance, at the angles of the layer to be covered, the preparation will be sufficiently closed up to prevent the slipping of the glass and the evaporation of the blood.

Taking the height of the cell as the fifth of a millimètre, which is the height regarded as most suitable by MM. Hayem and Nachet, it is easy by the aid of an eye-piece marked in squares to count the blood-corpuscles in the space of a square fifth of a millimètre.

Thus we can obtain the number of corpuscles contained in a cube of a fifth of a millimètre to scale, and a simple process of multiplication will give the contents of a square millimètre of pure blood.

The glass of the ruled eye-piece carries a square of which the scale acquires, on the index marked on

FIG. 1.

the tube of the microscope, the value of a fifth of a millimètre. This large square is divided into sixteen equal squares, and in the middle of each of

them reciprocally perpendicular lines not coming to the edges are traced (Fig. 2). This arrangement makes the counting of the corpuscles rapid and easy. This should be done at five or six different points of the preparation, not choosing the edges, at the level of which a slight modification in the equal distribution of the corpuscles occurs.

To make the sanguineous mixture, MM. Hayem and Nachet only employ two perfectly graduated pipettes, one intended to hold the blood and the other the serum. As additional liquid they prefer to artificial serums natural serosities, such as the liquid of the amniotic cavity of the cow, and above all, the serosity of the dropsical effusions which occur in the human subject in certain pathological cases. First the serum and then the blood are placed in a small glass test-tube, and the mixture is made by means of a small mixer in the shape of a palette (Fig. 3). This mixer is moved quickly backwards and forwards between the fingers, and soon disseminates the

FIG. 3.

blood-corpuscles in a very uniform manner throughout the mass of the liquid.

MISCELLANY.

CREMATION.—The Government of the Duchy of Gotha has promulgated a decree legalising the cremation of the dead.

M. DEMARQUAY has left 100,000 francs to the Academy of Medicine; an annual endowment of 300 francs for a quinquennial prize of 1,500 francs to the Société de Chirurgie; his library and instruments to his pupils; and to a friend, to whom is delegated the task of collecting M. Demarquay's writings, a sum of 10,000 francs.

THE PECULIAR PEOPLE.—The peculiar people, several of whose members are now awaiting trial for manslaughter in not calling in medical aid when members of their body were sick, have resolved boldly to put to practical test the question as to whether medical aid is really a necessity, or whether prayer alone is not sufficiently efficacious in all cases of sickness. For some time past a large twenty-roomed house, situated in Tower Street, on the north-east side of London Fields, has been empty. A few days since much excitement was caused in the neighbourhood by the appearance outside the house of a board bearing the following inscription:—'House of Faith, for the reception of such sick as are considered hopeless(ly) incurable, to be healed by the prayer of faith.' 'And all things whatsoever ye shall ask in prayer, believing, ye shall receive.'—Matt. xxi., v. 22. 'Is any sick among you, let him call for the elders of the Church and let them pray over him and anoint him with oil in the name of the Lord. And the prayer of faith shall save the sick, and the Lord shall raise him up; and if he have committed sins they shall be forgiven him. Confess your faults one to another and pray for one another, that ye may be healed. The effectual fervent prayer of a righteous man availeth much.'—St. James, chap. v., vs. 14-16. 'And these signs shall follow them that believe; in my name shall they cast out devils, they shall speak with new tongues; they shall take up serpents, and if they drink any deadly thing it shall not hurt them; they shall lay hands on the sick and they shall recover.'—St. Mark, chap. xvi., vs. 17, 18. There will be a strenuous opposition on the part of the inhabitants to the opening of the hospital.

USE OF RAW MEAT.—A recent case, reported by M. Castraux, seems to confirm the opinion that the use of raw meat in the treatment of certain chronic diseases is likely to engender tenia. M. Castraux thinks, however, that the use of alcohol in combination with the raw meat might interfere with the vitality of the cysticerci. Hence, the relative rarity of cases of tenia may be attributed to the association indicated which constitutes the basis of the regimen prescribed to many phthisical patients.

PROFESSORS AND TESTIMONIALS.—M. Pajot, who is one of the most popular professors in the Paris faculty, terminated one of his recent lectures by the following remarks: 'Gentlemen, I hear that you have opened a subscription in order to present me with a gold medal. I thank you for your intention, but wish to impress on you that I have no need of medals to bear you in remembrance. Your assiduous attendance at my obstetric course is the most precious reward which could possibly have been offered to me during my professional career. At the present time, there are many families wanting bread; I beg, therefore, that you will contribute the sum of money with which you intended to present me, to the relief of the sufferers from the late inundation.'

SCIENTIFIC INVESTIGATIONS.—A return has been issued, showing the separate payments out of sums voted to the Department of the Privy Council Office for auxiliary scientific investigations during the past four years. The amount voted in each year was 2,000*l.*, and the nature of the investigations undertaken in the various years, with the reports made, were as follows: In 1871-2, investigation of infective inflammations; of tubercle, with study of the lymphatic system of serous membranes, and of the chemical changes in cases of typhus. Reports were made by Dr. Klein, Dr. Sanderson, and Dr. Thudichum respectively on these subjects. In 1872-3 the investigation of tubercle was continued, with study of the lymphatic system of the lungs; and investigations of the febrile process and of the chemical constitution of the brain were made. A second report was made by Dr. Klein on the lymphatic system. In 1873-4 there were investigations of the febrile process; of the chemical constitution of the brain; of sheep-pox; and of cancerous infection. Reports were made by Dr. Klein, Dr. Creighton, Dr. Thudichum, and Dr. Sanderson. In 1874-5, the subjects of investigation were the febrile process continued; the chemical constitution of the brain continued; infective inflammations; cancerous infection; the disinfection of contagious matters; and enteric fever. A report was made by Dr. Baxter on disinfectants, and the following reports will shortly be presented to Parliament: report by Dr. Sanderson on the febrile process; further report, by Dr. Sanderson, on infective inflammations; further report, by Dr. Thudichum, on the chemical constitution of the brain; further report, by Dr. Creighton, on anatomical studies with reference to cancer; and report, by Dr. Klein, on the contagium of enteric fever. The payments made during the four years were,—to Dr. Sanderson, 4,079*l.*, and to Dr. Thudichum, 3,322*l.*

TWO NEW GERMAN SERIALS, dedicated to zoological and anatomical research, have been published this year. The *Morphologisches Jahrbuch*, edited by Carl Gegenbaur, Professor at Heidelberg, unites anatomy and the history of development of animals in their mutual and intimate relation as animal morphology. It has for its first object the recognition of the intimate relations amongst different degrees of animal organisation, and further, to consider the anatomy of man as illustrated by the knowledge of the construction of lower organisms. The first number contains papers on the extreme ends of the animal world, viz., man and infusoria, and thus illustrates the end in view most perfectly. The *Jahrbuch* will be supplemented annually by a yearly report of the progress of the anatomy of vertebrata. This serial appears quarterly in numbers of from six to ten sheets of text, with plates, at the price of from six to nine marks. The *Zeitschrift für Anatomie und Entwicklungsgeschichte* ('Journal of Anatomy and History

of Development'), is edited by W. His and W. Braune, Professors of Anatomy at the University of Leipzig. The principal object of this new serial is to be the knowledge of the human body; but papers will also be received which touch upon this theme from a somewhat more distant point of view. At the same time attention will also be turned to the practical side of this subject as well as the theoretical, and materials will be offered to the medical man which will be of immediate use to him in his sphere of action. The double number published of this serial shows that its programme has very wide limits, and will eventually be of interest to the zoologist and anatomist, as well as to the practical physician. A number of this serial will be published every two months, containing about five sheets of text and five plates, at the price of from six to eight marks.

A DWARFISH RACE.—The general report of the operations of the Great Trigonometrical Survey of India during 1873-74, contains an account of an interview which Mr. Bond, one of the staff, had with a couple of the wild folks who live in the hill jungles of the western Ghâts, to the south-west of the Palaneî hills. A strange dwarfish people had often been heard of as frequenting the jungles near the station of Pémalei, in the north-west corner of the Tinnevely district, but until Mr. Bond caught these two specimens no trace of them had been seen by the members of the Survey. These two people, a man and a woman, believed themselves to be a hundred years old, but Mr. Bond supposes the man to be about twenty-five, and the woman eighteen years of age. 'The man,' Mr. Bond states, 'is four feet six and a half inches in height, twenty-six and a quarter inches round the chest, and eighteen and a half inches horizontally round the head over the eyebrows. He has a round head, coarse, black, woolly hair, and a dark brown skin. The forehead is low and slightly retreating, the lower part of the face projects like the muzzle of a monkey, and the mouth which is small and oval, with thick lips, protrudes about a inch beyond his nose; he has short bandy legs, a comparatively long body, and arms that extend almost to his knees; the back just above the buttock is concave, making the stern appear to be much protruded. The hands and fingers are dumpy and always contracted, so that they cannot be made to stretch out quite straight and flat; the palms and fingers are covered with thick skin (more particularly so the tips of the fingers), and the nails are small and imperfect; the feet are broad and thick skinned all over; the hairs of his moustache are of a greyish white, scanty and coarse like bristles, and he has no beard. The woman is four feet six and a half inches in height, twenty-seven inches round the chest (above the breasts), and nineteen and a half inches horizontally round the head above the brows; the colour of the skin is sallow, or of a nearly yellow tint; the hair is black, long, and straight, and the features well formed. There is no difference between her appearance and that of the common women of that part of the country. She is pleasant to look at, well developed, and modest. Their only dress is a loose cloth, and they eat flesh, but feed chiefly on roots and honey. They have no fixed dwelling places, but sleep on any convenient spot, generally between two rocks or in caves near which they happen to be benighted. They make a fire and cook what they have collected during the day, and keep the fire burning all night for warmth and to keep away wild animals. They worship certain local divinities of the forest—Rákas or Rákári, and Pé (after whom the hill is named, Pémalei).' The woman cooks for and waits on the man, eating only after he is satisfied.

THE LATE PROFESSOR VON LUSCHKA.—The following interesting notes on the late Hubert von Luschka, Professor of Anatomy in the University of Tübingen, are extracted from the *Boston Medical and Surgical Journal*, June 3, where they appear under the signature of 'Ungenannt.' At the time of his death Dr. Von Luschka 'was still a comparatively young man, and although he spent his best

years in the little town where he died, he was connected with a flourishing university (the same in which Niemeyer held the chair of practice, now occupied by Liebermeister), and did noble work during his professorship. All his published works are on a grand scale. His imperial quartos on the larynx, and on the pharynx, his *Brustorgane*, and *Bauchorgane*, are superb evidences of his power and skill as an anatomist and prosector. His work, too, on general anatomy, is one I value highly. Whatever he published was the result of original research. The extremely fine plates in all his books are the work of an artist whom Luschka kept in his employ, and who copied them with fidelity from dissections made by Luschka's own hand. So long ago as 1858, when Bamberger published his work on the heart, Luschka's descriptions of that organ were considered the best, and Bamberger used them largely. Luschka's studies upon the anatomy of the heart were made upon the frozen body. Hence, and because of their exactness, they are invaluable. I have the pleasant memory of a visit to Luschka in 1872, during a stay of some weeks in Tübingen. I shall not soon forget the cordial genial warmth of his reception. When I entered he was writing the text of his splendid work upon *Die Lage der Bauchorgane*, which is uniform in size with *Die Lage der Brustorgane*, the plates being nearly of life dimensions. He showed me the drawings made by his artist for the forthcoming work. With charming simplicity he spoke of the probable usefulness of the work, and with modest pride alluded to the beauty of the plates in books already published. I saw, however, that he felt his works had not been sufficiently appreciated, for he very gently expressed his disappointment that they were not better known in England and America. To this day I do not understand why his publications have been so little used unless their expensiveness be the reason. I recall, too, that Luschka expressed great mortification concerning the flurry over the Löstorfer corpuscles. Before I left him he invited me to visit the anatomical museum of the university with him on the following morning, at the close of his lecture, which began at six o'clock! It was then that I saw the superb collection of his dissections of the larynx, copies of which illustrate his work on that organ. I suppose there could not be more exquisite dissection. The museum was not large, but was rich in anatomical specimens and anomalies of much value, of Luschka's own preparation. His work was not complete when he died, for he was one of the patient, persevering, large-minded workers, who are few, but who are ever finding newer and better means of developing and communicating knowledge.

THE INFLUENCE OF ARCTIC COLD ON MAN.—Lieutenant Payer, the Austrian Arctic explorer, has been laying some of the results of his explorations before the Geographical Society of Vienna. Referring to the influence of extreme cold on the human organism, he related that on March 14, 1874, he and his companions made a sledge journey over the Samiklar glacier, in order to make observations of Francis-Joseph Land. On that day the cold marked forty degrees (Reaumur) below zero. Notwithstanding this intense cold, M. Payer and a Tyrolean went out before sunrise to make observations and sketch. The sunrise was magnificent; the sun seemed surrounded, as it does at a high degree of cold, by small suns, and its light appeared more dazzling from the contrast with the extreme cold. The travellers were obliged to pour rum down their throats so as not to touch the edge of the metal cups, which would have been as dangerous as if they had been red-hot; but the rum had lost all its strength and its liquidity, and was as flat and thick as oil. It was impossible to smoke either cigars, or tobacco in short pipes, for very soon nothing but a piece of ice remained in the mouth. The metal of the instruments was just like red-hot iron to the touch, as were some lockets, which some of the travellers romantically, but imprudently, continued to wear next the skin. M. Payer says that so great an amount of cold paralyses the will, and that, under its influence, men,

from the unsteadiness of their gait, their stammering talk, and the slowness of their mental operations, seem as if they were intoxicated. Another effect of cold is a tormenting thirst, which is due to the evaporation of the moisture of the body. It is unwholesome to use snow to quench the thirst, as it brings on inflammations of the throat, palate, and tongue. Besides, enough can never be taken to quench the thirst; as a temperature of 30° to 40° below zero makes it taste like molten metal. Snow-eaters in the North are considered as feeble and effeminate, in the same way as an opium-eater in the East. The groups of travellers who traversed the snow-fields were surrounded by thick vapours formed by the emanations from their bodies, which became condensed notwithstanding the furs in which the travellers were enveloped. These vapours fell to the ground with a slight noise, frozen into the form of small crystals, and rendered the atmosphere thick, impenetrable, and dark. Notwithstanding the humidity of the air, a disagreeable sensation of dryness was felt. Every sound diffused itself to a very long distance; an ordinary conversation could be heard at a hundred paces off, whilst the report of guns from the top of high mountains could scarcely be heard. M. Payer explains this phenomenon by the large quantity of moisture in the Arctic atmosphere. Meat could be chopped and mercury used in the shape of balls. Both smell and taste become greatly enfeebled in these latitudes, strength gives way under the paralyzing influence of the cold, the eyes involuntarily close and become frozen. When locomotion stops, the sole of the foot becomes insensible. It is somewhat curious that the beard does not freeze, but this is explained from the air expired falling immediately transformed into snow. The cold causes dark beards to become lighter; the secretion of the eyes and nose always increases, whilst the formation of perspiration altogether ceases. The only possible protection against the cold is to be very warmly clothed, and to endeavour as much as possible to prevent the condensation of the atmosphere, whilst the much vaunted plans of anointing and blackening the body are pronounced to have no real value.

UNIVERSITY OF VIENNA.—Dr. Richard Heschl, of Gratz, has been appointed professor of pathology in this university, in the room of the celebrated pathologist Baron Rokitsky, who has retired. The appointment has only taken place after a considerable delay, the professorship having been for some months offered to and declined by several of the most eminent pathologists in Germany. The election of *Rector Magnificus* of this university took place lately, when Professor Baron Dumreicher was chosen to fill the office for the year. He has, however, declined for reasons which have not been made public. In consequence, a second election has been necessary, and the choice has fallen on Professor Langer.

STATUE OF MORGAGNI.—On May 27 the solemn inauguration of a statue in honour of Giovanni Battista Morgagni, the illustrious pathologist, took place in Forlì, where he was born in 1682. The ceremony was attended by a large number of persons, including the Minister of Agriculture and Commerce, the Secretary of the Minister of Public Instruction, representatives of the municipalities, of nearly all the Italian universities, and of many scientific societies. After the performance of the ceremony, appropriate addresses were delivered by Dr. Mazzoni and Dr. Casati, and one in Latin by Professor Bongiovanni, president of the Lyceum. The statue is the gift of Professor Camillo Versari, and is the work of Signor Salvini. It represents Morgagni as standing erect, and wearing his professional gown over the ordinary dress of the period. His countenance wears an aspect of meditation; his left arm is bent and supinated, and the hand supports a skull; his right hand holds a pen. Each of the guests was presented with a medal commemorative of the occasion, and with two printed volumes—one containing the correspondence of Morgagni with Francesco Zanotti; the other, six lectures on Morgagni by Professor Versari.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON THE LOCAL TEMPERATURE OF PARALYSED PARTS. BY PROFESSOR MAURIZIO SCHIFF, OF FLORENCE.

(Concluded from page 418.)

As I have already shown in a previous memoir, the difference changes when the animals become feverish, or are subjected to febrile excitement. In this case, during the hot stage, the temperature of the paralysed limb rises less than that of the sound one.*

I wish to take this opportunity of reminding you that some authors in commenting on this fact, which I published in 1855, attribute to me a so-called *neurotic* theory of fever, and believe that I attributed the phenomenon of the production of heat in fever to the nerves, and especially the dilating nerves of the vessels. I have not, however, said anything of the kind; and the authors in question have probably fallen into error through a mistaken interpretation of the expression 'febrile heat,' which I used in an article printed in a Vienna journal. The febrile heat of which I spoke is nothing but the subjective sensation of the patient, the sensation of heat which follows the chill.† This sensation I have derived from the vaso-motor nerves; but every one knows that it is not the same thing as febrile temperature, and even that the febrile temperature has already fallen a little when the sensation of febrile heat is felt. It has always appeared to me impossible to attempt to explain febrile temperature by a positive or negative action of the nerves, and I have always been convinced that its cause must be *chemical*. The singular modern theory of supposed heat-regulating centres has not been able to shake my conviction for a moment. From what precedes, it is seen that, if the oscillations of temperature always proceeded *pari passu* in the sound and in the paralysed limb, there would be the opportunity of occasionally finding the sound limb warmer than that in which the vaso-motor nerves are inactive, although the average temperature remains higher in the paralysed limb. But, as we have seen in the experiments in para-

plegia, it frequently occurs that the oscillations in a limb are independent of those of the other side, and the temperature of the sound limb is rising, while that of the other is falling; so that the difference at the moment becomes still greater in favour of the sound limb.

It is not impossible that this coincidence may recur several days successively at the same hour; and thus the ordinary method of taking thermometric measurements in patients may be the cause of great error.

If in man the differences between the limbs are not greater than in the dog, and everything rather leads us to believe that they are not, the difference between the maxima in favour of the sound limb can be but very small, inasmuch as in the dog it very rarely exceeds 3° Fahr. and is very often less than 1° 8'. This shows us that the difference found in your patient, which amounted to more than 16° Fahr., cannot be explained in the manner indicated. And it seems difficult to admit that in your repeated measurements, made at various times of the day, you always happened to fall on a time when the temperature of the paralysed limb was at its maximum; for this accident, of which I merely mention the possibility, was of extremely rare occurrence in my experiments. It follows, then, that the possibilities indicated do not comprehend all the cases in which a paralysed limb may have a lower temperature than the sound one, and that we must find out whether this effect is not produced by other causes or other conditions than those hitherto indicated.

And in this respect there seems to us to remain no other possibility than that which you have yourself pointed out in your letter, and of which you have spoken more explicitly in your interesting report of the diseases treated in the clinical hospital at Sienna.

You suppose that in the patient observed by you the dilating nerves of the vessels may have been paralysed, while the contracting nerves remained active; the result of which would be on the affected side an excessive constriction of the vessels, producing oligæmia and diminishing the temperature.

We are not acquainted with the course of the vaso-motor nerves in the spinal cord, but we know, as regards the foot, that both the dilator and the constrictor nerves remain without decussation as far as the medulla oblongata, so that a transverse section through the whole of one side of the cord produces paralysis both of the dilator and of the constrictor nerves of the foot of the same side. It is possible, though we do not yet know it, that the course of the dilator nerves is different from that of the constrictors. In this way it would be possible that in a case such as yours, in which an unilateral lesion of the medulla is in process of recovery, the course of the one set of nerves may be restored while the other set remains paralysed.

Such a supposition would probably explain the great difference of temperature found by you, a difference which is greater than that which has as yet been found in cases of paralysis from lesion of the peripheral nerves, in which the paralysed part was sometimes colder than the sound one. In these cases, in which your mode of explanation is most admirable, the difference in temperature amounted scarcely to 5° 5' degrees; and it seems to me that we must limit ourselves for an explanation of the difference to one of the possibilities mentioned in the first part of this letter, if in any case we desire to seek

* These observations of mine remained a long time without clinical confirmation. At last Ogle (*Lancet*, April 17, 1869, and *Medico-Chirurgical Transactions*) related a case of paralytic compression of the right cervical sympathetic; the right ear and cheek were redder than the other; but, after strong excitement, the left became warmer and covered with sweat, while the right did not perspire. Ogle adds that during a fever the difference in temperature between the two sides was lessened; probably there was a want of means for determining the small difference in favour of the sound side. In such a case, the thermo-electric apparatus would be useful.

† Connected with this febrile heat, in my opinion, are the greater congestion of the skin, and its increased secretion.

the cause of the phenomenon in a paralysis of the vaso-motor nerves.

I have not neglected to make various experiments to produce partial lesion of one half of the spinal cord. I have introduced a needle, moving it very slightly in the white and in the grey substance, but as yet I have not succeeded in producing a fall of temperature in the corresponding hind limb; whenever there was an alteration of temperature, it was always a rise.

This, however, forms no objection to your supposition. Our means of separating the parts of the nervous system from each other are much coarser than those which Nature sometimes uses. But a more serious objection would be contained in some experiments recently made by Vulpian, with which I have become acquainted within the last few days. From some experiments made on dogs, Vulpian concludes that, contrary to what we know regarding constrictor nerves, the dilator nerves do not possess a so-called *tonus*; that is to say, that these nerves are in no way active when not irritated, so that their paralysis does not produce a greater action of their antagonists, the constrictor nerves. I have not yet been able to examine this argument; and have not been able to repeat Vulpian's experiments; but if they are correct, as I have no doubt they are, I could not wish to prove from them an objection against your view.*

It might very well be admitted that certain nerves do not possess *tonus* in one species of animals, while they have it in other animals, and probably in man. Thus we know that the vagus nerve, which, as far as regards the heart, presents a great analogy to the dilator nerves, almost always possesses *tonus* in adult dogs, while it is destitute of this in most cats, rabbits, and guinea-pigs.

I would even doubt whether, if the absence of *tonus* were sufficiently proved for a certain region of the vascular system of the dog, we could absolutely generalise the fact by applying it to all the vessels of the dog. At least we know that, when the dilator nerves of the vessels of the submaxillary gland are divided, as Bernard has observed, the vessels become contracted, and the vein of the gland receives a smaller quantity of blood. As regards the rabbit, Samuel has pointed out that when the anterior auricular nerve is divided, the vessels of the ear are contracted, and the veins receive less blood. Long ago I pointed out that this nerve contained vaso-dilator fibres in the rabbit's ear, and it seems that Bernard sometimes saw the same thing. If the dilator fibres for the vessels of the ear do not always run in the interior auricular nerve, a good explanation is afforded of the exceptions which are not unfrequently seen in repeating Samuel's experiment on a large number of rabbits.

It seems to me then that clinical observations alone can decide whether the dilator nerves in man do or do not possess a true *tonus*; and until observations are sufficiently numerous to allow a decisive answer to be given, it seems to me more conformable to the laws of physiological induction to admit the existence of such *tonus* in man.

In the preceding remarks we have not yet exhausted all the conditions in which, according to our

actual knowledge, a paralysed part may present a temperature lower than that of the corresponding sound part. To complete the enumeration of these conditions, I may be allowed to add that, in my first publication on the vaso-motor nerves, I insisted on the influence of motion in the production of temperature. A limb which does not move is, *ceteris paribus*, colder than one in motion. Admitting, then, that a lesion of the centres, or perhaps of the peripheral nerves, does not involve any vaso-motor fibres, but only produces complete immobility, the limb thus deprived of motion must become colder in comparison with the sound one.

It seems that we have here an explanation of the fact that, in many cases of cerebral hemiplegia without lesion of a vaso-motor nerve, the paralysed part, if not warmed in the bed, is found to be a little colder than the sound one. And this conclusion appears to me so legitimate that, now as well as formerly, I admit that in all cerebral hemiplegiæ, in which the paralysed part has an average temperature a little above that of the sound one, there are secondary changes which extend the cerebral lesion as far as the region of the medulla oblongata.

Starting from cooling by immobility, I had come to the conclusion that, in dogs in which the temperature of a cold paralysed limb rises to the normal degree or even above it when a galvanic current is passed through the extremity, the current acts only in a secondary manner, by producing contraction of the relaxed muscles. Since more detailed observations have been made on the influence of the constant current on the vaso-motor nerves, this conclusion has seemed to me doubtful. It is possible that the current acts directly on the vaso-motor nerves, as Onimus and Legros appear to have seen in their experiments on the different influence of the ascending and descending currents on calorification. I intend to make new experiments in relation to this point.

I must speak of another fact which has forcibly struck me. In some dogs in which I had produced paraplegia by complete transverse section of the spinal cord in the lumbar region, I observed for some weeks together the oscillations of temperature of which I have spoken, when the animals, which had previously been in good health, began to lose appetite. They ate less than before, and especially selected the crumb of bread and refused the crust; they ate meat, but would have nothing to do with bones. They also drank a less quantity of water. The pulse retained its frequency, but was diminished in force. The quantity of urine seemed sometimes diminished, but of this I am not very sure. The most surprising symptom to me was that, even at the beginning of this pathological state, the oscillation of temperature ceased in the sound limb, which became colder; so that in the course of two days there might be a fall of the average temperature between the toes from 96.8° Fahr. to 59°, when the temperature of the surrounding atmosphere was 53.5° Fahr. I have kept some of these dogs till their spontaneous death, which sometimes occurred from eight to twelve days after the commencement of the pathological state. In those dogs there was observed, some time before death, more or less extensive rigidity of the muscles of the hind limbs. The thigh was rigidly drawn towards the abdomen; the knee was flexed; and the foot, which was generally less stiff, was in a state of extension. The toes remained quite mobile, and sometimes underwent transient contraction.

Others of these dogs were sacrificed two or three

* Since writing this, I have repeated Vulpian's experiment on the sublingual mucous membrane, and have observed, after keeping the animal two months, that after section of the chorda tympani the mucous membrane does not become paler.

days after the beginning of the continuous refrigeration.

In both one and the other group there was observed the beginning of a recent secondary change in the peripheral cut end of the medulla. Sometimes there was secondary change in the central end. This change, of which I shall give a description in another work, did not extend in the peripheral part more than about one-third of an inch beyond the wound. In the central part the extent was still less; but in one single case it was much greater. It is an interesting fact, that this secondary degeneration coincides with the continuous fall of temperature.

Hammond, in his work on the diseases of the nervous system, has stated that the muscular contractions which frequently occur in the course of a disease of the spinal cord, which at first produces paralysis, are a sign of the production of the often mentioned secondary alteration below the primary seat of disease; and it seems to me that, within certain limits, we may accept this view. The secondary degeneration which, at least as we have seen it in the medulla, has all the characters of a phlogosis, cannot spread without producing constant symptoms of irritation. If muscular contractions are a sign of direct or indirect irritation of motor nerves, the fall of temperature described by us appears to be a sign of the extension of irritation to the vaso-motor nerves. But, to go beyond the facts, we must declare that this fall has been only observed after section of the lumbar or lower thoracic portion of the cord; and the facts which precede justify the opinion that this fall of temperature is a more sensible index than muscular contraction of the secondary change. This appears to me proved by the fact that in our cases the fall of temperature preceded the contractions by some days. This conclusion of ours would not be contradicted if it should be found, in any clinical case in which the patient survived, that the contraction persists while the cooling ceases, to again give place to an increase and to oscillations of temperature.

The fall of temperature which arises from irritation of the peripheral end of the divided spinal cord, seems to me to explain still another fact which I have observed several times immediately after dividing the cord. It is known that the section generally produces an immediate rise of temperature in the paralysed parts. This rise is perceived in the majority of cases even before the animal is completely roused from the etherisation. But in some exceptional cases, both after semisection and after complete division of the cord, I have observed the paralysed parts to become cold and remain so for a variable time, perhaps an hour and a half; then they have become warmer, the pulsations of the arteries have become more perceptible, and after some time they have shown the raised temperature which is known as a general result of vaso-motor paralysis. I repeat that these cases of initial cooling were exceptional, and I have not been able to reproduce them at will, so far as I have endeavoured sometimes to combine an irritating influence with the process of separation of the cord. I cannot consider this cooling otherwise than as a product of irritation. This mode of viewing the subject is supported by what I have seen in some curarised dogs, in the interdigital membrane of which, before making the section, I had fixed an extremely delicate alcohol thermometer, one of those thermometers for which I am indebted to Signor Walferdin, and which

he calls *differential*. In some of these dogs, immediately after the section, I have seen the rise of temperature preceded by a rapid fall, which sometimes did not last forty seconds, and which reached about one-fourth of a degree Fahr. In these cases the fall would have escaped the ordinary means of observation. In some of these cases this fall appeared to be absent, or the cooling did not supervene which the anterior limbs sometimes show as the immediate effect of section of the lumbar portions of the cord.

We will now return to the periodical oscillations of temperature of which I spoke in the first part of this letter. A frequent variation of temperature in paralysed parts had not escaped my notice in my first researches on the effect of paralysis of the vaso-motor nerves. In my researches on the physiology of the nervous system (1855, page 144), I said:

'The difference of temperature (between the sound and the paralytic parts) remains, in the same conditions, the same after a year and a half as in the first week after the operation. I say in the same conditions, because that this difference always shows, according to the external or internal conditions, many regular oscillations; and these oscillations are the same immediately after the experiment and after a long interval of time.'

In order not to be led into error by these oscillations, I adopted the precaution of always taking the measurements at the same hour, generally between 4 and 5 A.M.

But later on, in a series of experiments on various dogs, which I made with the assistance of Dr. Angelo Mosso (which measurements were made between 9 and 10 A.M.), I was obliged to perceive that this precaution did not prevent the error which might arise from the oscillations. Here are the results of one experiment, selected at hazard. Small black bitch; section of right sciatic nerve, on March 13:

		Sound	Paralysed
		side.	side.
April 26	Interdigital membrane . .	92° 12'	94° 28'
May 5	" " " " " " " " " " " "	77° 0'	96° 8'
July 10	Beneath tendo Achillis . .	98° 06'	99° 68'
" 11	" " " " " " " " " " " "	95° 54'	93° 92'
" 11	After a short sleep . .	96° 26'	97° 52'
Aug. 28	Beneath tendo Achillis . .	94° 28'	91° 76'
Sept. 5	" " " " " " " " " " " "	88° 7'	93° 74'
" 5	Interdigital membrane . .	80° 06'	95° 36'
Oct. 3	" " " " " " " " " " " "	67° 82'	78° 08'
" 3	Beneath tendo Achillis . .	75° 2'	90° 14'
Nov. 1	" " " " " " " " " " " "	79° 7'	84° 56'
" 1	Interdigital membrane . .	68° 0'	78° 98'
	After injection of milk into the œsophagus.		
" 1	Interdigital membrane . .	71° 78'	66° 56'
" 1	Beneath tendo Achillis . .	76° 82'	74° 32'

At that time I sought the cause of these exceptions which the series of experiments presented in a transitory general agitation of the animal, because, as I had already proved in 1855 and pointed out towards the end of my memoir, and a little later in the transactions of the Natural History Society at Berne, a febrile excitement calls into action the dilator nerves of the vessels, and produces an excess of temperature in the sound parts above the temperature of the other parts, in which all the vaso-motor nerves are paralysed.

But, on continuing these experiments immediately after you did me the honour to send me your letter, I recognised that it was not a justifiable hypothesis to suppose the existence of a general excitement in all

hemiplegic animals, in which there is sometimes and temporarily a predominance of temperature in the sound part; and thus, in the course of the experiments to which I was led by your letter, I have found the regular return of oscillations independent of external circumstances and conditions. In the greater part of the animals examined by me I have found in the limbs a diurnal cycle, which recurs with an approximative regularity. But in certain paralysed parts this regularity altogether disappears.

After having by repeated experiments ascertained that these oscillations occur in hemiplegia and in paraplegia produced either by central lesion or by a peripheral lesion of the cerebro-spinal or nerve-trunks, I endeavoured to find if this rhythmical formation did not exist in the healthy parts.

On examining the temperature of the sole of the foot in dogs placed in a bag full of hay or tow, and kept as far as possible in the same conditions, I have found elevations and depressions of temperature which did not accord with the oscillations of the general temperature measured in the rectum. Up to the present time it has not been possible to subordinate the oscillations during the day to any fixed rule. Generally the temperature was low in the morning, rose towards mid-day, and showed irregular variations towards the evening. But in dogs and cats I have found, without exception, that between 8 and 10 P.M., when the animals were apt to sleep, the temperature rose to a maximum, remained high during the early sleep, and fell towards midnight.

In the ears of dogs and cats, the oscillations are much less than in the limbs; so that, without artificial or pathological excitement, a healthy ear rarely becomes much warmer than the other ear of the same animal in which paralysis of the vessels has been produced for the sake of comparison.

In the rabbit, on the other hand, the ear shows a double series of thermic oscillations. There are small oscillations which are very frequently repeated, and of which, with the aid of a very delicate thermometer or a thermo-electric apparatus, I have been able to count as many as five in the first minute, and then became convinced that there were no more. These small oscillations occur within a range (in an hour) which remains the same for several hours in succession. But when the temperature is frequently measured, both by day and by night, it is seen that this range shows great variations, and that it is generally higher between 11 P.M. and 2 A.M. than between 2 and 5 P.M. This is the more interesting, as the temperature in the rectum, if the animal have been kept alone in its box, is lower at night than in the day. In measuring the temperature in the rectum, I have first emptied it of faecal matter, to avoid error.

If these oscillations show us a new function of the muscles and nerves of the vessels, it will not be without interest to seek for them in man. I have not made any special researches on this point, but I have perceived that when I spend the whole day in the same way, either reading or writing, in a nearly equal external temperature, my hand shows at least twice in the day an increase of temperature, sensible even to the hand itself, and reaching to 7 or 9 degrees Fahr. One of these rises occurs in the day, the time of its appearance varying from 11 A.M. to 2 P.M. Towards 5 or 6 P.M. the hand has generally become colder. A second increase, much stronger and occurring in a more regular manner, takes place between 8 and 9 P.M., and lasts from four to six

hours. In the warm period, I have a sensation of heat if I touch with the palm of one hand the back of the metacarpal articulation of the other. In the cold period the sensation is the reverse, but is weaker.* I have observed also an analogous oscillation of temperature in my ears; I have not, however measured it with the thermometer.

It is evident *à priori* that the observations on the ears of the rabbit leave no doubt that the thermic oscillations coincide with or are preceded by oscillations in the diameter of the vessels. If it is so, the size of organs should be liable to changes isochronous with the oscillations, and these changes ought not to be absent in man. Researches on this subject have been made, as far as I know, by one observer only, and his researches were only made at night. According to him, the circumference of the breast diminished in the first half of the night, and again increased towards the morning. It underwent, two hours after the commencement of sleep, a diminution of $\frac{2}{35}$; after four hours of sleep, $\frac{3}{35}$; and after six hours it had again gained $\frac{2}{35}$. The size of the hand in the first two hours after sleep was reduced by $\frac{1}{18}$, after four hours by $\frac{1}{15}$, and two hours afterwards it had regained $\frac{1}{36}$. The circumference of the abdomen and of the foot had diminished after four hours' sleep by $\frac{1}{34}$; after six hours' sleep they had regained their former size. This last fact appears to indicate that the oscillations are independent of the horizontal position of the body during sleep, and the facts are probably allied to the oscillations which we have described. In the hand, in the abdomen, and in the breast, there was a diminution in the first hours of sleep, which would correspond (if the phenomenon depend on the vessels) to a contracted state of the vessels, while we have found in the hand during the first hours of the night, in the waking state, a dilatation of the vessels. It then seems that these phenomena either do not follow the same rhythm in all individuals, or that they are different in the sleeping and waking conditions.†

In speaking of these oscillations in man, we would not neglect to remember that phenomena of vascular and thermic oscillation have in some rare cases already been observed in man, in cases in which we might, probably without error, suppose the existence of a weakening or paralysis of the vaso-motor nerves.

Benjamin Brodie, in his work on local affections of the nerves, says that in some individuals in whom existed the so-called hysterical disease of the joints, the whole affected limb shows sometimes a singular alteration of temperature. Thus in the morning the whole limb may be cold and pale, as if there were no circulation of blood in it. In the afternoon the limb becomes warmer, and in the evening burning

* It would be very interesting to examine, by exact measurements, how far the superficial rise of temperature, and the loss of heat which follows it, is the cause of the lowering of the internal temperature which in man is observed during the night.

† In republishing the draft of this letter, I am very glad to be able to add that I have just received the *Philadelphia Medical Times* of February 20, 1875, which contains, at p. 330, a letter from a correspondent in Leipzig, showing that our friend Angelo Mosso, of whom I have already had occasion to speak in this letter as having assisted me in these researches, has lately occupied himself with investigating, by new methods, the oscillations in the size of portions of the human body. The very interesting facts observed by him appear to approximate more and more the contractions of the peripheral vessels in man to what I have observed in the vessels of the rabbit's ear.

to the touch, the vessels are turgid, and the skin darker and somewhat shining.

Graves observed something of the same kind in a woman. One leg became scalding hot and swollen; the skin became shining and of a dark venous colour; when this rise of heat ceased, a certain degree of swelling remained, but in the next stage the leg became pale, cold as a carcase, and comparatively painless. While this leg became cold, the other became hot and turgid; and the patient was entirely free from these attacks for three hours only out of the twenty-four. These singular facts are analogous to what we have observed in the dog, and are evidently nothing else than the exaggeration of the normal oscillations. The observation of Graves further shows, like our experiments on paraplegic dogs, that every part of the body may show its own oscillations independently of other parts.

After having found the oscillations, we had to inquire if the variation of local temperature could occur independently of a change in the general temperature; and already a long time ago we made an experiment on a rabbit, in which one thermometer was introduced into the rectum, and another into a small wound in the region of the tendo Achillis. We succeeded in rendering the animal motionless, and at the same time preserving the automatic respiration, by means of a section in the interior of the cranium, which separated, without any appreciable hæmorrhage, the upper part of the cerebellum, the cerebral lobes, the corpora striata, thalami optici, and anterior tubercula quadrigemina from the rest of the cerebro-spinal axis. While the animal was thus without spontaneous movement, and was cooling slowly, the pulse and respiration were counted from time to time, and the readings of the thermometer were taken every two minutes. Dr. Mosso was good enough to undertake to write down the details of the observation, and with his assistance it was continued from 3.15 to 9 P.M. We were fortunate enough to observe, two hours and a quarter after the commencement of the observation, an increase of heat in the leg, while the thermometer in the rectum continued falling as before. I will not copy the entire record of the observation, but only its most characteristic details.

[Dr. Schiff gives a table of the observations made, generally at intervals of two minutes, from 3.20 to 6 P.M., and then at greater intervals to 9 P.M. It is only necessary, nowever, to quote a few of the figures.]

Temperature in		
Hour.	Rectum.	Leg.
3.20	101°75	89°78
3.30	101°45	88°16
3.40	101°21	86°72
3.50	100°97	86°00

The operation was performed at 2.28 P.M.; immediately afterwards, the temperature was 15° and the pulse 25 in ten seconds. The temperature in the rectum was 102°92° Fahr.; fifteen minutes after the operation, 102°56° Fahr.; twenty-five minutes after, 102°02° Fahr. The temperature of the room was 69°8° Fahr. [See preceding table.]

At 3.20 the respirations were nine in ten seconds; at 3.34, seven or eight, and at 7.36, nine in the same time. At 4 o'clock the pulse was 153 in the minute, and at eight o'clock, 144. At 9 P.M. the respirations were fifty-four in the minute. The animal was now killed by destroying the medulla oblongata.

In this experiment it is seen that at 5.26 P.M. the temperature in the leg began to rise, and reached its maximum at 7.52. The maximum exceeded by 7½ degrees the temperature at the commencement of the increase, while in the rectum there was no trace of oscillation. This shows that in an animal not paralysed the local oscillations of temperature in the limbs are independent both of the general temperature and of the temperature of the surrounding atmosphere, and of the number of the pulse and respiration.

We still have some other less complete observations on curarised animals, with artificial respiration. But here the general cooling of the blood was too rapid, and the oscillations showed only the faintest traces. In three experiments, made on dogs, one or two thermometers were introduced into the substance of the tendo Achillis, and another very similar thermometer into the rectum. Artificial respiration was made with the hand, regulated by a metronome. Three of the experiments were without result, so far as no oscillation could be observed. The temperature fell too rapidly. In three or four other experiments a slight trace of oscillation was observed in the limbs, and this (an important point) occurred simultaneously in both hind legs.

In concluding this letter I will record two observations of some interest.

I have observed that the branchia of the *Proteus anguinus* present a phenomenon analogous to the oscillations which I have described. If the animal have been accustomed to bear daylight the branchia are sometimes for whole hours pale and, as it were, flattened; then they rapidly become red and inflated, and apparently increased in length. They remain in this turgid state for a time varying from half-an-hour to two hours, or more, and then again become pale and wrinkled. This change in the animal, left to itself, and living in water renewed daily, may be repeated three or four times a-day. If it be repeated more frequently the animal becomes restless, and makes rapid and continuous movements. When the animal is placed in water that has been boiled and then cooled, without contact with the air, the contracted state of the vessels predominates over the dilated state; and in this way it is possible to produce, after some time, a true atrophy of the branchia, which grows anew when the animal is again placed in aerated water. During the atrophic state, the proteus often comes to the surface and opens its mouth to breathe atmospheric air, and bubbles of expired air are seen to escape from the mouth.

This phenomenon, which is to be distinctly seen both in adult and young protei, differs from the oscillations observed in the limbs of mammalia, in the great rapidity which the variation is completed. While in the dog more than an hour and a half is required for the interdigital membrane to pass from

its cold state to the maximum of warmth, the change in the branchia of the proteus occurs very rapidly, and the transition from one extreme to the other takes place in a few seconds.

This appears to approximate the vascular movement of the branchia of the proteus rather to the movement seen in the rabbit's ear or in the bat's wing. In these, however, while the change is rapid, it is frequently repeated; in the proteus it is rapid, yet the stationary condition may be maintained for many hours.

From what precedes, it is plain that I wish to approximate the oscillations described in this paper to those which I have for a long time observed in the rabbit's ear. There is a great analogy between the phenomena; but I will not yet pretend to assert that they entirely correspond. In the rabbit's ear there are two series of oscillations, great and small. Perhaps the oscillations in the dog's foot and in the human hand correspond only to the more and great oscillations in the rabbit's ear, and that which corresponds to the small oscillations, and which in other parts is not distinctly shown either to the eye or to the thermometer, has yet to be found out.* The great influence of psychical excitement which I have found in the vessels of the rabbit's ear, is not without analogy in the vessels of other parts and of other animals.

I will add that my friend, Professor August Dumeril, to whom I communicated my observations on the proteus, was good enough to send me a white variety of axolotl, in the branchia of which the vessels are well seen; but I have not been able to detect in them any complete change, analogous to that in the proteus.

Some other observations have reference to the oscillations of temperature of paralysed parts during partial or superficial inflammation. You remember that long ago some authors endeavoured to prove that a strong hyperæmia cannot produce a change without contraction, and still less an inflammation, because, after division of the vaso-motor nerves, many organs are in a permanent state of strong hyperæmia with increase of heat without any disturbance of nutrition. I will not here inquire how far nutrition is or is not dependent on hyperæmia. You know that I hold that inflammation is not a product of hyperæmia, but that it is powerfully favoured by the hyperæmia which accompanies it. What I desire to here examine is, whether the experimental reason adduced by some authors in favour of the influence of hyperæmia is or is not justified by facts.

And in this respect it must be allowed that all that I have communicated in this letter shows clearly, that the argument derived from neuro-paralytic hyperæmia is not well adapted to afford proof that in the sense of the cellular pathology a high degree of hyperæmia does not produce a change of nutrition.

If some supporters of the cellular pathology allege that, after section of the vaso-motor nerves, the

organs are permanently in a state of extreme hyperæmia, I must repeat what I have already said, and which is confirmed by the facts mentioned in the beginning of this letter, that permanent neuro-paralytic hyperæmia is very far from being extreme, since the vessels contract and the hyperæmia is very greatly reduced, even at the end of the first week. But still more than by the reduction of hyperæmia is the argument in question contradicted by the new facts which I have communicated in the second half of this letter. If every neuro-paralytic hyperæmia shows, after a short time, the oscillations that have been described, the paralysed organs are under the influence of a true but not extreme hyperæmia, lasting only several hours of the day. During other hours the vessels are contracted, often very strongly; so that the influence of the hyperæmia, if it ever exists, is very powerfully limited.

As to the degree of this limitation, we have seen that it is strong in domestic herbivora (also in the horse, as I have seen in two experiments not yet published), and that it is less strong in the carnivora (dog, cat, fox). The hedgehog seems to resemble the carnivora in this respect. If all the chemical observations recorded in literature on the lesions of the cervical sympathetic and of the sciatic nerve be compared, man seems to approach the herbivora and not the carnivora in this respect. The neuro-paralytic increase of temperature was always small, sometimes so small that it could not be verified by the ordinary thermometers. In making these remarks, I do not wish to draw any conclusion against any thesis of the cellular pathology, but only against the manner in which some followers of that doctrine seek to use physiology to prove their opinions. It thus seems to me that no general statement can be made regarding the influence of a high degree of prolonged hyperæmia in man, and that this influence differs in different tissues.

It is a very interesting fact that the oscillations cease, or become imperceptible by the methods of research as yet in use, when an organ becomes the seat of inflammation. The inflammations which we have observed were in the ear, and were produced, as Samuel had already done, by covering the ear for some time with a paste of sulphuret of lime. Or the inflammations were produced in the paralysed toes or foot, and were produced by their rubbing against the ground during the movements of the animal. If the oscillations had ceased with the beginning of inflammation, to give place to a uniform dilatation, and if then the inflammation had been developed up to the maximum, this fact would favour the idea of those who regard permanent hyperæmia as one of the essential conditions for the production of inflammation, since in this case a true and strong permanent hyperæmia would have preceded the formation of the inflammation. But it is not so. Where there is seen on the foot or on the toes a slight puffiness of the skin with some small points of excoriation, the oscillations are not absent, but are weakened as the hot stage predominates.

When, after a few days, the various excoriated points have become united, when the whole of the surrounding skin is swollen, red, shining, and contains a serous secretion, the oscillations are scarcely perceptible; and when at last there is also ulceration of several points of the dorsal surface of the toes, they no longer exist. The more intense, again, the inflammation is in the dorsal surface of the foot or toes, the oscillations of temperature fail or are

* Since we discovered the rhythmic movement in the central artery of the rabbit's ear, several authors have pointed out that they have seen rhythmic movements and contractions in other vessels in mammalia or in man. Hoppe-Seyler entered such contractions in the iris, and observed them with the ophthalmoscope in the retina. Wegner says that he has found them in the iris of the rabbit. The rhythmic contractions of the vessels of the iris, according to him, are seen from three to seven times in a minute, and are independent of the pulse, heart, and respiration. Riegel and Lauder Brunton have found analogous contractions in the superficial vessels of the leg.

imperceptible in the tendo Achillis, although this is far enough from the point originally diseased. If at a later time, after the production of partial caries, the inflammations heal, leaving the foot lame and partly ulcerated, oscillations return in the tendo Achillis. Whether they return in the foot I have not examined.

We have in the preceding facts an arrest of the oscillations in the state of dilatation, of heat, and we are already acquainted with the fact of their arrest in the state of contraction, of cold, when degeneration in the peripheral part of the wound of the medulla produces a permanent irritation. I may be allowed to observe, that there may be cases of local spasm of the nerves, which may be capable of producing cessation of the oscillations in the contracted state of the vessels.

C. Handfield Jones, in his *Clinical Observations on Functional Nervous Disorders* (London, 1864, pp. 472-73), has communicated two clinical cases (157 and 158) which appear to illustrate this pathological point.

The object of the preceding observations has been to illustrate the value of local thermometry in diseases of the nervous system. The discovery of the thermic oscillations and of their modifications in paralysis shows that we must study the various forms of the thermic curve in the twenty-four hours, in order to deduce from them the medium temperature and the medium difference of local temperature in the sound and paralysed parts, and that a few daily measurements cannot lead us to a knowledge of the medium temperature and of its pathological modifications. If my observations have direct reference to disease artificially produced in animals and to healthy man, no one can better than you, my dear friend and colleague, fill up the vacant space which I have been obliged to leave, by clinical observations on the sick man.

ATKINS ON CHANGES IN THE BLOOD-VESSELS IN THE BRAINS OF THE INSANE.

In the *Dublin Journal of Medical Science* for June, Dr. Ringrose Atkins writes as follows of the minute morbid changes found in the cerebral blood-vessels of the insane.

The cerebral arterioles are found to possess three coats proper: 1. An inner fibrous; 2. A middle muscular; and 3. An outer fibrous coat. External to these, and surrounding them, is a fine hyalin sheath, formed by a prolongation of the pia mater inwards, and constituting a cylinder or canal, as it were, in which the vessels are contained. Between the outer coat and this sheath is supposed to exist a channel, the so-called 'perivascular lymph-space,' originally described by Robin, and supported by Obersteiner, Boll, and Roth, conveying the lymph and waste products to the great epicerebral lymph-space, if such can be believed to exist. This space, surrounding the vessels, plays, as we shall afterwards see, an important part in subsequent pathological processes, and has given rise to a great deal of error in its true recognition. In a diagram delineating this arrangement, the vessel is represented by an inner circle made up of three layers. The fine outer circle, separated from the inner one by a circular space, represents the hyalin sheath closely adherent to the brain-substance beyond. I need hardly say that, in

the actual tissue itself, such a differentiation of structure does not exist.

Commencing at the conditions found in the earliest stages, we come first to that of distension and dilatation of the arterioles, the result of congestion and stasis. This state of the vascular system is, in the great majority of cases, very difficult to account for; it cannot, for many reasons, be due to the increased mechanical pressure, pumping more blood than is normal into the cerebral circulation. Dr. Batty Tuke appears to think that it is rather due to some influence on the muscular coats of the vessels themselves, and advances three theories to account for this (*Edinburgh Medical Journal*, March, 1875, p. 803).

When the vessels are dilated and distended, we find the lumen increased in diameter, and often packed with dark-coloured and disintegrating blood-corpuscles, the walls of the vessels being in close apposition to the sheath and brain-tissue beyond, and their several coats appearing as if thinned and fused together. In many cases, however, the vessels are found quite empty, or perhaps with only a few blood-corpuscles still adhering to their walls. When this occurs, we must not hastily come to the conclusion that congestion did not exist during life, but we must look further for the effects it leaves behind it, which may generally, by careful examination, be detected. A drawing, taken from a vessel of the pia mater, shows the lumen filled with dark-coloured corpuscles; while another, taken from a section through the corpus striatum, shows the dilated arteriole completely occupying its canal, the lumen empty, and the walls appearing as if thinned. Should the condition here represented be of short duration, and be rapidly removed, no organic changes will follow, the vessels returning to their normal calibre in virtue of their elastic nature; but, on the opposite hand, should it persist for any length of time or increase, further morbid effects will ensue; and first amongst these is the occurrence of deposits external to the vessels, generally between the outer coat and the sheath. Of these there are three well-marked forms: (1) Crystals of hæmatoidin; (2) fatty granular masses; (3) a finely molecular material, when fresh generally of a bright yellow colour, and highly refractive, appearing like an aggregation of fat-globules, but which have not, as yet, reacted to the chemical tests for that substance. The individual particles are seen to be indistinctly corpusculated, and mixed with a finer *débris*. These particles have been likened, by Dr. Batty Tuke, to the spores of the *favus* fungus, which they strongly resemble. In a case I recently had an opportunity of examining, where the symptoms were only of a week's duration, I found this material present, in large quantity, on the walls of the vessels, and of a bright yellow colour. In this case the congestion was excessive, but in such recent cases it must be borne in mind that this deposit has been found in the brains of those mentally healthy.

Hæmatoidin-crystals are, perhaps, the most common form of deposit. They generally occur at the angle of bifurcation of a vessel; a drawing represents a collection of such crystals aggregated on the length of the wall of a vessel. These crystals are also found in the brains of those dying sane, and their presence appears to depend on the nature of the disease causing death. Accompanying or following upon these deposits, changes in the walls of the vessels ensue. The continued and excessive distension brings about an inelastic condition of the coats;

ampullations, fusiform dilatations, and, finally, true aneurismal sacculations take place. Of the normal triplicate structure scarce a vestige remains, the walls appearing as if composed of flat nuclei, until, at length, stretched beyond measure, they give way, and here and there hæmorrhages occur. The existence of these minute aneurisms, their mode of formation, and their relation to cerebral hæmorrhage, is of extreme interest. MM. Charcot and Bouchard ('On the Study of some points in the Pathology of Cerebral Hæmorrhage') have recently devoted considerable attention to this condition of the small arteries. They believe their formation to be due to a 'sclerous periarteritis,' which the authors also call 'arterial sclerosis,' and under this term describes a wavy appearance of the hyalin sheath of the vessels, with a large excess of spherical, ovoid, or irregular nuclei, existing in it. Sometimes these nuclei are present in such large numbers, that the proper coats of the vessel are almost entirely concealed. The outer fibrous coat of the affected arterioles may also be thickened and fibrous-looking, with fusiform cells lying in the direction of the long axis of the vessel, or this thickening may be absent; a large increase of the connective tissue nuclei being present in this tonic. The muscular coat is also affected, the fibres being more or less separated and thinned; this is, however, secondary to the changes taking place in the adventitia and depending on them. Little or no alteration takes place in the inner fibrous coat, the large ovoid nuclei, however, being sometimes multiplied.

In a drawing taken from a section through the optic thalamus, such an aneurismal sacculaton is seen, a distinct bulging being present on one side of the vessel; the preparation shows the outer fibrous coat thickened and wavy, while the nuclei on the walls are greatly increased both in size and number. In another drawing, taken from a section through an ascending occipital convolution of a chronic dement, a fusiform dilatation of a vessel is observed, the walls are thinned, and contained within is the remains of an old blood clot; while in a drawing copied from a plate published by Dr. Howden in the January number of the *Mental Journal*, a distinctly aneurismal condition of the vessels has been attained. When this stage has been arrived at, rupture is very liable to take place, and hæmorrhage, either punctiform or massive—as actually happened in the case from which the last mentioned drawing was taken—follows, giving rise to symptoms according to its extent. Many observers, however, differ in their explanation of the formation of these minute aneurisms from that put forward by MM. Charcot and Bouchard, referring the sacculations rather to degenerative changes of the nature of atheroma, akin to that occurring in the larger vessels, and due, probably, to the malnutrition of their coats, the result of the long-continued tension. From the specimens I have examined, I would be inclined to think that they might be the result of both conditions, fusiform dilatations and ampullations following an inelastic condition of the arterioles, while localised sacculations may be the consequence of an 'arteritis,' with proliferation of the nuclei, a part and parcel of a similar condition taking place in the neuroglia. These minute aneurisms are found both in the pia mater and in the substance of the convolutions, or motor tracts; although Dr. Batty Tuke localises them altogether in the corpora striata. They are

often found near apoplectic cysts, and are generally about the $\frac{1}{30}$ th to the $\frac{1}{40}$ th of an inch in length, and about $\frac{1}{4}$ th of that size in breadth. The rupture of these aneurisms is a fertile source of cerebral hæmorrhage. Charcot and Bouchard collected 100 cases, and in all these minute aneurisms were found to be present; and they allege that this is the one organic condition, worthy alone to be regarded as the direct cause of sanguineous extravasation.

Having arrived thus far at a frequent origin of punctiform hæmorrhage, a condition frequently found in connection with vascular changes in the brains of the insane, let us diverge for a few moments, and follow the further changes taking place in the clot effused. Soon after the minute hæmorrhage has taken place, coagulation in the centre of the clot begins to occur; a fine network of fibrin is formed, in the meshes of which the blood-corpuscles are entangled; by degrees a membranous investment is formed around the clot, constituting a complete capsule; this membrane is of variable thickness, and consists of a soft, originally homogeneous, translucent structure. This enveloping capsule is undoubtedly formed, as far as we can now see, by the precipitation of some albuminous material at the periphery of the extravasation. From the results arrived at by Schmidt, in reference to the coagulation of the blood, Rindfleisch alleges we can draw the explanation of this process, the 'encapsulation being due to the precipitation of fibrin—the fibrinogen being supplied by the nutrient fluid which bathes the clot, while the fibrino-plastic matter is derived from the blood-corpuscles within the clot.' This fibrinous capsule is always present, and Rindfleisch insists upon this, its real nature. In a drawing, taken from a section through an occipital convolution, with the pia mater adherent, is seen a well-marked example of one of these encapsulated blood-clots; it exists between the pia mater and brain-substance, and immediately beneath it is another layer of effused blood, in which the changes are not so complete. Should the condition proceed to perfect organisation, further changes will take place both in the capsule and in the clot; in the former, interstices become apparent, which increasing gradually divide the capsule into different layers; connective-tissue corpuscles appear in these interstices, and, finally, the organised membrane becomes incorporated with the connective tissue formed from the clot, the red corpuscles having been either directly converted into white ones, or the latter having immigrated from without, the mass of leucocytes thus formed becomes at once developed into fibrous connective tissue, and unites with that of the capsule, forming a small fibroid nodule. In a drawing, taken from the remains of a minute extravasation in the corpus striatum, the almost organised capsule is seen split into two, and contracting upon itself, as is evident from the rugose condition of its inner boundary, strongly resembling a section of a corpus luteum advancing in age; a few leucocytes still adhere to a portion of the membrane. As the age of these clots must be judged by the condition of the capsule, we must be careful in examining the latter, and ascertaining its reality. It often happens that the inner coat of the vessel may alone be ruptured; the blood then becomes effused between the other clots, forming a dissecting aneurism, which, on transverse section, presents all the appearance of a circular clot, with an enveloping membrane, the external coat of the vessel acting as

such; the discovery of the central canal of the vessel, however, at once points out the difference and clears up the doubt, rendering evident the recent nature of the extravasation. These organised clots or cysts, as they very often become, are found in the various stages of their development, and of various sizes, in almost every part of the brain and its membranes, though in different degrees of frequency; their occurrence in the arachnoid has been described by Drs. Wilks and Sutherland (vide *Journal of Medical Science*, October, 1865, and *West Riding Asylum Medical Reports*, vol. i.). The former observer mentions them as occurring only on one hemisphere in this situation, while the latter reports several cases where they were found on both hemispheres. These arachnoid cysts are generally found full of fluid, forming large pulpy swellings on the surface concealing the convolutions, the membrane surrounding them being tough and fibrous, and capable of sustaining considerable pressure. Such fluid cysts also occur in the choroid plexuses, and a specimen of such has been figured by Dr. Long Fox, in his work on the *Pathological Anatomy of the Nervous Centres*. In a specimen recently taken from the brain of a chronic dement of twenty-three years' standing, is seen a beautiful example of their occurrence in this situation; about the centre of the choroid plexus is seen a collection of clustered vesicles, each about as large as a small pea; when magnified, their walls are seen to be composed of a fine membrane, containing within it a clear colourless fluid. The corpus striatum is, perhaps, the most frequent seat of organised extravasations, but they are also found in the substance and on the surface of the convolutions, and often near the aneurismal dilatations, of which I have already spoken.

Having thus considered the changes produced by congestion and stasis, let us next direct our attention to the conditions in which the vessels are left after its subsidence. The elastic vessels, stretched beyond what they could normally bear, being suddenly released from the state of tension, recoil, as it were, on themselves, and consequently both their course and calibre become altered. They assume a tortuous and twisted direction, bending and coiling upon themselves, and even, in some instances, it is said, 'knots' and 'kinks' are found. This tortuous condition of the vessels is most commonly found in the pia mater, where the vessels, not running in unyielding channels, as they do in the brain substance, are free to become twisted and bent. A drawing, taken from a specimen under the microscope, well illustrates this state. The vessels are seen running in every direction, crossing and re-crossing each other, and forming regular coils. No drawing, however, could portray the beautiful appearance presented by these vessels. In the vascular channels in the brain-substance, the calibre of the vessels becomes contracted, the arterioles shrinking within their sheaths, and forming angles by the uneven contraction of their walls. Another drawing shows a vessel cut transversely, and shrunk in this manner within its sheath, leaving a clear ring between it and the brain-substance beyond. This drawing forms a strong contrast to that of the dilated arteriole, before referred to, where the vessel is in close apposition to the tissue outside, and its walls wasted and thinned. On the nature of this clear space surrounding the vessel, much confusion has taken place and error crept in, some authors considering it to be the normal perivascular lymph-space exaggerated;

others looking upon it as a dilatation of the cerebral tissue, which, from its nature, being unable to return to its normal state, on the shrinking of the vessel, leaves the clear space seen; while others, again, believe that these spaces are merely the result of contraction, consequent on the use of the hardening agents necessary in the preparation of the specimens. In all those I have myself prepared, I have never been able to observe any membrane lining this space, as is the case in the normal condition; and in many of the preparations the cerebral structure around has appeared as if condensed and granular. I look upon these appearances as pointing to a shrinking of the brain-tissue, from some cause, as the origin of these spaces; and, in addition, I may mention that I have often observed fine processes proceeding from the vessel across the space, as are well seen in the specimen from which the drawing last referred to is taken, described by Boll as existing on the outer surface of the sheath, and penetrating the cerebral substance, as if for the support of the sheath. It would, hence, appear that the sheath itself becomes closely adherent to the outer coat of the vessel, and as the latter shrinks it goes with it, and at the same time withdrawing from the cerebral substance these supporting processes, gives the vessel a thorny appearance as it here presents. Obersteiner looks upon these processes, or 'Deiters' cells,' as they are called from their first describer, as direct communications between a lymphatic space surrounding each nerve-cell and the perivascular lymph-space surrounding the vessels. This theory, however, requires confirmation. From these consideration we must look upon these spaces as abnormal formations, produced by the morbid processes going on, assisted probably by the hardening agents to which the tissues are exposed in their preparation.

We now come to the structural changes taking place in the several coats of the vessels themselves—a very important class, as on them many of the conditions of malnutrition of the nervous tissue—depend. We may have the three coats thickened, each of the tunics being quite distinct and separately affected; or, again, we may have the inner coat alone thickened, while, in many cases, the muscular layer is singly hypertrophied. It is in recognising these pathological conditions that we must exercise caution in drawing hasty inferences, as almost identical changes—especially as regard the fibrous coats—can, and often are, produced by reagents, such as glycerine, camphor-water, acetic acid, etc., used in mounting the specimens. That morbid thickenings, however, do occur, cannot be doubted, and their presence may be truly recognised by avoiding the use of fluids which have been found to produce similar artificial changes. The hypertrophy of the muscular coat is most probably due to the overwork consequent on the endeavours of the vessels to propel the blood through the tortuous and contracted vessels—such a condition being rarely present, save in long-standing cases, where obstructions of this nature are always found. In a section through an ascending frontal convolution, from a case of organic dementia, I have found a very different kind of thickening. In one the three coats are quite distinct and separate, the lumen unaltered in character, and filled with disintegrating blood-clot; while in the other the lumen is reduced to a mere furrow, so encroached upon is it by the thickened walls, the coats of which are completely fused, all trace of a division of the

layers, or the presence of muscular nuclei being obliterated, and fibroid-looking material substituted. This condition I believe to be produced by the infiltration of an albuminous plasm into the walls of the vessel, which glues the coats, as it were, together, and finally obscures and destroys their structure—encroaching, at the same time, by its distension, on the canal of the arteriole, and in time becoming converted into a fibroid connective tissue, which appearance it here presents. This specimen resembles, to a certain extent, that condition figured by Dr. Long Fox as occurring in ‘glioma,’ of the brain, and also that described and figured by Dr. Tuke as occurring in syphilitic disease of the organ; differing, however, from the latter in the absence of all trace of the muscular coat, and wanting the accompaniments of the former; and as no peculiar morbid appearances, save atrophy of the cells, were here present, in addition to this condition, and as no history or trace of syphilis could be discovered, it appears that obliterative thickening can take place independently of these conditions. As to the hyalin sheath, of which I have often spoken, this also becomes thickened by disease; but, from being frequently incorporated with the outer fibrous coat, its alterations cannot be so easily detected. I have, however, a specimen, where by chance the vessel itself has fallen out of its containing canal, leaving the sheath, slightly thickened, still adherent to the sides of the space. This condition of the sheath has been used as part proof of its normal existence.

Another condition of the minute arterioles still remains—namely, ‘fatty metamorphosis’ of the muscular nuclei, with granular masses of a similar nature (before mentioned) deposited on the walls. In another drawing the appearance presented by a vessel commencing to undergo this change is fairly seen; the specimen is taken from the pia mater, and minute oil-globules are seen dotted over its surface and around it. This condition is very important in its relation to cerebral hæmorrhage, as was first pointed out by Paget, and afterwards described by Kölliker and Wedl. Dr. Bouchard, on the other hand, thinks that the fatty granules seen are secondary to other changes, and do not give rise to a condition of the vessels favourable to hæmorrhage, averring that the granules are seen occupying the lymphatic space, and not taking the place of the muscular tunic, as supposed by Paget. Dr. Bouchard, however, acknowledges that primary fatty changes do take place in the capillaries of the brain, but says that they have been confounded with the above-mentioned secondary metamorphoses. I have examined many vessels, chiefly those in the pia mater, where the muscular nuclei were occupied by fatty granules, and no other appreciable change could be observed in their coats; and how such a condition could be secondary is difficult to understand. As regards the larger vessels, especially those at the base of the brain, atheromatous or calcareous changes are often found in those dying insane, leading to local softenings, as occurred in the case from which this preparation of the circle of Willis was taken; the left middle cerebral artery is seen to be almost occluded by calcareous degeneration of its walls, and the portions of the organ which it supplied were thoroughly softened, and in parts almost diffident.

Having thus reviewed, *seriatim*, as far as we are now acquainted, the morbid changes found in the blood-vessels, and the direct result to which they give rise, let me briefly picture, in a general way, the clinical

effects which may follow, deferring until a further period any account of the modifications occurring in the cells, neuroglia, etc., as a secondary consequence of primary vascular disease. Starting with the condition of dilatation, we can at once, on physiological grounds, portray the symptoms which will, and are found to, accompany it. Should active arterial hyperæmia be the initial cause, over nutrition of the brain-cells will take place, exaltation of function will follow, the ideas will flow free and fast, fancy will be excited, imagination roused, motor impulses become uncontrolled, and acute mania will be the result. Should this active hyperæmia change to passive congestion and stasis occur, a lowering of nutrition takes place, depression follows exaltation, the ideas come slow and shallow, indifference succeeds excitement, motion becomes impeded, and sluggish and secondary dementia gradually supervenes. Should stasis persist, organic changes in the cell-elements ensue, blocking up of the outlets for waste products follows, resulting in the infiltration of these products into the tissues; apathy succeeds indifference, consciousness and volition are gradually abolished, the calls of nature neglected, and the unfortunate sufferer sinks into a state of hopeless fatuity, life being often prolonged until the completely disorganised nervous system can no longer sustain the weight it has to bear. Although, however, I have described these changes so rapidly, yet years, aye, many years, may pass before the picture is complete; remission may follow remission, the intellect may brighten as the dilated vessels contract, opening up the blocked outlets, and allowing the waste material to be carried off, and the deteriorated but not shattered mind may be restored to reason, until a fresh attack brings the sufferer into a worse condition than before, perhaps again to remit, leaving him a step lower in the scale of mental power than he was previous to the last attack; until finally, as aggression succeeds aggression, the structures become incapable any longer of returning to the due performance of their functions, and then the mental, if not the bodily, end comes. But this dark picture has a bright side; instead of congestion and stasis following arterial hyperæmia, the latter may rapidly disappear, and mental health be restored—never again, perhaps, to be interfered with; or, should stasis follow, it may, perchance, after hope has almost well nigh gone, suddenly cease, and a similar result ensue.

ON THE FUNCTION OF THE LEVATOR ANI MUSCLE, WITH REFERENCE TO PATHOGENESIS. BY JULIUS BUDGE, PROFESSOR IN THE UNIVERSITY OF GREISSWALD.*

The levator ani is one of the few muscles of the human body, regarding which anatomists entertain not only different but diametrically opposite views. A discussion on this circumstance is not inappropriate here, as in my opinion not unimportant pathological conditions depend on disturbances of the innervation and nutrition of this muscle. I have examined it in many bodies, and have made experiments on it in animals, and have also taken comparative anatomy into counsel, in order to arrive at an insight into its action in the normal state. I will here only state what is of special interest in practice, and will publish the more minute anatomical details in another place.

* *Berliner Klinische Wochenschrift*, July 5, 1875.

The levator ani, as its name implies, is generally regarded as an elevator and dilator of the anus, and therefore a promoter of defæcation. A few anatomists only, especially Cruveilhier and Henle, regard it as a second sphincter; and, recently, Leshaft has expressed a similar opinion.

It is not possible to form a proper opinion concerning the muscle in question, unless we also examine the pelvic fascia which entirely covers it in from above, and becomes visible after removal of the peritoneum and of the thinner fasciæ formed partly by the prolongation of the fascia transversalis, partly of the fascia iliaca. The pelvic fascia consists, according to the direction of the bones of the pelvis, of a more exclusively lateral and a more transversely lying mediate portion. The first is named, after Hyrtl, the parietal, the latter, the visceral layer of the pelvic fascia. The name visceral is used, because this fascia is applied laterally to the organs lying in the pelvis, and is united with their coverings. These organs are, in the male body, the prostate, bladder, and rectum; in the female, the bladder, vagina, uterus, and rectum. It may therefore be even said that the whole surface of the pelvic fascia is interrupted by these organs. The parietal portion lies over the obturator foramen, and thence derives the name of obturator fascia. The pelvic fascia entirely covers the levator ani, and this is in various parts so intimately connected with it through its muscular fibre, that they seem to be blended together. The fascia must be regarded as partly affording points of origin, partly of insertion. A point of origin without doubt is the ribbon-like portion which is attached to the posterior surface of the pubic bone, near the lower end of the symphysis, and proceeds to the spine of the ischium—the so-called *arcus tendineus*. In other parts, the fibres may be regarded as being inserted into the fascia; and on account of their position these parts deserve our consideration. For, since muscular fibres spread out from the firm, almost immovable, points of origin as far as the pelvic fascia, the latter is put on the stretch, and so far the levator ani must be regarded as a tensor of the fascia. The immovable points of origin are the posterior surface of the pubic symphysis and a portion of the horizontal ramus of the pubic bone, the *arcus tendineus*, and the spine of the ischium. The tension of the fascia is, however, increased by another cause; viz., that underneath the pelvic fascia lie two other distinct fasciæ, in some parts very firm—the proper perineal fasciæ—which enclose the transversus perinei muscle between them. The entire plane on which lie the subcutaneous fasciæ, the perineal fasciæ, and the pelvic fascia, exerts a powerful resistance to pressure from above downwards on the contents of the pelvis. This pressure from below supplements the abdominal pressure, in consequence of which the contents of the pelvic organs are forced towards the parts where there is least pressure—the opening of the intestinal tube and of the uro-genital apparatus. For our purpose, we have only to consider the pressure on the rectum. It is well known that the rectum is divided into a suprapertitoneal and an infrapertitoneal portion. The former is movable by means of the mesorectum; the latter is fixed to the sacrum by connective tissue, and especially by the neighbouring parts, namely, the pelvic fasciæ and the levator ani. The abdominal pressure acts chiefly on the suprapertitoneal portion of the rectum, as well as on the sigmoid flexure. Three tendon-like expan-

sions are simultaneously put on the stretch, and act first on the small intestine, and thereby indirectly on the sigmoid flexure and the upper part of the rectum, which must be regarded as the reservoir of fæcal matter. The lower part of the rectum first receives the excrements just before defecation takes place; otherwise it is more or less empty. The tendinous expansions which come into action in abdominal pressure are, the central tendon of the diaphragm, the aponeuroses of the abdominal muscles, and the pelvic fascia. During ordinary respiration, the central tendon moves but little from its place, and remains arched towards the pericardium; in deeper inspiration, on the contrary, as is the case during abdominal pressure, it sinks, and presses the liver down on the small intestines. The aponeurosis of the abdominal muscles lies in such a direction that it acts backwards and downwards. This is brought about by the peculiar constitution of the posterior layer of the sheath of the rectus abdominis. This ceases below the umbilicus, and all the tendinous fibres which proceed from the transversalis, and part of those from the internal oblique, ascend towards the umbilicus, forming the *linea semicircularis* of Douglas. It hence follows that the lower section of the abdominal wall contracts less than the upper, if the oblique abdominal muscles are called into action. One may easily become convinced of this by laying both hands (not the thumbs) on the abdominal wall, in such a way that one hand lies with the edge of the little finger resting on the horizontal ramus of the pubic bone, while the other hand reaches as high as the umbilicus, and then making a deep expiration; the lower hand is drawn inwards very little or not at all, while the upper is very distinctly so. The cause of this is, first, that the lower fibres of the transversalis muscle are shorter than the upper, so that they cannot move so far; and, secondly, that the viscera lying here cannot slip aside. For the diaphragm presses down from above, the pelvis is filled with viscera, and especially the pressure exerted by the aponeuroses of the abdominal muscles is less, since even the posterior layer of the sheath of the rectus is wanting. Hence this portion of the abdomen is not much retracted in pressure on the abdomen; indeed, it is rather arched forward. If the sigmoid flexure, containing the greater part of the fæces, or the bladder be much distended, these organs occupy the space lying under the *linea semicircularis* of Douglas.

We have so far spoken of the levator ani as a tensor of the fascia. This, however, is by no means its sole, nor even its principal function. The muscle comes rather, in its course, into very near connection with the rectum, and also indirectly with the urethra. If the levator ani be looked at superficially from above, after the removal of the pelvic fascia, or from below after removal of the integuments and fat, it forms a muscular plane which, apart from the above-mentioned *arcus tendineus*, is attached to three bony points—the horizontal ramus of the os pubis, the spine of the ischium, and the anterior end of the coccyx; and, having a generally transverse course, extends to the infrapertitoneal portion of the rectum. Looked at in this way, the assumption that the levator ani dilates and elevates the rectum is understood. It was through the anatomical researches of Cruveilhier and Henle that other views were first entertained. They explained this muscle to be a second sphincter, arriving at the conclusion, from the course of its fibres, that it did not produce

dilatation, but contraction. I will first briefly describe the course of the individual bundles. In order to separate them, a ten-per-cent. solution of salt is employed with advantage; and it is better to use preparations which have lain some time in spirit than fresh ones.

If a plane be imagined as passing through the lower third of the posterior surface of the pubic symphysis, through the spines of the ischia, and through the front of the coccyx, the greatest part of this plane is occupied by the levator ani. At two points only is it not occupied by this muscle, but by other organs. These are in front, behind the os pubis, the prostate, the commencement of the membranous urethra, the vagina; behind, the infraperitoneal division of the rectum. Around the first-named the levator ani is arranged in an arched manner; its fibres are connected with the rectum. This connection takes place in the following manner. The rectum is surrounded by a thin but very firm fascia, which is insinuated between the muscular bundles just as is the case with the gluteal muscles. The fasciculi of the levator ani follow the fascia, so that in some degree they may be regarded as an aponeurosis of the muscle. From that division of the levator ani, which does not surround the rectum and which contains the greatest mass of fibres, must be distinguished—1. The portion lying between the prostate (vagina) and rectum, and in front of the latter; 2. That lying behind the rectum in front of the apex of the coccyx; 3. The fibres of communication with the deep transversus perinæi.

The muscular mass lying in front of the rectum, which for brevity we will call the prerectal portion of the muscle, is indeed for the present of less account than that lying behind the rectum; but it forms a point from which fibres pass backwards, while others go to the urethral muscle or even to the musculus bulbo-cavernosus, and others, again, unite with those of the opposite side. The prerectal portion arises in the middle, near the symphysis pubis, and forms a partial arch, while the fasciculi of one side unite with those of the other side either by muscular structure or by a septum. Another set of the fasciculi courses through this portion, and these partly remain on the same side, and partly decussate with the fasciculi of the other side; this combination passes behind the rectum, and forms a part of the postrectal fasciculi. Finally, a smaller number of fibres pass forwards towards the prostate (vagina), and are applied to the fibres of a muscle lying under the levator, but of less extent, the deep transversus perinæi, especially to that portion of it which is usually called the urethral muscle. As the muscle just mentioned compresses the membranous part of the urethra, it may be assumed that the contraction of the urethra is not unaffected by the contraction of the levator ani.

The external fibres of the levator ani, which spring laterally from the horizontal ramus of the pubic bone, as well as those which arise from the spine of the ischium, enter into the arch formed by the postrectal portion. A lower and an upper portion of these fibres may be distinguished. The former lies near the external sphincter, into which bundles of fibres proceed from it. The upper portion springs principally from the prerectal part; the posterior belongs mostly to the external fasciculi coming from the pubic bone and ischium.

From this description, it appears that the rectum is surrounded as with a sleeve by the different fasci-

culi of the levator ani; and that, when its nerves are irritated, this sleeve must contract and constrict the rectum above the anus. It may be said that the whole infraperitoneal portion of the rectum is enclosed by the levator ani, if it be remembered that, as above mentioned, it penetrates into the rectal fascia. The anus only remains free, if we leave out of account the scanty fibres which are connected with the external sphincter.

Physiological experiment also proves that the rectum may be constricted by the levator ani. In dogs this muscle is very strongly developed, and its course is, on the whole, similar to that in man. I have laid bare the muscle in a beheaded animal, while a preparation of the same part lay before me. I then placed each half of the muscle in connection with an induction apparatus. It was, of course, necessary to avoid passing the current through the external sphincter, and, on this account, separate stimulations were employed. The rectum was cut across, and a glass tube was fixed in it, through which water was constantly poured. So long as the circuit remained broken, the water flowed continuously from the anus; but when it was closed, the levator ani was seen to contract, and there was a decrease sometimes or complete arrest of the outflow.

There is also present a double sphincter cloacæ in birds, reptiles, and amphibia. Cuvier reckoned the levator muscle in these animals among the sphincters.

There can, then, be no doubt that the levator ani, when called into activity, is capable of narrowing and closing the rectum. Nevertheless, I consider it perfectly adapted to promote defæcation, without dilatation of the rectum.

The rectum is provided at its lower end, above the anus, with a considerable dilatation, which the French call *ampoule rectale* or *pouche du rectum*, also *cul-de-sac ovoïde*. This part is entirely surrounded by the levator ani, and must be narrowed when this muscle contracts.

The normal influences on which the contraction of the muscle depends, are the healthy condition of its fibres, its proper nutrition, and the stimulation of its nerves. First to speak of the latter, it is partly reflex, partly voluntary. There is, indeed, no doubt that stimulation of the centripetal nerves of the mucous membrane of the rectum reflexly calls into action the unstriated fibres of the rectum, and also the striated fibres of the levator ani which is so closely connected with it. The voluntary stimulus may act either in the levator ani or on the sphincter. In the first case, the already existing reflex movements are increased, and the fæces are expelled; in the latter, on the contrary, the anus is closed and evacuation does not take place. The fæcal masses, however, are not driven upwards by the contraction of the levator ani, because the resistance of the abdominal pressure downwards is too great. The reason why the influence of the will is superadded to the reflex irritation is easily to be perceived. The movement of the levator ani is felt, and produces the desire of defæcation. This sensation being present, the mind has the choice of voluntarily directing attention to one or the other muscle, and producing the corresponding action. If the voluntary contraction of the sphincter ani be continued for some time, the reflex action on the levator ani becomes relaxed and at last ceases; that is, in other words, if the impulse to defæcation be not allowed

to have effect, it ceases, until renewed by the presence of fresh masses in the infraperitoneal portion of the rectum.

From this explanation it follows, that the levator ani can only produce defecation when the abdominal pressure co-operates with it and the sphincter ani is not contracted.

It is perfectly clear that obstruction may occur when the contractile power of the levator ani is diminished by any cause. This may, for instance, take place when the muscular force is reduced by great fatigue or concussion. There are many persons who have obstinate constipation if they take long walks or travel long distances in carriages; and it may be also a result of want of ordinary food. Cases of the latter kind are not to be treated by laxatives, but by iron and similar remedies; while nervous affections demand the use of the constant current and other measures which act in a similar manner.

It finally remains for me to consider the question whether the levator ani may not in some circumstances act vicariously for the sphincter ani. The observation has been made that, after division of the external sphincter, and after extirpation of the rectum, the power of retaining the fæces is, nevertheless, still present. Bardeleben, in his *Lehrbuch der Chirurgie*, fifth edition, vol. iii., expresses himself in the following manner. 'If the entire sphincter have been removed in extirpation of the rectum, the ordinary result is incontinence of fæces. The fæces do not, indeed, escape continually as from a preternatural anus, but the patients are unable to resist the slightest pressure. That the retention of the fæces is possible up to a certain degree, and that a constant escape does not take place, depends on the action of the third sphincter, described by Nélaton.'

This sphincter is named by Nélaton superior sphincter (see Velpeau, *Traité complet d'Anat. Chir.*), and by Hyrtl sphincter ani tertius (*Lehrbuch der Anatomie*). According to Nélaton, it lies a little more than four inches above the anus, just at the point of junction between the suprapræperitoneal and infraperitoneal portions of the rectum. According to Velpeau, it extends in front about six or seven inches, behind about one inch. Regarding the functions of this sphincter, Velpeau expresses himself as follows. 1. By it, the fecal masses are probably retained above the lower dilatation of the rectum, into which they descend just before defecation. 2. During defæcation, its function seems to be to prevent the return of the fæces into the colon. 3. If the lower sphincter be divided during operation for fissure or fistula ani, or during extirpation of the rectum, it appears to afford a resistance to the involuntary escape of excrement.

This assumption, which seems to receive the assent of most surgeons, nevertheless proceeds from data which cannot be regarded as perfectly established. For, if the functions above mentioned were dependent on the superior sphincter, it would be necessary to prove that it is constantly present at the place named, just as there is here a valvular projection of a fold of mucous membrane. There must also be found a reason for supposing that, when the fæces reach the point in question, the muscle contracts so powerfully as to cause an obstruction. It is, indeed, correct to say that, as O'Beirne remarked, the principal reservoir of the fæces is the sigmoid flexure. This statement, however, may be improved by adding that not only the sigmoid flexure but the

suprapræperitoneal portion of the rectum has this function. It is also correct to say, that the infraperitoneal portion of the rectum generally contains no fæces, but that these are only carried into it before defæcation. It may be concluded from this observation, that conditions must be present which render the carrying downwards of the fæces more difficult than it was before; but it does not follow that the cause of this is to be sought in the sphincter referred to. It must rather be considered that the suprapræperitoneal portion of the rectum is much more movable than the infraperitoneal. By means of the mesorectum, the former can move from one side to the other; and a kind of bending occurs at the limit between the two portions which, as is the case with the fundus of the bladder, restrains the advance of the fæces until there is increased pressure from above.

It is, however, a question of special importance whether the upper sphincter is constant or not; that is, whether at the point described the circular fibres of the rectum lie more thickly near and on each other. That this is often the case cannot be questioned; and then a sphincter may be demonstrated as Velpeau has described it. But we also search often for it in vain. I have not made investigations on the bodies of adults, but only on those of embryos and new-born children; and I have not been able to convince myself that Nélaton's sphincter is constantly present. The assumption which Sappey gives of it in his *Traité d'Anatomie descriptive*, vol. iii., agrees perfectly with my observations. He says: 'It is an error to suppose that a superior sphincter always exists; for it is not very rarely seen that the circular fibres of the first portion of the rectum are not more developed than those of the sigmoid flexure and of the rectal pouch. In the more frequent cases in which these fibres are more developed, or, at least, more abundantly than those lying above or below, there is still no sphincter.' Richet expresses a similar opinion in his *Traité d'Anatomie Médico-Chirurg.*, and Hyrtl (*loc. cit.*), and Henle (*Anatom.* vol. ii.), dispute its constant presence.

For these reasons, it is scarcely probable that a special action can be attributed to a muscular layer which is so inconstant. The retention of the fæces requires the action of a voluntary, powerful, rapidly acting muscular structure, such as is not found in the unstriated, but in the striated muscles.

All this taken together, the opinion expressed by Henle is to be preferred, that it is not the superior sphincter, but the levator ani which renders the retention of fæces possible after loss of the external sphincter. A person operated on in this way will, indeed, not employ abdominal pressure either. He has the sensation of an approaching evacuation. But without this help, the levator ani does not arrest defæcation.

It is also to be remarked that there is not always a fold of mucous membrane at the part where the superior sphincter lies, when this is present. Further, the points at which these often very projecting folds are to be found are variable.

At the last half-yearly general meeting of the Scottish Meteorological Society two interesting papers were read; one on 'The Mortality of the Large Towns of the British Islands in relation to Weather,' by Mr. Buchanan; and the other on 'Weather and Epidemics of Scarlet Fever in London during the past thirty-five years,' by Dr. Arthur Mitchell.

FÜRSTNER AND SAVAGE ON MENTAL AFFECTIONS DURING PREGNANCY AND THE PUERPERAL STATE.*

On looking over the psychic literature of the last ten years, one is struck with the large share which progressive paralysis has contributed. From the time when Haslam set forth the fundamental characters of this frequent and deadly form of disease, clinical observers and anatomical investigators have been equally ardent in laying down on an anatomical basis the course of the disorder; for these, materials in all possible quantity have been forthcoming on the male side of asylums. The same cannot be said for the affections of pregnancy and the puerperal state, for these only occur in any number at long intervals of time. Dr. Fürstner's essay is a clinical history of thirty-four cases. The question as to the frequency of pregnancy and puerperal psychoses cannot be determined from the available statistics. If we take as bases the disease noted in lying-in hospitals, the total will be too small, for those affected during pregnancy are not admitted, whilst the lying-in women are discharged after eight or ten days, and any disorders that happen to them afterwards are not known. Hence it cannot be astonishing that Reid and Gream met with only twenty instances of puerperal psychosis out of 5,500 women confined in the Westminster and Queen Charlotte's Hospitals, and that Johnston and Sinclair met with twenty-six insane only out of 13,748 confinements. Again, if we add the cases received into an asylum, the necessary factors are missing of the number of the delivered and of those pregnant. Much more interesting is it, however, to the alienist how often the puerperal state appears as a cause among a given number of insane women, although even here there are difficulties, the chief being that for the puerperal period and the closely allied period of lactation a definite limit of time does not exist; for instance, one might hesitate as to placing a woman in this group who weaned a child after four months, and who became insane six weeks afterwards. It stands to reason that asylums in large cities, where, owing to deficiency of room and of still more necessary care and superintendence, it becomes impossible to admit all acutely suffering women, can arrange for a much more select class of cases than those in the country districts. Thus, it appears to be quite an abnormal proportion that in the Charité, at Berlin, there should be eighty-six puerperal cases among 508 insane, *i.e.* nearly 17 per cent; whilst the proportion drawn from other hospital sources appears to be about 9 per cent. There are three distinct periods, the far greatest contingent being contributed by the actual delivery-period, the next by the period of lactation, and the least by that of pregnancy. Of 310 cases collected by Marcé, 27 occurred during pregnancy, 103 during lactation, and 180 during the actual puerperal state; whilst in Fürstner's cases, out of thirty-four the proportions were five, eight, and twenty-one. Of a direct causal connection between these three phases, and the psychoses appearing in connection with them, we know nothing; but a series of predisposing and exciting causes have been studied, which are at all times liable to occur during the puerperal state, from whose interaction the psychosis results. Of these, hereditary taint is the

chief, and comprehends 24 to 30 per cent., when direct hereditary taint only is meant; but the proportion becomes vastly different when in 'heredity' are included epilepsy, hysteria, drunkenness, and neuroses of various kinds. Besides the nine cases, out of his thirty-four, where he found direct hereditary taint, there were three of drunkenness in the father, one of epilepsy, five of hysteria in the mother, and two of epilepsy in the patients' sisters, so that in twenty-one out of the thirty-four there were distinct traces of family taint, whilst eleven appeared to be quite free. It might have been expected that the hereditarily predisposed patients would have shown some uncomfortable nervous symptoms before the special disease broke out, but Fürstner's experience was quite opposed to this. The peculiarities of the 'nervous constitution,' as detailed by Arndt in the *Archiv für Gynäkologie*, were conspicuous by their absence. A second important element in the etiology of puerperal psychoses is found in the alterations of the circulatory apparatus and the blood, to which the female sex is peculiarly disposed, *e.g.* chlorosis, whether depending on deficient quantity of blood or defective quality of the corpuscles, or on imperfect arrangement of the vessels, to which must be added defective development or hypertrophy of the generative organs and abnormalities of function. There appears to be in these women a lessened capacity for withstanding somatic and psychic lesions. Anyhow, it seems clear that pregnancy and the actual puerperal state, with the unavoidable loss of blood, be it ever so little, together with the febrile conditions engendered, bring such predisposed women into so weakened a state that psychic disorders find a congenial soil. Fürstner then gives the case of a woman, hereditarily predisposed, who had nervous symptoms, who was very excitable, and suffered from defective circulation, lesions of menstruation, bleeding from the nose, etc. She was married at eighteen, and though suffering from two severe attacks of bodily disease, yet had no psychosis; but the first pregnancy brought on melancholia (a cysticercus was found, after death, in the second left frontal convolution).

Marcé thought that multiparous women were most disposed to psychoses; but in Fürstner's cases, eighteen were primiparous and sixteen multiparous. Although writers have given etiological importance to such causes as anxiety, shame, etc., yet Fürstner thinks that these have been overrated, for the mothers of illegitimate children have not been especially affected. Difficult labour does not seem to predispose. It has been the custom to blame 'milk fever' as the setter-up of psychic lesion; but whilst this fever generally comes on the third or fourth day, psychoses mostly appear on the seventh or eighth day after delivery. Mastitis, parametritis, and endometritis are much oftener seen. In one case the mania began with a 'parotitis' on the seventh day. On the other side he has seen in two persons already melancholy a steady elevation of temperature, signalling in one diphtheria, in the other pleurisy, without any influence on the psychosis.

Insanity following on eclampsia is rare; he gives, however, one instance of it.

Melancholia seems the most prominent form of disease, and its preponderance in these cases has not a little influenced statistics. A large number of these melancholics are kept at home by their friends, provided they are not suicidal and do not refuse food; but an acutely maniacal woman is put away at once.

* Fürstner, Dr. C., *Archiv für Psychiatrie*, Band v. Heft 2; Savage, Dr. G. H., *Guy's Hospital Reports*.

This holds more especially of the light forms of melancholia coming on during the first three or four months of pregnancy, which is favourable and rapid in its course, and disappears as pregnancy advances. The more serious cases that occur during the late months are melancholic as a rule. Many hope that the labour will end this melancholia; but they are in most cases deceived, for they lie quietly in bed, and very often they deny that they have been confined. This indifference to the difficulty of parturition is shown not only in melancholia, but in other nervous disorders, and contrasts markedly with the transitory maniacal condition that is seen in healthy women during difficult labour. A psychosis arising during the period of pregnancy does not directly affect the life of the offspring, though of course it is unfavourable to the later life of the child. The labour itself never influences favourably the psychosis, but rather in many instances augments it. The prognosis of these psychoses that occur in the last months of pregnancy is bad, and although as regards chance of cure these cases are far behind mania, yet by their consequences, chiefly from the want of nutrition, they endanger life.

The psychoses of the actual puerperal period are much different in form from those of pregnancy; this period may be said to extend over the six weeks after confinement. It would now seem that there are two sets of causes for the origin of a psychosis at this time; the first acting during the first twelve days after parturition, viz., loss of blood, lactation, mastitis, inflammation of the uterus and its appendages; the second acting during the remaining period of six weeks through the re-establishment of menstruation; and it is curious that the occurring of insanity is seen either in the first ten or twelve days or at the fourth or sixth week, the intermediate period being free. Among these are included a number of lying-in women who are only in a wider sense insane, *i.e.*, those with fever-delirium. The differential diagnosis here is not easy, for the delirium is neither characteristic nor specific; and moreover, a lying-in woman with endometritis or parametritis, or ulcerative endocarditis (Westphal) may have just the same form of delirium; the best way of diagnosing being the length of duration or a simultaneous accession or retrogression of the delirium with the exacerbations of the fever.

From his observations of the insanity of the actual puerperal period, Fürstner draws the conclusion that there is no specific characteristic, but that the prognosis is exceptionally good. He gives, however, three cases in which the symptoms were different in their origin and course from the ordinary mania. The variety in these is divisible into three stages, viz., an initial fury, a subsequent state of stupidity, and at last convalescence. The acute setting in of the first symptoms, going on rapidly to incoherence and great motor excitement, would appear to be the characteristics of the first stage, and have their origin in hallucinations of a terrifying nature, which disappear as suddenly in the first days of the disease. When in the 'stupid' stage, the patients would sit with folded hands, and were cataleptic, though sensible to pain. Feeding was rarely required, and the habits were cleanly, whilst at times sudden impulses to smash glass, throw away food, tear clothes, etc., would arise. The transition to convalescence may come either suddenly or gradually. Exceptions now and then arise (cases quoted) where the insanity, which lasts for six or eight weeks, consists of a protracted hallucinatory condition. In the sudden

upspringing of the symptoms, and the great part that hallucinations play in acting as basis for all the phenomena, the condition resembles that of epileptics; and he gives an instance of an epileptic, who up to the time of her pregnancy had had only a few fits, but in whom insanity of the hallucinatory form was developed by the puerperal state. The psychoses coming on during lactation, *i.e.* more than six weeks after confinement, are in no way specific. Such, too, is Marcé's experience.

In the current number of *Guy's Hospital Reports*, Dr. Savage makes some 'observations on the insanity of pregnancy and childbirth,' which, without professing to contain much that is new, are yet very interesting, lucid, and evidently the result of considerable labour. Dr. Savage thinks it a mistake to suppose that marriage is a cure for hysteria, and he draws attention to the 'unnatural longings' of pregnancy which most physicians are too apt to consider neuroses, though many of them should not be so regarded. It is a pity that Dr. Savage does not enter more into detail here, for we are much in need of definite ideas as to these longings, and it would be satisfactory to know what might be truly considered insane states, since he quotes cases where 'unnatural longings in the mother have reappeared as mania and melancholia in the children.' He thinks that illicit pregnancy is a special cause of insanity, in this particular being directly opposed to Fürstner. In most other points these two authors seem to agree; and it is noteworthy how Savage corroborates the presence of hallucinations, though he does not elevate them to so high a place in the causation of the conduct and habits as Fürstner does. Another coincidence in these writers is the noticing of the febrile condition called 'milk-fever,' which must not be confounded with the insanity of the puerperal state. The history that follows of the predisposing and exciting causes is good, and special distinction is made between causes of anæmia, such as flooding, leucorrhœa, and lactation, and causes of exhaustion, such as protracted labour and the shock of instrumental delivery. His experience coincides with that of Marcé, that moral causes have little causative power. Some very sensible remarks are made on the marriage of cured patients, a thing to be especially avoided if any hereditary taint exist.

In acute puerperal mania the suddenness of the on-coming of the symptoms is noted, as well as the fact that the temporary madness, which at times appears and 'exhausts itself in the impulsive commission of the crime' (murder of the child), should be, as it is, dealt with mercifully in a court of justice. There are many interesting points which can only be named here; such are, the description of the dementia which is seen in all grades of development, the combination of the states of mania and melancholia, the question of albuminuria, pulse-tracings, etc. Both essays are excellent, and require, as they deserve, attentive reading.

T. C. SHAW, M.D.

FAYRER ON ELEPHANTIASIS ARABUM.

Dr. Fayrer, C.S.I., contributes an article on this subject to the *Practitioner* for June. He describes it as a non-contagious disease, endemic in certain localities, generally intertropical, and near the sea-coast; characterised by recurrence of febrile paroxysms, attended by inflammation and hypertrophy of the integument and areolar tissue, chiefly

of the extremities and genital organs, and occasionally by swelling of the lymphatic glands and enlargement and dilatation of the lymphatics, with chyluria; the hypertrophy of the integument being accompanied by an albuminous deposit in the cells of the areolar tissue, and by degenerations in the muscles and bones.

It is totally distinct from elephantiasis Græcorum.

It would appear from the researches of Mr. T. Lewis, that elephantiasis Arabum is associated with the presence of hæmatozoa in the blood.

The ordinary condition of elephantoid hypertrophy of the limbs or genital organs no doubt frequently exists independently of chyluria, of the presence of hæmatozoa, or of any obvious change in the state of the lymphatics; but their frequent concurrence, and the difficulty of detecting the parasites in many cases where they probably do exist, seem to indicate that further minute investigation of the subject may reveal a common origin, due to the influence of tropical and malarious climates, and throw light on its relation to them.

Elephantiasis Arabum affects both sexes, and persons of all ages and conditions of life. No race is exempt, but it is much more frequent, relatively, in the dark than in the fair races, and in men than in women. It occurs at all ages, is rare in the young and old, and is most common between twenty and forty. It commonly occurs without disturbance of the general health; at other times it is accompanied by febrile attacks, and with pain and exhaustion. Sometimes, however, the growth ceases after considerable bulk has been reached. In some cases fluid exudes from the surface, while in others it is dry. The rate of growth varies much. It would appear that the disease has little influence in shortening the duration of life. It does not interfere with the procreative powers except mechanically, and after the removal of the tumour no impotence remains. Women, however, are apt to miscarry when suffering from elephantiasis.

Various causes are assigned for the disease in the regions where it prevails. Air, water, food, and (as it is frequent near the sea-coast) eating fish, have been frequently credited with it. The presence or vicinity of certain forms of vegetation, the geological formation of the soil, have each and all been regarded as predisposing and determining causes, but not with sufficient reason. Climate and locality, combined with bad living, are doubtless the real predisposing causes; and it is probable that, as Mr. T. Lewis has suggested, like other unhealthy conditions observed among persons residing in tropical climates, especially those implying disturbance of the lymphatic system, it may be found to be intimately associated with the presence in the blood of certain parasites.

Dr. A. Webb thought the disease had a syphilitic origin.

No race is exempt from the disease, but white races suffer less than dark races. Waring says that the lower animals are not entirely free from it; not even excepting birds.

The hypertrophy commences in an increase in the normal elements of the part.

The treatment of elephantiasis is both medical and surgical. But little impression has as yet been made by constitutional treatment. Remedies, though useful during the febrile paroxysms, in moderating their severity and the excess of local action, have

little power in preventing recurrence or in checking the onward progress of the disease.

Preparations of iodine, in combination with quinine, arsenic, and iron, have all been found useful to a certain extent. During the febrile state salines, diaphoretics, and such remedies as are needed during the pyrexial state of malarious fevers, are indicated. The internal use of opium in some form may be necessary to relieve the intense pain which often accompanies the onset of the stage of excitement, when the suffering in the spermatic cords, testes, and generally in the lumbar regions, is sometimes so intense, combined with the depression caused by nausea and retching, as almost to prostrate the patient from exhaustion.

The local application of iodine or some of its preparations, by inunction or otherwise, of such forms as the iodide of lead or the biniodide of mercury, have been thought to be useful; but as they are generally applied in conjunction with pressure when the patient is kept in a recumbent posture, the benefit is probably quite as much, if not more, due to the mechanical action of posture and pressure, as to drugs.

A due combination of local and constitutional remedies, with rest, improved diet, and changed, *i.e.*, improved, hygienic conditions, may, and no doubt do, materially control the progress of the disease and relieve suffering. No remedy, however, is so potent as change of climate, by removal from the endemic site of the disease. This, if effected in the earliest stages, may completely arrest the disease, and perhaps, but this is doubtful, even disperse any incipient structural change that may have occurred.

This has occasionally been observed in the rare cases in which it happens in Europeans, that, returning to Europe, they have after a time lost the disease, and almost, if not entirely, any hypertrophic changes that may have occurred. Natives of India improve, and the disease often ceases to progress, if they leave the endemic area during the early stages and go and reside in other and drier localities.

Surgical treatment is often necessary, and not only removes the growth, but relieves the constitutional symptoms found to accompany it. The removal is effected by incisions along the cords and the dorsum penis. No attempt should be made to preserve flaps of integument, either for the penis or testis. It is unnecessary, and almost certain to be followed by recurrence of the disease. The healing process occupies from two to four months, but when complete is very satisfactory.

It has been suggested that elephantiasis of the limbs may be treated by ligature of the main artery. It is difficult to understand on what physiological principle this mere temporary starvation of the limb should have any efficacy in permanently removing the local expression of a constitutional disease. That it might temporarily ameliorate it, there is no reason to doubt, but the same effect could be produced by pressure on the limb or its artery, or by continuance in the recumbent posture; and such, indeed, has been the result of experience in certain cases in India. Ligature of the femoral artery, which was necessarily accompanied by protracted rest in bed, the application of bandages, and the general diminution in size that would follow such an ordeal, was followed by a considerable reduction in the size of the leg. The improvement, however, was temporary, and the disease returned to its original dimensions on the patients resuming the usual mode of life.

There is probably not sufficient reason on any sound physiological principle for expecting permanent improvement in the case of true elephantiasis by merely temporarily arresting the flow, and subsequently altering its channel of distribution in the limb through the anastomotic circulation, to warrant the performance of so serious an operation as ligature of the main artery; and, as has been stated, the results of ligature of the femoral artery for elephantiasis of the leg failed in Calcutta to produce any permanently good result. It is not supported or confirmed by experiment.

J. MILNER FOTHERGILL, M.D.

ANATOMY AND PHYSIOLOGY.

KEEN ON EXPERIMENTS ON THE LARYNGEAL NERVES AND MUSCLES OF RESPIRATION, ETC., ON A CRIMINAL EXECUTED BY HANGING.—Dr. W. W. Keen read to the College of Physicians of Philadelphia (February 3, 1875), an account of these experiments (*Philadelphia Medical Times*, March 20).

Dr. George Johnson had expressed the belief that, while pressure on one recurrent nerve will cause direct unilateral palsy of the larynx, but not bilateral spasm or palsy, pressure on the vagus involving its afferent fibres may cause both. The reason of this he supposed to be that the nerve-nuclei of both sides are so connected that each possesses bilateral activity. Dr. Mitchell having suggested the probability of a chiasma of the minuter fibres of the recurrents in man, which, though not demonstrated anatomically, might be proved physiologically, the following experiments were undertaken upon a criminal recently executed by hanging. After hanging about half an hour, the body of the criminal was cut down, and immediately examined. The left vagus and recurrent laryngeal were dissected as low down as possible in the neck, and the vocal cords examined while the nerves were excited by electricity. Repeated faradisation with weak and strong currents, and galvanisation with from four cells up to forty, of the recurrent and also of the vagus nerves, produced decided movements of the left cord only, and none of the right. The wires were applied directly to each nerve, and the irritating action of a tumour simulated as nearly as possible. Careful dissection showed that in all probability none of the fibres of the vagus were injured. The definite conclusion to be drawn from the experiment is, that no chiasma of the inferior laryngeal nerves exists. No reflex motion was observed in the larynx, although the absence of this may have been due to violence done the parts by hanging.

Experiments upon the muscles of respiration were then undertaken. The left phrenic nerve, having been insulated, was excited as in the previous experiments, but without result; no movements whatever of the chest were produced, nor was greater success obtained by one wire applied to the nerve while the border of the diaphragm was followed with a sponge, nor when both sponges were applied to the diaphragm.

The intercostals were then examined. These having been exposed from the median line to the line of the axilla, the interrupted current was applied to the intercartilaginous portion of the internal intercostals by means of small sponges, when it was found that

they all raised the cartilage below them. The external intercostals were then faradised, when the upper rib was pulled down very markedly, while the lower one was just perceptibly raised; the movement increased from the first to the seventh, the last four not being examined. These experiments seemed to point to the conclusion that the internal intercostals are inspirators, and the external expirators.

The muscles of the face still retained their electro-muscular contractility; but one was examined carefully, the pyramidalis nasi, which appeared, as a result of the electrical excitation, to act as the direct antagonistic of the central portion of the occipitofrontal. Dr. Keen pointed out, in conclusion, the important results which this new method of investigation—the faradisation of the muscles on the recently dead—promises to yield.

TARCHANOFF AND SWAEN ON THE WHITE CORPUSCLES OF THE BLOOD OF THE SPLEEN.—The spleen is, as is well known, regarded as a former of white blood-corpuscles, and the splenic venous blood is generally admitted to contain a disproportionately large number of white blood-corpuscles. J. Tarchanoff and A. Swaen (*Archives de Physiologie*, July, 1875) were led to test the accuracy of this statement. Their experiments were made upon dogs and rabbits, which had had no food for sixteen or eighteen hours previous. The method adopted for counting the blood-corpuscles was that of Malassez. They found that in the dog, under conditions as normal as possible, there is never such an enormous quantity of white blood-corpuscles in the venous blood of the spleen as is usually attributed to it. Dilatation of the spleen (such as is produced by section of its nerves) is immediately followed by a diminution of the number of white corpuscles in the splenic veins.

Immediately after section of the nerves there is a considerable diminution of the number of white blood-corpuscles in the splenic veins, but the longer the time after section of the nerves, the more pronounced is the diminution of their number. This diminution of the white blood-corpuscles in the total mass of the blood can only be accounted for by a mechanical accumulation of the corpuscles in the splenic pulp, by their destruction in the interior of the spleen, or by their transformation into red corpuscles. The experiments were made in Cl. Bernard's laboratory.

TARCHANOFF ON THE CANALS WHICH ARE SUPPOSED TO CONNECT THE BLOOD-VESSELS WITH THE LYMPHATICS.—J. Tarchanoff (*Archives de Physiologie*, July, 1875) reviews the opinions of Kölliker, Virchow, von Recklinghausen, and specially of Arnold upon the direct communication of the blood with the lymphatic vessels. He has injected the blood-vessels and lymphatics of the web of the frog's foot with Prussian blue solution, either alone or mixed with gelatine. Even after ligature of the veins of the limbs, followed as it is by œdema, the author's uniform result was that the injected mass was never found outside the walls of the vessels, unless there had been rupture of the walls of the vessels, when the mass spread itself between the interstices of the connective tissue outside. As to the injection of the corpuscles of the connective tissue by such a method, the author believes that such a view is quite untenable. He utterly denies

the existence of a set of canals connecting the blood-vascular and lymphatic systems.

TSCHIRIEW ON THE DIFFERENCE BETWEEN THE GASES OF THE BLOOD AND LYMPH OF ASPHYXIATED ANIMALS.—S. Tschiriew (*Sächs. Acad. Sitz.-Ber.*, 1874, 116; *Centralblatt*, no. 21, 1875), under Ludwig's direction, investigated the above subject. The arrangement of the experiment was the following. Cannulæ were introduced into the left thoracic duct, and into one of the carotids (dog); the trachea was exposed, and closed by means of a screw-clamp. As soon as the asphyxia had progressed so far that the eye did not react to touch, several portions of blood were, by means of forked cannulæ, caught in vessels over mercury; two of these were used to obtain lymph, and one was used for shaking to obtain blood. Now the lymph was collected, and the secretion hastened by bending and extending the limbs. It took twenty to thirty minutes to obtain sixty to eighty cubic centimetres of lymph. The percentage composition of oxygen from the gases obtained was always minimal, and the quantity of nitrogen also does not here come into count. The quantity of carbonic acid in the lymph was always lower than that of the blood as a whole, and pronouncedly lower than that of the serum. Compared with the values fixed by Hammersten for the lymph of the respiring animal, the quantity of carbonic acid in the asphyxia-lymph is only unimportantly higher than that of the normal, whilst the quantity in the serum appears to be pronouncedly higher. Remembering that the lymph arises from the confluence of the juices of the tissues, and thus is saturated with carbonic acid, one must conclude that a part of the carbonic acid arises even in the blood-vessels themselves by decompositions in the blood-corpuscles, lymph-corpuscles, or endothelium. If the carbonic acid arising in the tissues can reach the blood only by the way of the slowly moving lymph, then, in opposition to the accepted views, the quantity formed in the tissues would only be small compared with what is formed in the blood itself. This assumption would be rendered more probable, if it were possible to find in the lymph a substance which in connection with blood-corpuscles would be oxydised and produce carbonic acid. This proof was sought for in vain by Hammersten, who employed the lymph of the normally respiring animal. The author repeated the same experiment with asphyxia-lymph, and did not succeed.

PFLÜGER ON SLEEP.—Our existing knowledge about the physiology of sleep does not go much beyond the fact that the phenomenon in question is invariably associated with a comparatively bloodless condition of the brain. Pflüger attempts to take us a step farther by constructing an elaborate hypothesis of a physico-chemical order (*Pflüger's Archiv* x. 8, 9). Starting from the view that the functional activity of any organ, and more especially of a nerve-centre, depends upon a dissociation of living matter, which is itself only a modified form of albumin, the author goes on to speculate that the chemical potential energy which is used up in the formation of every molecule of carbonic acid is transformed into heat. In other words, the atoms of which this molecule consists are thrown into a state of very active vibration. These intramolecular explosions are propagated in all directions along the nerves to the muscular and glandular systems, which are in structural continuity with the nerve-centres. Frogs,

deprived of oxygen, are thrown into a state of apparent death, precisely similar to sleep; from this they may be roused by a fresh supply of oxygenated blood. A certain proportion of intramolecular oxygen in the nerve-centres is thus essential to the waking state, since it enables a given number of explosions to occur in an unit of time at a given temperature. But, during the waking state, the energy of chemical affinity is used up much faster than the intramolecular oxygen of the grey matter of the brain can be replaced; consequently the formation of carbonic acid steadily diminishes; and when the number of explosions per unit of time sinks below a certain minimum, sleep ensues. The entire energy of the brain is never really used up; but it sinks to a point at which, in the absence of all external stimuli, it is incapable of maintaining functional activity. This theory may be so developed as to explain most of the phenomena of ordinary sleep, such as its periodicity, etc. The author likewise attempts to bring the winter sleep of hibernating mammals, and the summer sleep of tropical amphibia, into harmony with it.

RÖHRIG ON THE COMPOSITION AND FATE OF FATS INTRODUCED INTO THE BLOOD.—A. Röhrig (*Sächs. Acad. Sitz.-Ber.*, 1874, and *Centralblatt*, no. 26, 1875) remarks that the statement in the ordinary text-books, that the blood contains soaps, must appear surprising considering the quantity of potash-salts present. In fact, even blood-serum, treated with soap solution, yields a precipitate of chalk-soap, which gradually becomes crystallised. Blood-serum, therefore, does not contain any soaps. The direct test yielded the author only negative results.

In order to estimate the fats in the blood-serum, it was shaken with several times its own volume of alcohol, and then completely extracted with alcohol and ether. The residue which remained after evaporating the ether, consisting of the fats, cholesterol, and lecithin, was then weighed, and the cholesterol and lecithin estimated according to the usual methods. The blood was at once treated with its own volume of water and two cubic centimetres of a 1 per cent. solution of oxalic acid to prevent coagulation, and then the above process was repeated. Double estimation of this description gave good coinciding results.

By this method it was then tested how rapidly fat, when once introduced into the blood, disappeared from it again. For this purpose an emulsion, formed by shaking together oil and water, to which a little carbonate of soda had been added, was employed. This emulsion was injected into an artery towards the periphery. The injection was made by mercurial pressure. The blood was investigated before the injection, immediately after it (from the central end of the artery), and some time later. In one experiment the blood contained immediately before the injection, 0.504 per cent.; immediately after, 0.668 per cent.; and thirty minutes later, 0.636 per cent. The increase was obvious, but small. In the following experiments the time of injection, which in the first injection reached sixty-five minutes, was diminished. The differences became larger, but were not very important. The difficulty of the experiment led the author to adopt another method. After the dogs had fasted, they obtained a large quantity of hog's lard. Four hours after feeding, the

thoracic duct, the subclavian vein, and the lymphatic ducts of the chest and neck, on both sides, were carefully ligatured. In all cases the quantity of fat rose after the feeding, and after closure of the thoracic duct again fell. The cholesterin showed a tolerably constant value. In one experiment there was formed :

	Fat.	Cholesterin.
Shortly before feeding . . .	0.74	0.11
Immediately after ligature . . .	1.24	0.21
Three hours . . .	0.89	0.19
Eight and a half . . .	0.52	0.18
Twenty-two . . .	0.50	0.19

The cholesterin, without doubt, arises from the bile which is richly poured out with the feeding. After several days' fasting, the fat in the blood is 0.5 or 0.7 per cent., and after feeding with fat may rise to 1.25 per cent. The quantity of fat falls after ligature of the ductus thoracicus; at first rapidly, then slowly. The fats probably do not leave the blood without undergoing a change. Supporting this is the fact of the constancy of the quantity of cholesterine, and further that the lymphatics of the corresponding extremity do not contain any fat. Röhrig thinks it is probable that the fats are oxydised in the blood with the formation of carbonic acid.

W. STIRLING, D.Sc., M.D.

SAMELSOHN ON THE PHYSIOLOGICAL AND THERAPEUTIC ACTION OF NITRITE OF AMYL.—The author (*Berliner Klinische Wochenschrift*, June 14, 1875) protests against the prevailing idea that our knowledge of the physiological action of amyl-nitrite is sufficiently complete to serve as a basis for its remedial use. We are still ignorant of the precise mode in which it occasions dilatation of the small arteries. On the one hand, Brunton, Pick, and Schüller agree in believing that its action is peripheral, on the strength of the ascertained fact that its inhalation causes a fall of blood-pressure, even after the influence of the vaso-motor centre has been cut off by dividing the spinal cord in the neck. On the other hand, Bernheim finds that the arterioles, when dilated by the nitrite, may be made to contract by electric stimulation of the corresponding vaso-motor trunks; from which he infers that the action of the nitrite is primarily central. Pick contests the validity of this inference, arguing very justly that the excitant influence of electricity may be able to overpower the paralysing effect of the nitrite. Filehne, however, believes himself to have established Bernheim's conclusion on an unassailable basis. One of his experiments consists in laying bare a rabbit's lung, and then causing the animal to inhale the vapour; the pulmonary arterioles, which are the first to be exposed to the direct influence of the nitrite, do not dilate before the systemic ones. Another experiment was carried out as follows. The cervical sympathetic was divided on one side in a rabbit; its peripheral extremity was then stimulated by a current just strong enough to maintain the paralysed vessels in a state of contraction exactly equivalent to that of the normal vessels on the opposite side. The nitrite vapour was then administered; and it was found that the arterioles underwent dilatation on the sound side only, showing that the vaso-motor nerves and the muscular walls of the minute arteries were not directly influenced. Further experiments were made to prove that the nitrite does not cause vascular dilatation by stimulating the depressor nerve. Hence Filehne concludes that the drug causes paralysis of certain vaso-motor centres

similar to, or identical with, those which preside over the act of blushing.

Granting that these experiments are correct, Samelsohn disputes the conclusion drawn from them. We do not know, he says, what becomes of the nitrite in the blood; its specific effects may possibly be indirect, and due to some product of its decomposition. Should this be so, the experiment on the rabbit's lung would only indicate that the decomposition of the nitrite had not had time to occur before its entrance into the pulmonary capillaries. The *experimentum crucis* on the cervical sympathetic is also open to question. We have no proof that the electrical stimulation of the nerve is identical, either in kind or in degree, with the influence normally conveyed to it from its proper centre.

We cannot, therefore, be said to understand the exact mechanism of the vascular dilatation caused by amyl-nitrite, and we are equally ignorant of its extent and distribution. Our ignorance on these points should make us cautious. Observers have hitherto been at one on the absence of danger from the vapour. To this reassuring unanimity there is one exception. (*See LONDON MEDICAL RECORD*, March 17, 1875, p. 168.)

Sander has recorded cases in which sudden collapse followed closely upon its administration. Samelsohn furnishes a detailed account of a similar instance. The patient, a somewhat anæmic young woman, suffering from symmetrical blepharospasmus, was being exhibited before the Medical Society of Cologne. It was suggested that the effect of nitrite of amyl upon the spasmodic closure of the eyelids should be tested. A narrow-necked phial, containing about fifteen grammes (225 grains), was held under one nostril, and the patient directed to take several deep inspirations. As soon as the usual change in the pulse occurred, the phial was withdrawn. The face, previously pale, was now suffused with a crimson flush, and the eyes opened widely. In an instant, however, the flush was replaced by a deadly pallor; the pulse became thread-like and slow, the skin cold and clammy, respiration difficult and gasping; consciousness was retained. These alarming symptoms passed off, but only to recur again and again; a full hour elapsed before the patient could be said to be out of danger. Even after the pulse and breathing had become normal, she still complained of feeling very cold; and this sensation lasted till the next day. The blepharospasmus disappeared for thirty-six hours, at the end of which time it returned. To what ought these symptoms to be attributed? The sample of the drug was perfectly pure, and was repeatedly inhaled by other patients without producing any unusual effect. The dose was measured by its effect upon the pulse, and there was no reason to suspect that it was excessive. Sander ascribed the collapse which occurred in some of his cases to a contraction of the vessels of the pia mater, immediately consequent upon their undue dilatation, and causing cerebral anæmia. But on this hypothesis convulsive symptoms might have been expected to occur, and none such were noticed. Samelsohn prefers to explain the phenomena otherwise. As a general rule, the vascular tension is quickly restored after its depression by amyl-nitrite. In anæmic persons, however, we may suppose that the muscular walls of the vessels react less promptly, and that the elasticity of the arterial coats is impaired. Now it is well known that a sudden accumulation of blood in any part of the vascular area diminishes the supply

of that fluid to the heart, placing it in the position of a pump with too little water to fill it, and thus embarrassing its action. Moreover, the girl was menstruating at the time, and her pelvic viscera were loaded with blood. That this was one of the factors concerned is rendered likely by the circumstance, that she subsequently inhaled the nitrite vapour more than once without any return of the symptoms which caused so much alarm on the first occasion.

E. BUCHANAN BAXTER, M.D.

DE SINÉTY ON THE MAMMÆ OF NEW-BORN INFANTS.—De Sinéty (*Journal de Physiologie*, July, 1875) confirms the well-known fact that the mammæ of new-born children of both sexes, specially at the third and fourth day after birth, secrete milk. The author finds that the milk which is obtained from the mammæ of new-born children, several days after birth, is the result of a true secretion, and that the anatomical and physiological state of the mammary gland corresponding to that period is in many respects comparable to that which is to be observed during lactation in the adult female.

WM. STIRLING, D.Sc., M.D.

PATHOLOGY.

JEWELL ON THE PATHOLOGY OF EPILEPSY.—Dr. Jewell, in a lecture on the above subject (*Chicago Journal of Nervous and Mental Disease*, January, 1875), discusses, and endeavours to explain, the two characteristic classes of phenomena, namely, the loss of consciousness and the convulsive disorder.

1. The loss of consciousness.—How is it brought about? So far as we know, it is due to a sudden change in the quantity of blood in the brain. Is it, Dr. Jewell asks, on account of too much or too little blood in the brain that consciousness is temporarily lost? It may be either; but he believes that in the majority of cases it is due to the latter—sudden anæmia. The question then arises, How is this anæmia produced? It is not caused by the failure of the heart's action, as in syncope, for the heart continues to beat perfectly. The blood is sent freely toward the brain, but in some way is prevented entering it in due quantity. In what way? By a sudden contraction of the small arteries of the brain. Then, again, What is the cause of this contraction? The answer is, An irritative influence conveyed to them through the channel of the vaso-motor nerves; this sudden influence coming from the vaso-motor centre for the head, which Dr. Jewell places in the cervical portion of the spinal cord, or in the medulla oblongata. Dr. Jewell further, however, raises the question, What causes this centre to emit such a sudden tide of nervous influence? And this he traces to an impression conveyed from some more or less distant quarter, and hence holds that its action is reflex, either from the peripheral nervous system below, or from the brain above.

Although the sudden loss of consciousness is attributable in the first place to sudden anæmia of the brain, it does not explain the same condition in the later stages of severe cases. In the severer, the respiration is embarrassed by spasm of the muscles of the chest, hence the lividity of the surface from carbonisation of the blood. The effect of the carbonic acid in the blood, Dr. Jewell states, 'is probably twofold: first, to stimulate powerfully, in a

reflex way, the resumption of action on the part of the respiratory muscles; and, second, to benumb, by a kind of anæsthetic action, the excitability of the nervous system.' This benumbing effect perpetuates the loss of consciousness, which in the first instance depended on sudden anæmia of the brain. The continuance of the loss of consciousness is in part due to the now enlarged state of the vessels in the brain. The muscular vessels have temporarily lost their tonus, and are as much larger than they ought to be as they were before too small. After a variable time the vessels recover their tonus, and consciousness slowly returns.

With reference to the convulsions of epilepsy, Dr. Jewell contests the views lately put forward and forcibly expounded by Dr. Hughlings Jackson. Dr. Jewell, in the first place, dwells upon a point that is scarcely disputed, viz., that the respiratory muscles, or those innervated from the medulla, are involved in epilepsy; and further, that the medulla oblongata is the chief seat of the disease, the true *nodus epilepticus*, as he designates this part of the nervous centres, under morbid conditions.

The convulsive action of the motor centres may depend on one or both of two conditions; either it may depend upon some structural peculiarity which shall render it more liable to such action, or it may depend upon some extraneous, perhaps remote influence, exerted upon them. The morbid excitability inherited with structural peculiarity, Dr. Jewell proceeds to show, may be brought into operation by variations in the supply of blood, and by the abolition of the inhibitory power of the brain over the medulla and cord. Furthermore, some special excitant to action on the part of the motor centres is required; and this excitant can be none other than a nervous impression or influence conveyed into them from some other part of the nervous system, either the spinal cord, or the spinal or cranial nerves, or from the brain above.

With reference to the morbid impression from the brain, Dr. Jewell writes as follows. 'In this case the irritation is supposed to be located in some part of the brain, either in the great ganglia at the base of the brain, or, as is probable, in the cortex of the same. It is only in recent times that this view has received much attention. Of all other observers, Dr. Hughlings Jackson, of London, has done more than any one, perhaps, to invite attention to the brain as concerned in epilepsy. He supposes, for example, that the cortex of the brain in epilepsy is often the seat of limited disease, which is of such a nature that the affected part of the brain, more or less, gradually stores up nervous force, which at a certain time is discharged—if you please, as a Leyden jar is discharged—downward on the motor centres of the medulla, perhaps in such a way, that by reflex action not only the convulsive but the vaso-motor disorders are produced. Such lesions of the cerebral cortex he would call "discharging lesions." For my own part, I do not doubt that the brain may be the seat of lesions, which in a reflex way produce epileptic seizures; yet I do doubt the truth of Dr. Jackson's hypothetical explanation of the morbid process in the cortex. Such lesions of the cortex, if they exist, would require a gradual storing up of nerve-force in the diseased part, until its tension becomes so great that we have relief by a discharge leading from the cortex downwards to the motor ganglia at the base of the brain, or even to those in the medulla, in this way rousing them to action as we see in epilepsy.' Upon this

exposition of Dr. Jackson's hypothesis, Dr. Jewell thus comments.

'Have we any reason for thinking that such *discharging* lesions exist in the cortex of the brain? I think not. There is really no more evidence of it, so far as I can see, than there is of a discharging lesion in the medulla, or in the spinal cord, or in a diseased part of a spinal nerve, from which the aura appears to start. It seems to me no more difficult to understand how one kind of source of irritation should act occasionally or irregularly than another. And certainly Dr. Jackson does not appear to think of discharging lesions for the spinal cord and peripheral spinal nerves, which are often the sources of the irritative action that constitutes apparently the first step in a typical attack of epilepsy.'

'For my own part, it seems to me far more probable that the cause of the discharge from the lesion of the cortex is due to a sudden vaso-motor disturbance in it, rather than a gradual storing up of nerve force, until finally the tension becomes so great as to lead to a discharge on the motor centres below, either with or without provocation.' This would make the final discharge to depend upon a sudden modification in the blood supply of the diseased part—through the agency of the vaso-motor nervous system. To the preceding argument Dr. Jewell adds the following question, 'Why does the vaso-motor system act on the vessels of such parts in an intermitting way?' The reply that he feels constrained to give is, 'I cannot answer this question, and I do not know that we should seriously try to answer it, until we are more sure that it is a legitimate question.' The views above cited Dr. Jewell believes to be in accord with the results of treatment and of experiment, and to be supported by pathology.

[Our readers will find Dr. Jackson's theory of the nature of convulsive action clearly set forth in a paper entitled 'A Study of Convulsions' in the *Transactions of the St. Andrew's Medical Graduates' Association*, 1870. To this paper we may add many other articles on this and allied subjects in other medical journals.—*Rep.*]

W. B. KESTIVEN, M.D.

MAJOR ON THE HISTOLOGY OF THE SANE BRAIN.

Dr. Major, of the West Riding Asylum (*Journal of Mental Science*, July, 1875), urges the necessity of examining the brains of persons dying sane as well as of the insane, and narrates the examination of the brain of a man, aged forty-seven, who died from the effects of a compound fracture of the leg nine days after the accident. He was previously a perfectly healthy and intelligent man. The brain presented no features of abnormality. There was no wasting of the convolutions, no thickening of membranes, and no appearance of vascular disease. Nevertheless, on submitting thin sections to the microscope, the fact was established beyond a doubt that in many instances the pyramidal nerve-cells of the cortex were morbidly affected. In the majority, indeed, no change could be detected, but in a considerable proportion it was quite distinct and conclusive. The abnormality consisted in the accumulation of yellow granules in the interior of the affected cells, in no case going to the extent of producing destruction of the corpuscle, but at most a slight bulging and alteration in its form. The nuclei and nucleoli appeared to be unaffected. The condition above described could only be seen among the large pyramidal cells of the deeper layers of the grey

matter, and not in the smaller superficial bodies; and, lastly, at the posterior extremity of the occipital lobe the nerve-cells, with rare exceptions, presented no evidence of any morbid process. Dr. Major thinks that this case shows that some of the corpuscles of the cortex may be morbidly affected without any appreciable mental impairment, and that while to ordinary appearances the brain may seem quite healthy, the microscope may reveal commencing change. It affords additional evidence of the fact always maintained by the writer, that the nerve-cells of the occipital lobe are the last, as they are the least, affected by the atrophic process. And it impresses the necessity of the utmost caution in connecting histological changes in the brain after death with mental phenomena manifested during life.

G. FIELDING BLANDFORD, M.D.

VIRGILIO ON A CASE OF MICROCEPHALIA.—

Gaspari Virgilio describes, in the *Rivista Sperimentale di Freniatria e Medicina Legale*, 1875 (abstract in *Lo Sperimentale*, June), a case of microcephalia observed by him in an idiot in the asylum at Aversa. The subject was of low stature, and had a short neck, broad shoulders, a very small head, and long arms; he squinted, and there was defective co-ordination of movements. He preferred to climb like a monkey; he manifested neither affections, wishes, nor desires. He scarcely possessed the fundamental instincts. He did not speak; but emitted harsh acute cries. He died in consequence of a fracture of the thigh while climbing.

Dr. Virgilio remarks that the absence of speech, places this case in the most advanced class of idiocy. As in the lower animals, reflex images of the exterior of objects could be formed on the sensorial apparatus, and when these images excited his wants he was led to employ actions and movements which by no means expressed the idea which he might have. If this individual be placed at the level of the apes by the absolute want of articulate speech, by the defect of intellect and by many other characters, such as the mode of walking, the bending of the head forward, the length of the arms, the uniform curvature of the spine and the bending of the lower limbs at the knees, and by his habit of climbing, he ought to be placed in a still lower scale, as he did not present those mental manifestations which are common to all apes.

The face lay remarkably in front of the cranium, so that an imaginary plane dividing these two parts would be nearly perpendicular to the horizontal plane between the occipital condyles and the upper alveolar ridge. The skull was oxycephalic, terminating in a point at the vertex, the parietal protuberances being absent. The forehead was very narrow; there was a sudden contraction above the orbital apophyses. The coronal suture was very strongly marked internally, and the fronto-nasal suture passed 0.16 inch below the horizontal line joining the two orbital apophyses. The fronto-parietal suture ran parallel to the facial line. The roof of the orbit was extremely concave. The zygomata were very prominent, and the canine fossa were strongly marked. The face was eminently prognathous, the upper dental arch projecting far beyond the lower. The chin, however, was prominent. The lineæ temporales were raised so far upwards as to make the skull appear as if enveloped in the temporal muscles—a simial character. The temporo-parietal sutures were completely closed.

When placed on a flat surface, the skull rested on the last molars in front and on the condyles behind, like the skull of an ape. The posterior border of the occipital foramen was 0·27 inch above the plane. The foramen was situated entirely in the posterior third of the base of the skull.

In the interior, deep digitations were observed; all the sutures were distinct. In other respects the skull was symmetrical. The following were the principal measurements: horizontal circumference, 13·3 inches; antero-posterior curve, 8·6 inches; transverse curve (from one ear to the other), 7·5 inches; longitudinal diameter, 4·5 inches; maximum transverse diameter, 3·6 inches; vertical diameter, 3·8 inches.

From a table given by the author, it appears that this skull is one of the smallest known; in this respect it approaches the skull of the chimpanzee, the circumference of which is about 12·5 inches.

STEFANINI ON ELECTRICAL CHOREA.—Dr. Stefanini, of Pavia, describes in the *Annali Universali di Medicina*, no. 231, 1875, two cases of electrical chorea, which, in his opinion, support the idea expressed by Pignacca,¹ Hoertel, and Tommasi, that this form of disease arises from a lesion of the spinal cord, and consists externally in an inflammatory process, the last stage of which is softening; that is to say, that electrical chorea has a form of myelitis as its anatomical cause.

In Dr. Stefanini's first case, the patient was a robust young man, who was suddenly seized with rhythmic convulsive movements of the left shoulder. These movements gradually extended to the whole left side of the body, then to the tongue, the diaphragm, and the right lower limb, and were at last followed by paralysis and atrophy of the affected muscles. The temperature rose during the last days of the patient's life to 105° and 111° Fahr.; the urine, which was at first acid, became alkaline. Dr. Stefanini calls attention to these two phenomena as of great importance in the diagnosis of lesions of the medulla. The patient died after he had been three months in hospital. At the necropsy, there were found congestion of the pia mater of the spinal cord, and softening of the substance for a space of four-fifths of an inch in the vicinity of the cervical enlargement. Microscopic examination of the softened parts showed the presence of fat granules and globules, granular nerve-tubules, ganglionic cells with a rather obscure protoplasm, and turgid capillaries.

The other case differed from the preceding one in its shorter duration (three days), in the occurrence of general convulsive attacks with loss of consciousness, and in the presence from the commencement of muscular contraction extending to the whole left side of the body. The temperature rose to 106·25° Fahr. On *post mortem* examination there was found to be hyperæmia of the cerebral membranes and of the white substance of the brain and spinal cord, the latter having also an increased consistence.

HEDENIUS ON A CASE OF DISSECTING ANEURISM OF THE THORACIC AORTA.—P. Hedenius reports, in the *Upsala Läkareforenings Förhändl.*, Band ix. (abstract in *Nordiskt Medicinskt Arkiv*, vol. vii.), a case in which a dissecting aneurism was found in a woman aged seventy-eight, who died of cerebral hæmorrhage. It extended for about nine and a half inches from opposite the left subclavian

artery down to the celiac axis, and was about 0·8 inch wide, being somewhat smaller below. It was formed by a separation of the outer from the middle coat, was filled with a grey-brown firm laminated thrombus, and communicated with the lumen of the vessel by sharp-edged slits in the inner and middle coats both above and towards the middle. At the upper part the outer coat was perforated, and there was a little extravasation into the anterior mediastinum. At the lower part of the aneurism the outer layer of the muscular coat was separated from the inner, so that the outer coat had a lining of muscular tissue. The aneurism was partial, not engaging the whole circumference of the aorta, as occurred in a case formerly described by the author. There were extensive endarteritis deformans, and hypertrophy of the left chambers of the heart.

A. HENRY, M.D.

ROBERTSON ON HÆMATOMA AURIS.—Dr. Alexander Robertson, in the *Glasgow Medical Journal* for July, says that the condition known as hæmatoma auris, or bloody tumour of the ear, is one met with almost solely in asylum practice.

Hæmatoma auris consists of an effusion of blood from the perichondrium, the fibrous membrane that invests the cartilage of the ear. This effusion is dark and venous in its character, and continues long fluid. The swelling is usually first seen on the posterior part of the concha, rather above its centre, and thence extends inwards to the meatus, which it occasionally occludes; and outwards over the pinna sometimes, but not generally as far as the helix. The tumour so formed varies greatly in size in different cases, there being in some only a slight thickening of the concha, while in others the distension of the auricle is extreme, all the normal irregularities being entirely effaced. When thus severe it occasionally bursts, giving vent to a quantity of blood having the appearance described. It does not usually attain its full size till after several days' growth. The integument over it retains its natural colour in the first instance, but should inflammation set in, as in the more severe cases, particularly those that burst, it becomes red and has the ordinary aspect of an inflamed surface. In exceptional cases the inflammation is so high that suppuration takes place, and there may even be gangrene of considerable portions of cartilage. In many, probably in most cases, the cartilage involved in the tumour is somewhat softened, but in milder forms this is scarcely appreciable. Generally after two or three weeks it begins to subside slowly, but the pinna is never restored completely to its natural condition, as after many years it continues irregular and shrivelled in aspect.

It is not confined to any particular form of insanity. Thus it is found in mania, melancholia, and in dementia. Dr. Robertson does not remember having seen it in idiocy. Probably it is most frequently met with in the insanity associated with general paralysis.

After recording two cases Dr. Robertson goes on to say: A very simple explanation has been given of this remarkable condition by some writers, such as Dr. Wilks, but one which, if correct, would have left me no apology for occupying the time of the reader with this paper. It is that the hæmatoma is the result of violence either self-inflicted or by others. I am satisfied, however, that in most cases this is not the real cause. Certainly some instances have

been reported by physicians to asylums, in which it seemed to have been caused by an injury to the ear. But in some of these there may not improbably have been a constitutional disposition to this sanguineous effusion at the time of its appearance, so that the slight blow or fall to which it was ascribed was only a secondary and minor agent in its production. At all events, my own experience would lead me to this conclusion. In the course of a long connection with asylums, many cases of it have come under my observation. In not one of them have I been able, either by a careful examination of the patient or by inquiry of attendants or fellow-patients, to find indications of injury to the ear, though obviously where it occurred in acute mania it could not be shown absolutely that no hurt had been sustained by the patients, particularly at night when alone in their bedrooms.

How then are we to account for it? It is, I think, most probably due to functional disorder of the cervical sympathetic, associated with and perhaps resulting from the existing cerebral or cerebro-spinal disturbance. The grounds for this opinion are these. (1) It not unfrequently appears in both ears simultaneously, without any indication of either having been injured. (2) In a case of dementia in my own practice, some years since, I observed an effusion of blood under the conjunctiva of the eye on the same side as the tumour of the ear, both effusions having appeared at the same time; and neither ear nor eye showed the least mark of hurt having been sustained. In this case there was no general purpuric affection; nor in any case, so far as I have seen, can the disease be ascribed to that condition of the blood. And (3) a hæmatoma of each ear occurred in a case recorded in this paper, in which Graves's disease and the peculiar band described indicated very clearly that the vaso-motor system was disordered. No doubt there was an interval of several weeks between the latter symptom and the ear-affection, but the goitre still existed though the exophthalmos was in abeyance at the time. It may be urged, supposing the sympathetic in the neck to be affected, how does it happen that the other symptoms produced by a known lesion of that system are not generally present, such as redness of the side of the head, contraction of the pupil, etc.? To this it may be answered that in functional disturbance of the nervous system, whether sympathetic or cerebro-spinal, it is by no means unusual to find a single nerve, or even a single branch of a nerve, alone affected. And further, various considerations lead me to think that in most cases in which the ear-tumour is found there is hyperæmia—implying vaso-motor disorder in the pia mater cerebri and hemispherical ganglia—parts whose blood-vessels, like those of the auricle, derive their regulating nerves from the cervical sympathetic.

CAVAFY ON THE INJECTION OF PUTRID FLUIDS. In the present number of the *St. George's Hospital Reports* is a paper on this subject by Dr. J. Cavafy. The experiments were conducted upon amphibia, and consisted of the injection into the lymphatic system of frogs of blood and pus which had been allowed to putrefy until an enormous number of energetically moving bacteria were developed. The experiments of Greveler and Hüter were not thoroughly borne out by observations made on the frog. A number of experiments were made on the

toad, and the observations are summed up in the following conclusions.

1. The injection of putrid animal fluids in relatively small quantities into the lymphatic system of amphibia is followed by inflammation, which is not to be distinguished from inflammation produced in other ways, except by the fact that it supervenes more rapidly.

2. Large doses act as a direct poison to the nervous system, causing paralysis of the heart, with consequent general circulatory stasis.

3. The accumulation of colourless corpuscles and the formation of thrombi cannot be attributed to any local action exercised by bacteria on the walls of the blood-vessels, or on the protoplasm of the colourless corpuscles, but must be ascribed (*a*) to inflammation, (*b*) to paralysis of the circulatory centre, (*c*) to alteration of the normal condition of the walls of the vessels produced by dragging, or (*d*) to a varying combination of these causes.

J. MILNER FOTHERGILL, M.D.

MEDICINE.

PYE-SMITH ON ADDISON'S DISEASE.—In the *Guy's Hospital Gazette*, June 26, Dr. Pye-Smith makes the following comments on a case of Addison's disease.

This is a typical case of Addison's disease, without phthisis, or other tubercular disease, or caries of the spine, its most frequent complications.

The constitutional symptoms were but little marked, though feebleness of the heart's action, muscular weakness, slight nausea, and occasional vomiting, with headache and pains in the back, were all observed more or less during the course of his illness. Notice, that while asthenia, cardiac feebleness, and nausea, are characteristics of the disease, there is no extreme emaciation or anæmia. Nor does leucæmia form any part of the symptoms.

The affection of the skin was in this case unmistakable. The conjunctiva remaining white distinguishes it at once from jaundice. The tint is not characteristic. It is like what is seen from exposure to sun and air, and like that of the darker races. From the former it is distinguished by affecting parts covered by the clothes; but this boy, when stripped, looked, but for his English features, light brown hair and grey eyes, exactly like a Moor or mulatto. The parts most affected are the face, the extremities, and especially the back of the hands, and the genitals. This distribution and the gradation of colour should prevent its being confounded on the one hand with the darkening of the skin seen in some cases of malaria, of malignant disease, of plumbism, or of syphilis, and in most cases of prurigo (or phthiriasis) senilis; and, on the other, with the circumscribed patches of chloasma in pregnant or womb-sick women, and of tinea versicolor, and with the macule of old syphilitic and other ulcers, blisters, burns, etc. The ink-like stains of the mucous membrane of the mouth and the pin's-head scattered dark spots have never been observed except in Addison's disease. Occasionally the discolouration of the skin is little marked; but even in such cases, where death usually occurs prematurely from some other concomitant disease, it is quite possible to make a correct diagnosis. A good example of this occurred at the same time

that the present case was under observation. A woman under Dr. Moxon's care died of chronic phthisis, but disease of the adrenals was recognised during life, and the diagnosis was confirmed by the necropsy.

The result of this malady is uniformly fatal, though there are often intervals of apparent improvement, and patients live for months and even years. Death occurs (1) from concomitant phthisis, (2) from increasing asthenia, vomiting, and failure of the heart, (3) from sudden 'cerebral' attacks like the present. In the last cases the brain is found apparently normal. We may compare this result with the fatal coma which sometimes ends cases of Bright's disease, of cirrhosis of the liver, and of diabetes.

We know of no treatment available. This patient took phosphorus, because Mr. Ashburton Thompson, one of our own number, has strongly recommended its use in neuralgia and other conditions of nervous depression, and Dr. Broadbent has also used it with apparent benefit in similar cases and in some forms of anæmia. In the present case, and in one of idiopathic anæmia in which I prescribed it, the drug had no ill effects, but I doubt whether it did any good.

The *post mortem* examination showed the adrenals in the state which accompanies the symptoms observed during life. There is, first an enlargement and infiltration; then, and probably very quickly, a caseous degeneration, with softening into a spurious abscess, or with earthy concretion, or dense fibrous contraction, or mere yellow cheesy, *i.e.*, fatty degeneration. This is the change seen in the so-called 'scrofulous' lymph-glands, in carious bone, and in soft or yellow 'tubercle' of the lungs. Whether it is, as Laennec taught, always the result of true (miliary) tubercles degenerating, is still a disputed point. At all events we see from this case that the adrenals may be thus diseased without any other sign of tuberculosis.

J. MILNER FOTHERGILL, M.D.

HAKENSCHMIED ON A CASE OF HÆMOPHILIA. In the *Vienna Medicinisch-Chirurgisches Centralblatt* for April 30, 1875, Dr. Hakenschmied relates the following example of the hæmorrhagic diathesis or tendency. S. K., a Bohemian mountaineer, aged thirty, by no means anæmic, and presenting no external signs of anything abnormal, was attacked with pleuro-pneumonia. Venesection was prescribed, when the patient said that 'he bled for two days after the extraction of a tooth, and it became necessary to plug the cavity. Slight wounds at various times had bled furiously, and to syncope.' Other stories of the like kind were mentioned. He was bled notwithstanding, and with apparent benefit, for he recovered this attack perfectly. Two years afterwards, in a quarrel, he was stabbed with a hunting knife, which entered the right elbow-joint, and, being very sharp, removed the cartilage and a thin lamella of bone from the external condyle of the humerus. He pressed his handkerchief on the wound, and in ten minutes reached home, in spite of the severe bleeding. On the arrival of the medical man he found a stream of blood, of the thickness of a wheat-straw, pouring from the wound, and the patient exhausted. He applied cold compresses and pressure. Four hours afterwards there were pain and fever, but no hæmorrhage. In the night the patient drank a large quantity of water, and whilst the man appointed to nurse him slept, the wound burst out bleeding. Three medical men saw him, and applied

styptic compresses, and the actual cautery, and plugged the wound with kino, etc. But the bleeding recurred again and again, and he died the next day. [In commenting on this case, Dr. Hakenschmied is inclined to blame the water imbibed by the patient for the fatal result. The reporter, however, believes that more energetic measures would have saved the man's life. It is at least singular that no mention is made of any attempt to relieve the hæmorrhage by position or by pressure on the brachial or subclavian artery; and the idea of ligaturing any vessel does not seem to have been entertained by any of the surgeons in attendance.—*Rep.*]

W. B. WOODMAN, M.D.

HAYDEN ON SCARLATINA.—In the *Dublin Medical Journal* for June, Dr. Th. Hayden gives an account of the late epidemic of scarlatina as observed in the Mater Misericordiæ Hospital. The cases are classified under three heads, viz.:

1. 'Mild,' in which the eruption was florid, the throat but slightly engaged, and no complication existed.

2. 'Severe,' or those in which the fever was high, and accompanied by a copious and florid eruption of a somewhat miliary character, diffuse inflammation and ulceration of the tonsils and fauces, delirium, and diarrhœa.

3. 'Malignant,' or cases in which the eruption was dusky and imperfect, the surface in some degree livid, the temperature low, the throat in a sloughy condition, and in which, moreover, diarrhœa, vomiting, suppression of urine, and coma were exhibited. The total of cases was 105; viz., mild, 73; severe, 24; malignant, 8.

The 'mild' cases (of which, in twenty-four instances, the patients were over four and under ten years old, and in forty-nine over ten years), all recovered.

The 'severe' cases yielded a mortality of fifteen out of twenty-four; of the fatal cases four were under ten years, and eleven over that age.

The 'malignant' cases amounted to eight—viz., three under ten years, and five over ten years. All these were fatal.

No case was presented under four years of age.

The treatment adopted in the 'mild' cases consisted in the administration of the chlorate of potash with dilute hydrochloric acid (five to ten grains of the former, and five to ten minims of the latter, with syrup and water, every third hour); astringent gargles, compound powder of chalk as demanded by the state of the bowels, and fifteen to twenty grains of the bromide of potassium at night. The average period of illness was twelve days.

In the 'severe' cases the same treatment was pursued, with the addition of the free application of the glycerine of carbolic or of tannic acid to the fauces, and of poultices to the neck. The average duration of illness was twenty days.

The 'malignant' cases were treated chiefly with diffusible and alcoholic stimulants; the average duration of illness was twenty-six hours.

The complications were almost exclusively anasarca, glandular inflammation and suppuration in the neck, and bronchitis. Anasarca was exhibited in a very large number of cases, chiefly those of a mild character, during convalescence. Consecutive abscesses in the neck were of very frequent occurrence, but in almost every instance the patients recovered. Bronchitis, which was occasionally at-

tended with interstitial congestion of the lungs, was developed in the course of the fever. Most of these cases terminated favourably, but pulmonary tuberculosis followed a few instances.

HUNT ON SCARLATINA.—In the *New York Medical Record*, June 19, Dr. Ezra Hunt writes as follows.

'While infection is the chief source of these zymotic diseases, we do not believe it necessary to assume either that it or contagion are the only sources. They have their laws of origin and propagation, and spread mostly by infection; yet the same conditions which finally occurred and produced cholera in India might occur and produce elsewhere. Given the same combination of conditions at New Orleans, it might originate there. Whether, as a matter of fact, it does, is a question to be settled only by aggregation of facts and difficult exclusion of all outside possibilities. The spontaneous generation of any given disease, or of any new disease, is quite a different question from the spontaneous generation of animal life. I know not why the combination called gunpowder did not get together long before, why lucifer matches waited for the present century, or why nitro-glycerine so long waited its union. Filth has its laws as well as other chemistries. It is quite possible that, while the zymotic diseases spread by infection mostly, once in a thousand times just that correlation of degenerations may occur, of which the result is this or that disease. A manufactory for making nitro-glycerine and giant-powder in this State had to import from Germany an infusorial earth needed. Some of the giant-powder contains 25 per cent. of it. In a swale or depression covered by a swamp of low bushes near the factory, some one found a whitish earth. Examination showed it to be the very article they were importing, entirely made up of the silicious skeletons of diatoms. I know as little how they got there as I know why some diseases which we get from abroad or from infection are found on the spot. We know no reason why the chemistry of decay and its combinations should not have as many originalities as the chemistry of life. Some day we will know more on these points, as we are getting hold of some great outlying and underlying truths. But we feel sure of some things about these zymotic diseases, and that some of the indications are plain. We want that each and all of us shall watch closely, and see how far, in addition to the principles of treatment set forth, we may get aid from proper surroundings. Bad sewage and sinks do not all the foul work. Bad kitchens, close basements full of the fungus of dampness, uncleansed corners up-stairs, dirty drawers and closets never scrubbed or aired, furniture never washed, soiled carpets used more than that of parlour, but not shaken as often, soiled beds and manifold neglects of good old-fashioned house-cleaning, now and then let a disease out of the Pandora-box, or make it rampant when it comes along. Doctors often fail, not because of a weak science or art, but because conditions of failure are all about them. There is much twaddle about the uncertainty of medicine, and the failure to find out remedies. There are scores of physicians in New York City so skilled in this and some other diseases, that it would be no vain boast to allege they could stamp out the disease as Hamilton did cholera on Blackwell's Island, if only they can command and execute.'

J. MILNER FOTHERGILL, M.D.

GROSSIN ON A CASE OF NODULAR ARTHRITIS CURED BY ARSENIC AND ARSENICAL BATHS.—M. Grossin (*L'Union Médicale*, July 8) reports a case of nodular arthritis, in which an affection of the knee of six months' duration was cured by arsenical baths, combined with the administration of arsenic internally, when all other treatment had entirely failed. Each bath contained one and a half grammes of arseniate of soda, with 100 grammes of carbonate of soda and 250 grammes of gelatine to the ordinary quantity of water, according to a formula recommended by Dr. Gueneau de Mussy. The bath was given at a temperature of from 90° to 98° Fahr., and continued for three-quarters of an hour to an hour. Internally, from two to ten drops of Fowler's solution were administered in the twenty-four hours. Fifty baths were given in the course of five months, at the end of which period the patient was able to walk about, and the knee has since remained perfectly well. The fingers of both hands, however, where the disease was of six years' longer standing, were not benefited by the treatment.

OBET ON THE TREATMENT OF SEA-SICKNESS BY CHLORAL.—Dr. L. C. Obet (*Archives de Médecine Navale*, June, 1875), after four years' constant experience in the treatment of sea-sickness, concludes that chloral-hydrate is the remedy which unquestionably gives the best results. Electrification, the hypodermic injection of morphia, and other means of more or less repute in this affection, afford but temporary relief. Bromide of potassium gives more satisfactory results than the rest; but the slowness of its action, the largeness of the doses, and the quantity of liquid in which it requires to be given, are great drawbacks to its administration.

The chloral is given the first day in a single dose of from one to two grammes. On the following days the same quantity is given again, either in a single dose as before, or in divided doses taken every hour.

Under this treatment, the patient becomes able even to join the dinner table in the course of two or three days.

With pregnant women also the result proved equally satisfactory, not a single case of miscarriage or premature labour having occurred.

The experiments of Carville, Oré, and Vulpian have shown that chloral, when given in sufficient doses, diminishes the general sensibility and the reflex action of the nervous system; that its effects are due to it as chloral and not to chloroform produced by the decomposition of chloral in the blood; and that the drug acts directly upon the elements of the spinal cord itself, and not through the medium of the vaso-motor nerves. If it be admitted that sea-sickness is chiefly dependent upon irritation of the medulla oblongata, the action of chloral in this affection is intelligible.

BONNEMAISON ON A CASE OF HYSTERIA IN A MALE.—Dr. Bonnemaison of Toulouse (*Archives Générales de Médecine*, Jan. 1875) relates a case of hysteria in a man aged seventy-two. The brother of the patient was a hypochondriac, and his mother, who died at the age of eighty-one, suffered from various forms of nervous disturbance, analogous to those of her hysterical son, after reaching her seventy-sixth year. The attacks in the case of Dr. Bonnemaison's patient came on three or four times in the twenty-four hours; ushered in, when occurring during the night, by nightmare; when in the day, by various sensations, and usually by pain in the

epigastric region. An aura proceeding from this point travelled along the sternum to the throat, and thence to the mouth and tongue, and other regions of the body, the muscles of the parts affected by this sensation being thrown into violent, rapid, and unaccountable convulsive action. The patient uttered strange cries and yells, or repeated the same word over and over again with extreme rapidity. At times the tongue would be smacked violently against the roof of the mouth, the cheeks spasmodically puffed out with the action of blowing or whistling, and the jaws snapped violently together, without, however, biting the tongue. The arms were moved rhythmically together with the action of flying, or drumming, or playing the piano. Sometimes the lower limbs shook violently, or executed the movements of dancing. The attacks bore a strong resemblance to those of the 'convulsionnaires' of St. Médard, or the rhythmic chorea of the epidemics of Louviers, Toulouse, and Morzic. The disturbance of the voluntary muscles might be accompanied by spasm of the involuntary muscles also, or the latter might form the chief phenomena of the paroxysm, consisting in hiccup, eructations, sighs, and borborygmi. During the whole of the attack the hyperæsthesia of the skin was excessive, especially at the forehead, epigastric region, and sternum; there was no loss of consciousness. The attack ended either with a copious flow of limpid urine, or a discharge of tears. There was never any pain or sensation referable to the generative organs, nor anything whatever in the history or the symptoms indicative of their implication in any way whatever. The same absence of any pathological condition of the organs of generation has been observed in cases of male hysteria observed by others. Grisolles, again, met with hysteria in a woman, in whom congenital absence of the uterus and part of the vagina was proved by *post mortem* examination. Children of six or seven years old are liable to hysteria. From these and other considerations, M. Bonnemaison concludes that pathological conditions of the uterus and ovaries are not the necessary cause and organic foundation of hysteria. He regards it as a neurosis, an expression of a nervous diathesis, having often an hereditary connection not only with hysteria, but with other neuroses such as epilepsy, idiocy, or hypochondriasis. The point of departure of the symptomatic explosion may be sometimes in one organ, sometimes in another; the uterus, the ovaries, the stomach, the intestines, functional disorder of different cerebro-spinal regions, etc. The predisposition may be developed by errors of education, luxury, excess or other surrounding conditions; but the constitutional foundation is always the same.

W. B. CHEADLE, M.D.

FABRE ON HYSTERIA IN MAN.—Dr. Paul Fabre (*Annales Médico-Psychologiques*, May, 1875) relates a case of hysteria occurring in a man, and quotes the opinions of various authors upon the question of hysteria in the male sex. With M. Briquet, he holds that an increased impressionability of the affective element in the nervous system is at the root of the predisposition to hysteria; that hysteria is confined almost entirely to the female sex because this affective element predominates there. Nevertheless, it may be found in males if there be the same predominance. The cause is not connected with the genital organs of the female, but is to be looked for in the sensitive nature of women. The passions and the

gloomy emotions alone predispose to hysteria. The man whose case is related was timid, credulous, and very impressionable. He was thirty years of age, pale, and debilitated. Both parents had died of phthisis, and he was the last of four children. His build and voice were somewhat feminine. He indulged in masturbation and drink, and was confined, as of weak mind with hallucinations and excitement. After being in the asylum a few days he had attacks of a convulsive character, lasting from ten to forty-five minutes, and returning every third or fourth day. Sometimes convulsive movements commenced in the lower limbs, and thence extended to all the rest. At others, the upper portion alone was convulsed, the abdomen and lower limbs remaining unmoved. Consciousness was partially or altogether lost. He described the attacks as commencing in various parts, the genital organs, the head, or stomach. For fear of bringing them on, he at one time refused food. He heard voices of the devil, his father, mother, or sister. He calmed down in about two months, the attacks left him, and he was able to give an account of himself. In his case all the common symptoms of hysteria were well seen; the partial loss of consciousness, clonic convulsions and spasms, sensations of globus, hyperæsthesia, and analgesia. There was also a constant spitting, which is frequently found. Without discussing the whole question of treatment, Dr. Fabre mentions a method of cutting short an attack by compressing the testicles. Two attacks in this patient were arrested, one by this method, and another by compression of the carotids. The latter plan operates, he believes, through the effect produced on the larynx; the former through the pain it causes. Bromide of potassium is useful, but it must be employed along with agents calculated to remove the cause of the malady. Here anæmia and disturbance of the digestive organs called for appropriate remedies.

G. FIELDING BLANDFORD, M.D.

BOURNEVILLE AND REGNARD ON A CASE OF HYSTERO-EPILEPSY WITH ANURIA.—At the meeting of the Paris Society of Biology on July 3, M. Bourneville communicated the particulars of a very remarkable case of this kind. It related to a woman aged forty-six, Justine Echeverry, who, having enjoyed good health up to twenty-three years of age, was then, in 1854, exposed to sudden fright. The following year she had an attack of hystero-epilepsy, fell into the fire, and burnt her face severely. In 1859, 1860, 1863, and 1865, she had similar crises. Having gone into the Sainte-Eugénie Hospital in 1865, she had cholera in 1866. After that time there was suppression of urine for a week; it re-appeared, but it was necessary to catheterise the patient daily until May, 1875. After having had several crises, she went into the Salpêtrière in 1869. There she had several hystero-epileptic attacks, followed by contractions in the upper and lower limbs, which contractions decreased at different times and were partially cured, recurred, and remained permanent in several parts. Abridging the history of the patient, we come to May 17, 1875. On that day at mid-day, she had an hystero-epileptic attack preceded by an aura (ovarian and anal pains with irradiations to the epigastrium, neck, and temples). The attack was accompanied by cries, deviation of the eyes, distortions of the face (which was of a violet tinge); the right arm was bent and remained fixed for three hours. On May 18 she presented the following

condition: contraction of the legs and arms, complete anæsthesia, double amblyopia, contraction of the jaw. The patient could no longer speak; there were neuralgic attacks, for which injections of morphine were administered. This condition lasted, without notable change, until May 22; on that day there was a fresh attack, and the singular part of the case is that at eight o'clock the patient was completely cured. Thus disappeared in a few minutes a retention of urine which had lasted since 1866; a contraction of the members of the left side dating from 1869; a contraction of the jaws necessitating alimentation, by the aid of a sound, during ten months, and aphonia of equal duration.

M. Charcot had in 1870 made the following prognosis. 'It is possible that, notwithstanding its lengthened duration, this contraction may vanish without leaving any traces, perhaps to-morrow, perhaps in some days, in a year; nothing can be pre-judged in this respect. But in any case, if there is a cure at all, it may be sudden. From one day to the other everything may become normal; and, if it so occur that at the time the hysterical diathesis is exhausted, she will regain her accustomed health' (*Leçons sur les Maladies du Système Nerveux*, first edition). This case should be collated with those collected by M. Bourneville, in his *Memoir on Hysterical Contraction*, published in 1872.

To the details of this case, M. Regnard added diagrams showing the amount of urine and the amount of urea excreted during the period of ischuria. He made 112 analyses under so much the more precise conditions, that, on the one hand, the patient was fed by the œsophageal sound with an unvarying amount of food; and that, on the other hand, catheterism was performed in consequence of the contraction of the neck of the bladder. During three months the patient voided daily fifteen or twenty grammes of urine, containing three or four decigrammes of urea. The details of M. Regnard's investigations are printed in the *Comptes Rendus* of the Société de Biologie. It will suffice here to state that the secretion of urine, which had been completely suppressed during many months, was suddenly re-established at the time when the other hysterical manifestations ceased.

BRIAND ON PERIPHERIC TRAUMATIC EPILEPSY. Dr. Briand relates, in the *Bulletin de la Société de Médecine d'Angers*, ann. lxxvii. p. 121, the case of a young man aged twenty, in whose family there was no history of epilepsy, nor of any kind of nervous disorder having any relation to epilepsy. The patient himself, until the occurrence of the injury, had never felt anything in the slightest degree resembling epilepsy. He had not contracted any venereal disorder, and did not show any symptoms which could give rise to suspicion of the existence of any cerebral affection.

At the battle of Mans in January, 1871, he was struck by two fragments of shell at the level of the nates. The marks left by these wounds prove that both the sciatic nerves were touched; there is likewise no possibility of doubting this since there was an attack of paraplegia with anæsthesia, which only disappeared at the end of a year. Eight months after receiving the wound this young man had an epileptic attack, and since that time has had several, returning at variable intervals, but always strongly marked.

HUTCHINSON ON THE USE OF THE OPHTHALMOSCOPE IN THE DIAGNOSIS OF CEREBRAL DISEASES.—Dr. Hutchison (*Philadelphia Medical Times*, May 8) discusses the distinction between the swelling of the discs dependent on mechanical obstruction to venous return, and that caused by descending optic neuritis. It is doubtful whether there is not, in all cases of so-called choked disc dependent on congestion, if of long standing, more or less optic neuritis. All therefore which can be truly said is, that the existence of an appearance of exudation in the swollen disc early in a case indicates optic neuritis rather than simple choking. The choked disc is, however, a condition of congestion, which may on the one hand be the result of descending neuritis, or on the other of intracranial pressure; and the inflammation which may be present, may be the consequence, not the cause of the choking. In the first case, the cause of the congestion is local, viz., pressure of inflammatory products upon the sheath of the nerve; in the second case it is seated within the brain, viz., pressure of a tumour or inflammatory products upon the sinuses. Dr. Hutchinson insists upon the value of ophthalmoscopic evidence in the diagnosis of cerebral affections, and in the detection of disease which would otherwise escape observation. Cases are given illustrating these points, in which the ophthalmoscope revealed optic changes indicative of cerebral mischief previously overlooked or unsuspected, or gave decisive confirmation to a diagnosis founded on general symptoms; or, on the other hand, almost proved the negative, by showing the fundus of the eye to be free from any marked changes. Statistics are also given, compiled from cases collected by Annuske and Reich, which show that optic neuritis is a constant and usually very early symptom of cerebral tumours. Of the cases in which an ophthalmoscopic examination was made, in 95.65 per cent. there was found optic neuritis or atrophy ex neuritide, and of these it was double in 93.5 per cent., single in 2.15 per cent. In 4.35 per cent. only of the whole number examined no ophthalmoscopic change was discovered.

W. B. CHEADLE, M.D.

LYMAN ON A CASE OF MYELITIS ENDING IN RECOVERY.—In the *Boston Medical and Surgical Journal*, May 20, Dr. G. H. Lyman, of Boston, relates the following case.

The patient, Mrs. E. S. S., aged twenty-five, was married at nineteen and had one child, now five years old; no other conception has occurred. Her parents are healthy. She had typhoid fever six years ago; she had been in good health since, though not as strong as before; her complexion was clear and healthy, her nutrition good.

On December 16 she had a severe attack of measles; the attendant cough was very urgent. The disease went through its usual stages without any other complication than the unusual severity of the cough, which remained troublesome. The bowels were constipated. There was slight febrile disturbance, and some pain on pressure over the lumbar vertebrae; there was no muscular twitching; the urine was normal. The patient reported that a week ago (January 1) she found on awaking in the morning that there was numbness of both feet, with pricking sensations as though the 'legs were asleep,' though she could stand, and even walk with difficulty. In five or six days the numbness gradually extended to the hips, with manifest increase of loss in muscular power. Hot and cold applications to the spine

caused no pain. She was unable to distinguish any difference between a piece of ice and hot water.

January 12. In attempting to walk across the room the right leg was found to be completely paralysed, the left nearly so; loss of sensation was nearly complete below the hips, and there was some numbness on the right side of the chest.

January 16. There was slight relaxation of the vesical sphincter.

January 19. Both legs were completely paralysed, the right more so than the left. If rubbed, forcibly extended, or placed in an uncomfortable position, they became rigid and painful, and spasmodic action was induced, more in the right than in the left. During the past week the spine, below the shoulder-blades, had been sufficiently painful to awaken her at night. The past two days the patient had had a decided feeling of stricture about the waist, as though laced too tight. The ominous affection of the vesical sphincter had disappeared. The patient was now unable to stand or walk, and was obliged to be lifted; with much effort she could turn over in bed, and when at rest suffered no pain. She had slight headache occasionally, which she attributed to the medicine. The cough had nearly gone; the appetite was good; the bowels required a daily laxative. There was no affection of the special senses. The catamenia were regular. Electricity caused imperfect muscular reaction in both extremities, most in the left.

When she was first seen, on January 8, a laxative pill of quinine, sulphate of iron, colchicum, and aloes was ordered. As the paralysis was not complete, and in the hope that it might be simple congestion of the cord, six leeches were applied to the lumbar region. There being no improvement, but a decided increase of the disease, this was followed in a day or two by ergot and bromide of potassium, a drachm of the former and half a drachm of the latter, three times daily, with good diet, and enough morphia and camphor to insure quiet nights.

January 27. In addition to the above, one-thirtieth of a grain of strychnia, with fifteen drops of dilute phosphoric acid, was given twice daily, alternating with the ergot, one dose of the latter being omitted. She was also given lager beer and a still more generous diet.

January 30. There was some return of sensation, and ability to flex the foot upon the ankle.

Two weeks later (middle of February) the patient was able to rise slowly from her chair without assistance. The ergot and bromide were continued three times daily, the strychnia being omitted. Iodine was applied daily to the lumbar region. Slow but steady improvement continued until March 20, when the patient was able to walk up and down stairs.

April 1. The patient had recovered entirely both sensation and motion, with no more weakness than would naturally result from her long confinement. The ergot had been gradually reduced during the past fortnight and cod-liver oil substituted.

April 3. The ergot was omitted entirely; the oil was continued for a short time.

As recovery from myelitis is rare, it may perhaps be suggested that this was a case of reflex or neurolytic paralysis; but the completeness of the paralysis, the slight pain in the spine caused by pressure on the processes, the stricture about the waist, the pricking sensations, the anæsthesia so complete, and the total absence of gastric or urinary derangements, all point to inflammation of the substance of the cord, which

fortunately had not progressed so far as to prove intractable to remedies.

ERB ON AN IMPERFECTLY RECOGNISED COMBINATION OF SPINAL SYMPTOMS.—Dr. Erb, of Heidelberg (*Berliner Klinische Wochenschrift*, June 28, 1875), has met with about a dozen cases of affection of the spinal cord, in which he considers that the symptoms were sufficiently distinct and well marked to justify their separation from other forms of spinal paralysis, such as myelitis, ataxy, tabes dorsalis, etc. The clinical evidence of distinctness, he adds, is clear, constant, and well marked, although as yet it is not confirmed by *post mortem* examination. The cases described by Dr. Erb exhibit a malady slow in progress, not tending to death, but an essentially chronic form of disease, extremely gradual in its development. It seldom begins with abnormal sensation, but almost always commences with impairment of the motor functions, especially by the lower limbs, as shown in the uncertainty of gait and tendency to falling. Frequently at the outset spasmodic action and cramps of single groups of muscles are observed. The disease being progressive, the patient after months or years presents a peculiar appearance from the strangeness of his gait, and later still becomes more or less paralysed and unable to stand or walk. The staggering gait reminds one of ataxy, but closer observation detects the difference. The patient drags the limbs after him, his feet appear to adhere to the ground, the toes catch upon every unevenness of the ground, and are dragged along with a shuffling noise. Every step is performed by a distinct heaving effort of the body, which acquires a tendency to fall forward. This is caused by contraction of the muscles of the calves, by which the toes are bent downwards. The knees are bent forward, as also the whole body inclines forwards. In the recumbent posture, movements of the body are at first not much impeded, but at a later period become difficult and painful. Standing is possible, either on one foot, or with the feet close together. Closing the eyes does not cause giddiness or staggering. Muscular contractions ultimately cause fixed positions of the limbs. The muscles continue to be well nourished, and retain their normal electro-excitabilities. It frequently occurs that the muscles of the trunk become feeble, so that it is with difficulty that the erect posture can be maintained. The upper extremities seldom become affected. There is seldom any impairment of the sensibility or of the muscular sense. In only one case was slight cutaneous hyperæsthesia. A very marked reflex susceptibility is observed in many of the tendons, *e.g.* the ligamentum patellæ, the tendo-Achillis, the adductors, the biceps femoris, the tibialis anticus and posticus. This reflex property of tendons, the author states that he has formerly described, in conjunction with Professor Westphal. The vaso-motor functions are not interrupted, except that in a few cases there is coldness and blueness of the extremities. The cerebral functions are also unimpaired. The general health is but slightly interfered with. The progress of most of these cases has been a gradually increasing loss of power in the lower limbs, until the patient has become bedridden.

These cases are compared differentially with other forms of spinal disease by Dr. Erb, who, failing an opportunity of *post mortem* examination, finds it very difficult to localise the affection. The pathological condition which the author regards as nearest to that

under consideration, is that of sclerosis of the lateral columns of the spinal cord, as described by Charcot. Their prognosis is not unfavourable, indeed the author has seen several cases that have been greatly benefited by galvanism.

[May not these cases be regarded as instances of chronic myelitis?—*Rep.*]

SURGERY.

SCHWENINGER ON ENCHONDROMA.—Dr. Ernst Schwenger, of Munich, publishes in the *Aerztliches Intelligenzblatt*, no. 24, 1875, an interesting case of enchondroma that was treated by Professor Nussbaum. A young woman, aged seventeen years, applied with a very large and firm tumour of the left tibia, which had commenced two years before, shortly after a fall. It appeared first as a small outgrowth from the bone about four inches below the knee, and increased slowly in size until three weeks before the patient came under notice, when, immediately after a second fall at that time, it began to spread very rapidly, and involved almost the whole of the leg. Amputation at the lower third of the thigh was performed on the day after admission, and the tumour on subsequent examination was found to be a good specimen of enchondroma. The case did not progress well after the removal of the limb; the flaps sloughed, the granulating surfaces at the extremity of the stump afterwards became diphtheritic, and suppuration was profuse. At the end of six months, when the stump had almost quite closed, the general health commenced to fail, and the patient gradually sank in consequence of severe pains in the lower limbs, and of an exhausting discharge from a large bed-sore. Death took place thirteen months after the amputation, from general exhaustion. On *post mortem* examination the lungs were found to be studded with small secondary enchondromatous growths, and in front of the lumbar vertebræ was a large nodulated tumour which passed downwards and occupied a greater part of the pelvic cavity. A portion of the walls of the vena cava, in contact with this tumour, had been removed, and soft masses of enchondroma were found projecting into the interior of this vessel. The pulmonary tumours, like the primary growth of the tibia that had been removed by amputation, presented on microscopical examination, well-marked cartilage-cells, a few bone-corpuscles surrounded by fibrillated and vascular connective tissue, and at the periphery of each tumour and constituent nodule, a profusion of small embryonic cells resembling white blood-corpuscles—the so-called indifferent cells. Besides these indifferent cells and the well-developed cartilage and bone-cells, were found a number of cells presenting transitional forms. The basis-substance in both the primary and secondary growths was hyaline at some parts, mucous at other parts, and

here and there much fibrillated. The primary tumour and most of the internal growths presented patches of calcification and fatty degeneration. Dr. Schwenger, in commenting on the case, points out the undoubted traumatic origin of enchondroma in this instance, and dwells specially on the position and minute structure of the secondary growths as indications of the course and manner of infection, and of the pathogenesis of such tumours. The large pelvic tumour was, he holds, due in all probability to infection through the lymphatics, whilst the smaller growths in the lungs were doubtless formed from small masses carried by the blood from the eroded portion of the vena cava. The malignancy of enchondroma and its frequent appearance in the metastatic form are to be explained by the soft, loose, and vascular structure of the mature growth, and by its tendency to undergo fatty degeneration. The growth and further development of the secondary tumours take place, according to the author, through proliferation of the original specific elements—cartilage cells, and through the gradual transformation of embryonic or indifferent cells into the cells of cartilage, bone, and connective tissue. Investigation of the processes of calcification and ossification in enchondroma, together with observations of normal cartilage, have led Dr. Schwenger to the conclusion that the developed cartilage-cells and the intercellular substance never ossify, but only undergo calcification; whilst the process of ossification, in enchondroma at least, is always carried on by the embryonic cells.

W. JOHNSON SMITH.

MARCEZ ON A CASE OF PAPILLARY GLOSSITIS.—M. Marcez reports the following case in the *Gazette des Hôpitaux* of June 29, 1875.

The patient was a married lady, aged forty-five. She had no children, had never miscarried, her menstruation had always been regular, and she had no specific antecedents, either acquired or hereditary. She was, however, of an extremely nervous temperament—so much so that for some time previously a very slight degree of excitement disturbed her appetite and her sleep for days, and had even on two occasions caused a severe attack of jaundice. Another peculiarity in her case was the extreme sensitiveness of her skin. The slightest cold air gave rise to a furfuraceous desquamation of the face, particularly on the forehead and lips. And a sea-bath was sufficient to cause erythematous patches all over the surface of the body.

In July, 1871, Madame X., when under the influence of very violent emotion, was attacked, as on former occasions, with gastric disturbance, characterised by abdominal pains, abundant evacuations, complete loss of appetite, great thirst, and slight feverishness. A homœopathic practitioner, who was consulted, ordered calomel—fifty centigrammes (seven and a-half grains) night and morning. The patient was not seen for forty-eight hours, by which time she had taken more than thirty-eight grains. Her symptoms at this time were much aggravated; and her tongue was so much swollen that it protruded beyond the dental arch, filling the mouth, causing a feeling of suffocation, and preventing both speech and deglutition. The symptoms did not entirely disappear for six weeks, and for some time the patient's life was in danger. Rather more than a year later she had a similar attack. The treatment on this occasion was

chiefly by soothing drinks, and the symptoms rapidly disappeared, leaving, however, a feeling of heat and discomfort at the tip of the tongue, which nothing seemed able to remove. The tongue appeared in all respects normal, except that the tip was very red, and here and there on its surface were little red dots. In these places the papillæ were distinct, hardened and hypertrophied. When examined with a lens, it was found to be the fungiform papillæ which were thus affected. With the finger, the difference between the healthy and the unhealthy portion could easily be distinguished. The papillæ appeared as if distended and ready to burst; and were each about the size and shape of a pomegranate seed. The patient complained, not so much of pain, as of a constant uneasiness, which was increased by almost every kind of food. Various lines of treatment were tried, but although after eighteen months the patient's condition was certainly improved, yet the cure was far from being complete. She is subject to frequent relapses, and although there are occasional periods of almost complete relief, yet the papillæ have never returned to their normal state. It is not possible to trace these recurring attacks to any distinct cause. The subsidence of the symptoms seems generally to coincide with the use of very slight cauterisation, repeated at short intervals. Emollient applications appear to have no effect, whilst astringents, such as alum, borax, and chlorate of potash, do more harm than good.

This case has been reported because of the limitation of the inflammation to the papillæ, because of its apparent origin in a nervous shock, and also because of its obstinately chronic nature, as well as the impossibility of obtaining a cure by any medical or hygienic treatment.

FÉRÉOL AND OTHERS ON BLACK PIGMENTATION OF THE TONGUE.—In the *Gazette des Hôpitaux* for June 29, 1875, attention is drawn to this subject. Four cases of this affection have been already recorded by M. Maurice Raynaud, a fifth by M. Gubler, and to this a sixth has now been added by M. Féréol. M. Raynaud termed the disease in question a parasitical affection of the lingual mucous membrane, and believed it to be due to the presence of the spores of the 'trichophyton tonsurans.' But in the six cases which are now on record the parasite was only discovered in one. It would appear, therefore, that there is a contradiction between M. Raynaud's facts and his deductions. M. Féréol gives the affection the name of 'piliform epithelial hypertrophy.'

W. FAIRLIE CLARKE.

HENSCHEN ON A CASE OF RECOVERY AFTER COMPLETE DIVISION OF THE LARYNX AND ŒSOPHAGUS.—S. Henschén reports the following remarkable case in the *Upsala Läkareforenings Förhandlingar*, Band x. (abstract in *Nordiskt Medicinskt Arkiv*, Band vii.)

A peasant, aged forty-three, attempted suicide by cutting his throat with a knife, and then with a razor. On the front of the neck was a transverse gaping wound about four-and-a-half inches long, the ends of which passed through the skin and subcutaneous tissue, laying bare the sterno-cleido-mastoid muscles. In the centre it exposed the prevertebral fascia, which was cut. The incision had thus divided the trachea and Œsophagus, and the recurrent nerves.

The cricoid cartilage was divided just below the vocal cords; the upper part of the cartilage was

drawn upwards with the larynx, while the lower was drawn down with the trachea. Around the upper end of the trachea the surrounding tissues had swollen and pressed on the opening, which was also partly covered by a piece of the wounded thyroid cartilage; respiration was considerably impeded. Behind the trachea, though with difficulty, the end of the divided Œsophagus was seen. This had been so much drawn down towards the thorax that it was only with great difficulty, and after a search of two hours, that Dr. Landgren was able to find it at the bottom of the wound, and to prevent its further retraction by passing some suture threads through it.

At the sides of the Œsophagus the carotid arteries in their sheaths were seen quite unhurt. The bottom of the wound was formed by the prevertebral aponeurosis, which was wounded at one part, so that a probe introduced into the opening passed back to the vertebrae. At the upper part the wound was limited by the upper part of the Œsophagus, or perhaps more correctly the pharynx and larynx, in a state of œdematous swelling: the inferior vocal cords lay exposed.

The space between the upper and lower ends of the Œsophagus was so great that a closed hand could reach the bottom of the wound when the patient lay with his head bent backwards.

From the pharynx and larynx there constantly escaped quantities of saliva and buccal secretion, which, mixed with the discharge from the wound, threatened to block up the trachea, as the patient could not swallow nor free his mouth by coughing.

The first question naturally was, how to feed the patient, and at the same time make the breathing less difficult. By means of an œsophageal tube he was given abundance of milk, raw eggs, wine and water, and afterwards infusion of meat, prepared with hydrochloric acid at a temperature of 113° to 116° Fahr. He bore the food very well.

In order to prevent the discharge from the wound and the saliva from running down the trachea, and to favour its escape, the patient was laid on his side, and was kept clean by the assiduous use of sponges and charpie. The flap of thyroid cartilage lying over the opening of the trachea had to be cut away. The patient's condition was tolerably good, and there was no general reaction.

An attempt was made to unite the two ends of the Œsophagus by sutures. But as these could not be brought accurately together by simple traction, it was found necessary to separate them from the surrounding parts both above and below. At the lower part, this was done easily enough, partly with the edge and partly with the handle of the scalpel, but above some dissection was necessary. Four sutures were now introduced into the Œsophagus, two behind and two in front, and an œsophageal tube was introduced for the purpose of being retained. By means of traction and placing the patient's head in a favourable position, the two ends of the Œsophagus could be approximated to within about half an inch, at which point the sutures were tied.

It was found impossible to invaginate the upper portion of the Œsophagus into the lower one. The patient retained the Œsophagus tube without difficulty; for some days a solution of bromide of potassium was applied to the throat.

It seemed impossible even to attempt to unite the trachea, as the larynx (in consequence of the division of the recurrent nerves) was partly paralysed, and with each act of deglutition the whole of the

buccal secretion was carried down through the larynx, so that the closing of the trachea was incompatible with the employment of the necessary means for cleansing the tube.

By means of abundant granulation, the wound soon assumed the form of a funnel, the lower part of which was formed by the trachea, where all the secretion was collected. It was difficult to prevent this from closing the tube, but fortunately the patient learned, with the help of a hand-mirror, to dress his wound.

During the next two weeks the patient's condition was less satisfactory than before. He had slight fever, lost his appetite, and an erysipelatous redness appeared around the edges of the wound. Afterwards, however, his strength increased under the use of nutritious food, quinine, etc., and in a month he was able to return home. In the anterior part of the œsophagus there was still a small opening of the size of a small goose-quill. Around the trachea induration had taken place, which kept the aperture open, even when a trachea-tube was not used; the wound had become filled with granulations; supuration had nearly ceased, and the edges of the wound had united.

After he had been at home two months, the patient was obliged to remove the œsophagus tube, which had become plugged with remains of meat, etc., and he found that without much difficulty he could swallow small pieces of bread, etc. Drink, however, escaped from the fistulous opening in the œsophagus through the trachea; the patient, therefore, of his own accord, plugged the opening with charpie, which naturally prevented the healing of the fistula. After five months the patient was admitted into the Seraphim Hospital, to have a stricture of the œsophagus dilated. His general health had been continuously good, but he was of course deprived of the power of speech.

STAGI ON A CASE OF COMPLETE DIVISION OF THE TRACHEA: RECOVERY.—In a letter to Professor Corradi, published in *Lo Sperimentale* for June, Dr. Luigi Stagi relates the following case.

On the evening of June 6, 1874, he was hastily called to see a case of cut-throat. He found, lying in a bed, covered with blood, a young man, aged about twenty-four, of ordinary height, nervo-sanguineous temperament, and with a scanty development of fat. On examining his neck, he found a transverse wound, nearly two inches long, from which escaped blood and bubbles of air. The instrument, a razor, had penetrated between the first and second rings of the trachea, and the edges of the wound were nearly an inch apart. The upper part of the trachea was drawn upwards, and the remaining portion was retracted and almost hidden among the neighbouring parts; the breathing was difficult and noisy; there was complete aphonia. The mouth and nostrils were open; but respiration was performed solely through the wound. No vessel of importance was injured.

Frequent paroxysms of cough expelled a quantity of blood which threatened to pass down the trachea. To avoid this, Dr. Stagi turned the patient on his face, while an assistant bent the head backwards so as to keep the wound open. In this manner, the blood, obeying the laws of gravitation, escaped through the wound. Cold applications being made

to the wound in such a way as not to interfere with respiration, the hæmorrhage ceased. Dr. Stagi then left the patient to see a woman who had also cut her throat. On his return, an hour and a-half later, he found that there had been a constant flow of blood, not so copious as before, but enough to prevent an apparatus from being yet applied. He then again left, ordering the patient to be kept in the same position. About six hours later he was summoned by the judicial authorities to assist in the ordinary legal formalities. The patient was in a very bad state, constantly troubled with attempts to cough. He could only answer questions by moving his head. Dr. Stagi did not try to bring the edges of the wound together, so as to render speaking possible; first, because it was known that the man had attempted suicide, and secondly, because he feared that the proceeding would cause distress to the patient. The next morning the hæmorrhage had ceased, and respiration was carried on freely through the wound. The position of the patient was then changed, and his head was bent down towards the chest, and retained there for eighteen days. The parts had scarcely been brought together when the patient, in a weak voice, explained to the bystanders the reason of his attempted suicide. On the twelfth day the trachea was perfectly reunited; a little pus escaped from the wound in the integuments. He was then taken to the hospital, in order that he might be more conveniently watched, and was discharged on July 8, perfectly cured, except that his voice was rather hoarse. The only trace of the wound was a linear cicatrix.

A. HENRY, M.D.

DUPLAY ON AN OSTEOPLASTIC METHOD OF OPERATION FOR HARE-LIP.—In cases where the nose is much flattened, and the two moieties of the dental arch are not on the same level, M. Duplay (*L'Union Médicale*, February 13, 1875) has invented the following method of proceeding.

In order to raise the nose he divides with the scissors the cartilaginous part of the septum, after having prepared the borders of the fissure in the lip (for which purpose he employs Clémot's method of leaving the flaps attached and reversing them), and after having also rapidly divided the mucous membrane of the alveolar process and every adhesion which may exist. It is now easy to raise the nose as far as may be necessary, so that the lobule is placed in the median line, and the flattening is quite corrected. Then if the hare-lip be simple, the operation is finished by attaching the parts together, by means of the twisted suture. If there be besides a fissure of the palate and of the dental arch, he corrects the difference in level between the two parts of the latter, before sewing up the flaps of the lip, in the following manner. He detaches from the free extremities of the projecting half of the jaw a tubercle of bone, which he leaves adherent by its posterior part, and which he turns on itself and attaches by suture to the free end of the other half, refreshed for the purpose, so as to produce a median tubercle something like that which exists in double hare-lip.

TILLAUX ON GRAFTING OF THE EXTENSOR TENDONS OF THE HANDS; ANASTOMOSIS OF THE TENDONS.—A very interesting case is shortly detailed in *L'Union Médicale*, February 13, 1875, under the care of M. Tillaux, in which a man had received a wound on the back of his hand, by which the two extensor tendons, belonging to the fourth and fifth

fingers had been divided, and those fingers had lost all extensor power and were permanently flexed. The blood having been excluded by Esmarch's bandage, two flaps were turned back, so as to expose the peripheral ends of the divided tendons, and these were then implanted or grafted into the uninjured tendon of the middle finger. This was done by making a sort of button-hole in the tendon (or in its sheath?) into which the two divided tendons were implanted by means of several points of metal suture. The operation was performed without anæsthetics, and the tendons (which were completely free from any trace of inflammation) presented evidences of lively sensibility.

The wound cicatrised kindly, and the man recovered the motion of both fingers.

The only case which the relater of this case (Dr. Gillette) could refer to as analogous is one mentioned by Velpeau (*Méd. Opér.*, ii. 507) in which a surgeon named Milla had united a divided tendon to the edge of a sound one, but without actually grafting it. Several successful cases of suture of divided tendons are referred to.

T. HOLMES.

RICORDI ON A CASE OF RESECTION OF TWO-THIRDS OF THE RIGHT HUMERUS: COMPLETE REPRODUCTION OF THE BONE.—Dr. Ricordi relates the following case in the *Bulletino delle Scienze Mediche di Bologna* for May, 1875.

A boy, aged twelve, presenting some amount of rickety deformity, was admitted into the hospital at Milan with fracture of the arm, in consequence of a fall from a tree. The external part of the elbow had come into contact with the ground; and a portion of bone protruded from the fracture, which was reduced by the district surgeon.

On removing the dressings, Dr. Ricordi found a fracture of the humerus a little above the condyles, and a lacerated wound about two inches long at the outer side of the lower part of the arm, from which a little blood escaped. On making the upper end of the bone project, it was seen that there was a V-shaped fracture, and that there was a longitudinal fissure about 1·2 inch long in the bone, which was extensively denuded of periosteum. By drawing the forearm towards the chest and raising it, Dr. Ricordi exposed the bone more completely, and, on enlarging the wound upwards, he found that the periosteum was stripped off for a space of four inches. He decided on removing the denuded bone; and with a chain-saw divided it about two inches from the head of the humerus, and trimmed the lower end of the bone with bone-forceps. The portion removed from the upper part measured four inches; that from the lower about 0·4 inch. Three points of suture were applied to the wound; the arm was encased in a cardboard splint with an opening opposite the wound, and the forearm was placed in a sling. There was but slight reaction, and the cure was complete on the fortieth day. During this period the bone was completely reproduced, without any shortening.

This case is remarkable on account of the extensive separation of the periosteum. The boy struck the ground with the outer side of the elbow, and the humerus was broken at the lower third; the force of the fall then being continued, the upper fragment of bone burst through the soft parts and protruded. The effect of the fall, however, was not arrested here; the periosteum, adhering more to the neighbouring parts than to the bone, was separated for

some distance. And the case is interesting on account of the amount of bone removed, and of the rapidity with which recovery took place. This, however, does not cause surprise when we consider that the periosteum only suffered a longitudinal fissure, preserving its vascularity, and retaining its adhesion to the neighbouring parts, thus presenting the most favourable conditions for rapid and regular formation of new bone.

MATERIA MEDICA AND THERAPEUTICS.

HOLMES ON BRAZILIAN DRUGS.—The following are extracts from an article by Mr. E. M. Holmes, Curator of the Museum of the Pharmaceutical Society, published in the *Pharmaceutical Journal* for June 12, 1875.

Erva do Rato.—The leaves and fruit, in the state of powder, are used in Brazil to poison rats and mice. Dr. Barnsley attributes the drug to *Palicourea Maragravii*, St. Hil. He states that it is a most deadly poison, and that a great number of mules and sheep are annually killed by eating it, death following in five to eight hours after ingestion. According to Martius, both this species and *P. nicotianaefolia* are powerful poisons, but the latter in small doses is used in veterinary practice for dysuria in horses and mules, while two other species, *P. officinalis*, Mart., and *P. densiflora*, Mart., possess diuretic properties, and are used in syphilis, rheumatism, etc. He states that their action resembles that of digitalis in its effect upon the heart. There can be no doubt that the plants of this genus possess powerful properties, and are certainly worthy of scientific investigation.

Fruita de Gentio.—This drug consists of small baccate fruits of a yellowish colour, about the size of a filbert, and containing from four to six flat seeds immersed in dried pulp. Each seed is about half-an-inch in diameter, and one-eighth of an inch in thickness; the seed is notched at the base, with the micropyle forming a little projection in the notch; the nucleus is oval, and occupies only a small portion in the centre of the seed; the circumference of the seed, to the depth of one-eighth of an inch, consists of a hollow raised rim, so that the portion of the seed containing the nucleus is oval and depressed. The nucleus is exalbuminous, and consists of two flat, oily cotyledons, with the radicle near the hilum. The cotyledons are tasteless, but the pulp in which the seeds are immersed is extremely bitter. According to Dr. Barnsley, the fruit and seeds are used in the form of powder and tincture as a drastic purge, and are a favourite remedy with the lower class of

Brazilians. He does not know the plant yielding the drug, but the characters above described show that the seeds probably belong to the Cucurbitaceæ.

Japicanga.—This is the rootstock or 'chump' of some species of sarsaparilla. It has but a small portion of rootlets attached; these have a hard woody medullium, a thin dark-brown cortical portion, and are smooth externally. It has no distinct taste. According to Dr. Barnsley it is used in the province of Rio as a substitute for the sarsaparilla of the Amazons. He refers the drug to *Smilax glauca*, Mart. The name Japicanga, which is variously spelt Japecanga, Jupicanga, Inhapecanga, is a generic term for any kind of sarsaparilla in Brazil.

Jarrinha.—This drug occurs in slices about half-an-inch thick, and two inches in diameter; the medullium is about one inch in diameter, and has a radiate appearance owing to the presence of a number of very narrow yellowish woody wedges which have thick white medullary rays between them, and the woody wedges when examined with a lens are seen to be full of large porous vessels. Outside of the medullium is a horny portion a quarter-of-an-inch in thickness, and outside this layer is a soft corky layer of the same thickness. It has the peculiar camphoraceous odour common to several nearly allied species of *Aristolochia*. The taste is slightly acrid, but not bitter. It is certainly the root of a species of *Aristolochia* and is attributed by Dr. Barnsley to *A. cymbifera*, Gom. (Mart.?) He states that the root is very useful for colicky pains, and that it is used as a tonic, and for gangrene. By the natives it is esteemed a sure remedy for snake-bites. It is very abundant in every part of Rio and S. Paulo. Several species of *Aristolochia* are used under the name of Sipo de Jarrinha or de Mil-Homens. According to Martius they are used for the same complaints for which valerian is used in this country, and are considered superior to *Aristolochia serpentaria*.

Pipi.—This drug is a long-branched woody root, about eighteen inches long, half-an-inch in thickness in the upper part, and tapering downwards to one-eighth of an inch. The root is pale brown and smooth externally; a transverse section shows a large white woody medullium, filled with minute pores, but with the medullary rays indistinct, the cortical portion very thin, of a brown colour, and readily scaling off when the root is bent. The taste is slightly bitter, and causes a sensation of tingling when chewed. Dr. Barnsley states that a tincture of the root forms an admirable remedy for chronic rheumatism, lumbago, and muscular paralysis, and that it is much used in the province of Rio by country physicians. Martius refers the plant yielding the root to *Petiveria tetrandra*, Gom. The leaf which accompanied the root is, however, not that of *Petiveria tetrandra*, Gom., but that of some twining plant with opposite leaves—probably belonging to the Malpighiaceæ.

Quina quassia.—This drug is a bark of a greyish colour externally, with a number of short pale brown transverse scars. The epidermis is very thin, and can be readily scratched off by the finger nail, leaving the white portion underneath exposed. The bark is fibrous, but is nevertheless very tough, and breaks with a rather short fracture. When cut transversely with a sharp knife the layer just inside the epidermis (mesophloeum) is seen to be irregular

in outline and much whiter than the inner portion. The taste is intensely bitter. Dr. Barnsley does not know to what order the plant yielding it belongs; but, he having sent a portion of the plant with the barks, I have been enabled (with Professor Oliver's kind assistance) to identify it as the *Picrasma Velosii*, Pl., of the natural order Simarubaceæ. With regard to this bark, which is not mentioned by Martius, Dr. Barnsley states that it is used in dyspepsia and in intermittent fevers, and that he has employed it in the latter with decided success. With the bark he sends a portion of white crystalline powder, which he says was given to him by a native forester and gold miner of the woods of S. Paulo, who was well acquainted with the medicinal herbs of that district, and who stated that he obtained it from this bark. This crystalline powder has been examined by Mr. S. Plowman, who finds it to be chiefly sulphate of quinine with a little hydrochloride. The barks of the Simarubaceæ are not known to yield quinine, hence it is probable that Dr. Barnsley has been imposed upon.

Saponacea.—This is a kind of soap berry, the fruit of a species of *Sapindus*, possibly of *S. divaricatus*, Willd., to which Guibourt refers the soap berries he received from Brazil (*Histoire des Drogues*, 6th edition) and which is the only species mentioned by Martius. Dr. Barnsley states that he has made an excellent tooth-wash from them, and suggests that, perhaps, some species of this berry is used in making the London 'Floriline.'

Tayuyá.—This is a long slender root varying in size from a quarter to one-third of an inch, scarcely branched, brown externally, internally of a paler brown, and full of large pores, which are easily visible to the unaided eye. The cortical layer is not very distinct. The taste is bitter. Dr. Barnsley refers this root to *Trianosperma Tayuyá*, Mart., but Martius describes the root of that plant as being tuberous and turnip-shaped. The leaf sent with the root is apparently that of a *Trianosperma*; but as there are no tuberous roots with the *Tayuyá* received, it is probably the root of another plant of the same genus. An infusion, tincture, or extract of the root is used as a drastic purge. It has properties analogous to *Elaterium*. In the province of Rio it is a common plant.

Timbo.—This drug consists of a very large woody root or prostrate stem, three or four inches in diameter, and much branched. Externally it has a dirty-white colour, with numerous warts scattered over it, and is of a rough aspect, owing to depressions, scars, and a few transverse ridges; the smaller portions are, however, only wrinkled longitudinally. The central portion or medullium of the root is yellowish white, with a number of fine horny concentric rings; the bark of the root is distinct, thick, and starchy, and of the same colour as the medullium. The taste is not bitter. When chewed the root causes only a slight but persistent tingling of the tongue. According to Martius it is the root of *Paullinia pinnata*, L., and possesses acrid and narcotic properties, acting especially on the kidneys and brain; he compares it to aconite and states that the negroes prepare a slow poison from it. Dr. Barnsley is inclined to think that the above-named plant does not produce it, but that it is the root of *Physalis heterophylla*, Nels. The leaves accompanying the specimen being imperfect it is impossible to say what the plant is, but the leaves are more like those of a Sapindaceous than of a Solanaceous plant. It seems

to possess powerful poisonous properties, which may perhaps be worthy of investigation.

Velame or *Braço de Preguiça*.—This is the root of *Solanum jubatum*, Dunal. Through an oversight its description was not given under *Braço de Preguiça*. The root is in somewhat flexuose pieces, externally resembling belladonna root in colour, varying from half to one inch in thickness. Internally the root is woody, the medullium being of a pale yellowish colour, with very numerous medullary rays, which are not visible to the naked eye, but are readily seen with the aid of a lens. The cortical portion is very thin and seems to consist of several extremely thin layers; the outer layer when scraped with the nail or with a penknife shows that the under layers are of a pale lilac grey colour and chalky appearance. This character does not occur in any other root with which I am acquainted, and at once distinguishes this drug. It appears to be almost tasteless. Martius does not mention either *Velamé* or *Panacea* in connection with *Solanum jubatum*, Dunal.

EVERS ON INDIAN MEDICINAL PLANTS (*Continued from page 255*).—Surgeon B. Evers continues, in the *Indian Medical Gazette* of June 1, his notes on Indian medicinal plants as follows.

Thenetia Bark.—Bark of the *Thenetia neriifolia* (N. O. Apocynaceæ). A plant of the West Indies, but now seen in almost every garden in India. It is commonly known as the 'exile' or yellow oleander. The antiperiodic properties of this plant were first noticed, it is said, by M. Descourtilz. Drs. Bidie and Shortt's experiments with the drug are confirmatory of that writer's observations. I have made trial both of the tincture and the powder of the bark, and can bear testimony to the value of the drug as a febrifuge. One hundred and twenty-one cases of ague were treated with the tincture, and twenty-one with the powder (in doses of a half to one grain three times a day), and in all the results were most satisfactory. The most obstinate cases have yielded to the drug in from five to eight days; with many of these patients quinine had been previously tried in vain. Administered in the hot stage of an ague-fit, the drug rapidly reduces the force and frequency of the pulse, and appears to hasten on the sweating stage. Great care, however, is necessary in its administration, for it belongs to the class of acronarcotic poisons. The symptoms that indicate that a sufficiency of the drug has been administered are, dryness and numbness of the tongue, dryness of the throat, and thirst; most of the patients complained of these sensations in from three to five days. It is a most powerful drug, and not one therefore to be entrusted to everybody; but it might be more extensively employed in dispensary practice, I think. From the kernels of the seeds 'a clear, pale, amber-coloured, slightly viscid, acrid oil' is obtained. The natives recommend the oil as a cathartic, but Dr. Shortt reports that hypercatharsis results from its administration. A case of poisoning by one of these kernels is recorded by Dr. J. Balfour in the *Madras Journal of Literature and Science* for 1857.

Clitoria Ternatea (N. O. Leguminosæ).—A very beautiful garden-plant, commonly known as the mussel-shell creeper. Drs. Shortt and Dymock report that the powder of the roasted seeds acts as a purgative; and they recommend that it be given in combination with the acid tartrate of potash. The

dried seeds, powdered and rubbed up with water, form a milky mucilaginous compound of very active purgative properties; much too strong in fact for ordinary purposes. The powder of the roasted seeds is not so active; administered in drachm doses it produces from four to five copious evacuations; it causes a good deal of griping. Combined with the acid tartrate of potash and ginger, it is a very good substitute for the compound powder of jalap; it is a less nauseous drug than jalap. Mr. Moodeen Sheriff recommends an infusion of the root-bark as a demulcent in irritation of the bladder and urethra; it is also said to act as a diuretic. A syrup of the blue flowers has been recommended as a colouring agent by Dr. Haines. Ainslie attributes emetic properties to the root, and considers it useful in croup cases. Sir W. O'Shaughnessy, however, states that, although he has employed the root extensively to ascertain its alleged emetic properties, he has never found it act as such. The alcoholic extract however (in doses of from five to ten grains), he remarks, acts as a brisk purgative; 'but as griping, tenesmus, and feverishness often result from its use,' he does not recommend its administration.

Urginea Indica (N. O. Liliaceæ).—A sherbet made of the bulbs is considered by the Gonds as almost a specific in enlargement of the spleen. I have given the drug several trials, and cannot say that it has been successful. It certainly possesses diuretic properties, and we can readily understand therefore how it might afford relief in the dropsy attendant upon visceral enlargements. Mr. Moodeen Sheriff states that, in doses of from ten to twenty grains, it is a more powerful diuretic than even the officinal squill. Dr. Oswald has employed it (in five-grain doses) as an expectorant in bronchitic affections. The burnt bulb bruised is considered a valuable application in the affection known as 'Ignipeditis.' The drug is said to be largely used by farriers for horses, in cases of strangury and fever.

Celastrus Paniculata.—(N. O. Celastraceæ.) The oil obtained from the seeds is a most powerful diaphoretic administered internally; and applied externally, it acts as a vesicant. The native practitioners obtain the oil by distillation. A ghurra is buried up to its neck in the ground, and above this is placed another ghurra with its bottom perforated; 'the seeds with benzoïn, cloves, nutmegs, and mace,' are placed in the upper vessel, its mouth is closed, and heat is then applied; the oil now rapidly drains from the upper vessel into the lower one. A considerable quantity of the oil, however, is wasted in this way, and I have preferred therefore obtaining it by expression, a common oil-mill being used for the purpose. The oil thus obtained possesses more active properties than that obtained by distillation. I have not found it necessary to combine cloves or other aromatic with the pure oil. The oil is that known as 'oleum nigrum.' It was considered by the late Dr. Herklots, 'a sovereign remedy in beriberi.' I have found it useful in the treatment of dropsy. It is an extremely useful application to rheumatic swellings, and is frequently used for this purpose by the natives. It should not, however, be applied too often, as vesication results. Sir W. O'Shaughnessy states that this oil 'does not differ in any sensible degree from the empyreumatic products of the common fixed oils, containing naphtha and other carburets of hydrogen.' 'Large quantities would doubtless yield paraffin and creasote,' Ainslie informs us that 'the bitter and brownish seed is prescribed

in conjunction with other ingredients, in cases requiring stomachics, and in those diarrhoeas that are supposed to arise from want of tone in the abdominal viscera.' In January last I resolved to give the oil a trial in the treatment of leprosy. Nine patients presented themselves for treatment; I administered the oil (in five-minim doses, with mucilage, three times a day) internally, and applied it externally at the same time. We are all aware that with lepers, sexual vigour is either very much impaired, or altogether lost; this condition appears to be connected with the anæsthesia present; *i.e.*, the more complete the anæsthesia, the greater the loss of virile power. After the oil was administered, there appeared to be a partial restoration of sexual vigour, evidenced by erections and nocturnal emissions, and this led me to hope that benefit would accrue to the system generally also. After two months' trial, however, I must confess, that the oil possesses no power to arrest the morbid changes in the skin.

MAISCH ON POTENTILLA REPTANS.—In an article on potentilla in the *American Journal of Pharmacy*, vol. v. 109, Mr. Maisch writes as follows on the *Potentilla reptans*.

P. reptans, Lin., creeping cinquefoil, is a European and Asiatic plant, growing in damp localities. Its thin, creeping stems bear solitary flowers on long peduncles, and are of a golden yellow colour; the leaflets are elliptical to oblong-ovate, sharply serrate, bright green and slightly hairy above, paler and somewhat pubescent beneath. The taste of the root and herb is sweetish and astringent. This plant (or the tormentil) was probably the *pentaphyllon* of the ancients.

As far as may be judged from the taste, and from the few published chemical experiments, all the species enumerated before contain some tannin, upon which the comparatively feeble medicinal properties mainly depend. The indigenous *P. canadensis*, Lin., the common cinquefoil, or five-finger, resembles the former in taste, and, like them, may be supposed to act like a mild astringent. In the January number of the *Charleston Medical Journal and Review*, however, this plant is highly recommended for other purposes. Dr. Wm. Hauser, of Bartow, Jefferson county, Georgia, writes of it as follows.

'It is the best and most powerful sudorific I have ever found. And like all of its class, it is, under certain circumstances, diuretic also. Dr. Edwin Le Roy Anthony, son of Dr. Milton Anthony, founder of the Medical College of Georgia, assured me, many years ago, that he had cured gonorrhœa with it. But my purpose, in this short article, is to ask the attention of the medical profession to it in the treatment of peritonitis of any kind, but especially puerperal peritonitis. In a large practice of more than twenty years, I have never found anything, nor all other things combined, to equal this simple plant in the treatment of this exceedingly painful, dangerous, and sometimes stubborn disease. I have never failed with it once in all this time, to the best of my recollection. A recent case that gave much trouble and anxiety to two of my honoured medical brethren has brought it afresh to my mind, though I have not been in practice myself for eight years. My method with it is simply this. Make as strong a decoction of the plant (leaves, vines and roots) as possible, and give the patient, at any stage of the case, large draughts of the tea, as hot as she can

drink it, every half hour, or oftener, till she be thrown into full perspiration. All pain and fever will soon be gone, and then you have the entire mastery of the case.'

Some years ago, Dr. Richard Moore, of Sumter District, South Carolina, called attention to this plant as an efficient and useful remedy in the treatment of chronic colds, threatening phthisis; he used it in the form of decoction.

KRAUS ON CREAM OF CAMPHOR.—In an inaugural essay written for his degree of Graduate in Pharmacy of the Philadelphia College of Pharmacy, Dr. O. Kraus states that cream of camphor prepared according to the following formula has been used successfully in inflammatory affections of the throat, also catarrhal and other pectoral complaints of children, it having the advantage over the linimentum ammoniæ, U.S.P., of being free from all oily matter.

Take of—

White Castile soap (in shavings)	3jss
Camphor	3ij
Carbonate of ammonium	3ij
Water	Oiv
Tincture of opium	f3j
Oil of origanum	f3j
Alcohol and oil of turpentine, of each a sufficient quantity.	

Dissolve the soap shavings in three pints of water and stand aside. Dissolve the carbonate of ammonium in the remainder of the water, and mix the two solutions. Then add the camphor, previously reduced with alcohol to a thin paste, and agitate briskly. Oil of turpentine is then to be added in sufficient quantity, to bring the mixture to the consistency of cream, on brisk agitation; after which the tincture of opium and oil of origanum are to be added,—then the whole is to be thoroughly mixed.

As it is readily absorbed by the skin, it may be applied by the hand, or by saturating a piece of flannel and placing over the affected part.

GRASSET ON EMETIC MEDICATION.—M. Grasset's thesis on this subject is thus analysed in the *Archives Générales de Médecine* for June, 1875.

The most recent experiments tend to prove that for the reflex act of vomiting there exists a vomitive centre in the medulla oblongata, in the vicinity of the respiratory centre. The vomitive centre may be directly excited either by an impression imparted by different nerves of general sensibility, as the pharyngeal nerves, or special, as those of the sight and smell, or even by a cerebral irritation. In vomiting of gastric origin, the irritation would be transmitted by the pneumogastric, and not by the great sympathetic. Emetic agents may be divided into three classes, according to their mode of actions in the act of vomiting. (1) The peripheric emetics excite vomiting by exciting the extremities of the pneumogastric nerve; the excitement may occur at the moment of ingestion, if the drugs be absorbed by the digestive passages, or at the moment of elimination by the intestine, if the drug have been ingested into the blood. Ipecacuanha belongs to this class of emetics. (2) The central emetics, of which apomorphia is the type, cause vomiting by directly exciting the vomitive centre. (3) Mixed emetics cause vomiting by simultaneously exciting the peripheric extremities of the vagus nerve and the vomitive centre itself; such as tartar emetic. Eme-

tics, besides the property of bringing on sickness, also possess a certain number of other actions. They generally have a local irritant action on the skin and the mucous membrane; they modify the respiration, the circulation, and the temperature, and increase the secretions; they diminish the excitability of the striated muscles and paralyse them. It is by utilising these different properties of emetics that, by varying the doses, evacuant, irritant, local hyperæmic, hypokinetic, antispasmodic, antiphlogistic, perturbing, or expansive action can be obtained.

CASPARI ON NITRATE OF SODA IN DYSENTERY.—Dr. Caspari (*Bulletin Général de Thérapeutique*, June 30, 1875) recommends nitrate of soda in large doses for the treatment of acute dysentery. This salt was largely employed by Rademacher, who asserted its superiority to all other antidiysenterics. Caspari's experience is chiefly derived from the Frankfort Hospital, where 30 per cent. of the cases, in the autumn of 1871, consisted of acute dysentery. The remedy is as effectual in the rectal form of the disease as in the intestinal variety; when there is reason to believe that the small bowel is much involved, smaller doses ought to be given than when the inflammatory mischief is limited to the lower end of the large intestine. From three to six drachms of the salt may be administered in the course of twenty-four hours, in divided doses; the solution should always be given warm.

E. BUCHANAN BAXTER, M.D.

OBSTETRICS AND GYNÆCOLOGY.

SMITH ON QUININE AS A STIMULANT TO THE PREGNANT UTERUS.—Professor Albert H. Smith, of Philadelphia, in the American Supplement to the *Obstetrical Journal*, offers some practical conclusions of great interest. He thinks that, when the uterus is in a quiescent state, quinine has no power in itself to excite uterine contractions. As to the effect of quinine upon contractions of the uterus developed prematurely from accidental causes, in abortion or early deliveries, in five instances fifteen grains of quinine were administered after the process had advanced beyond the possibility of arrest and the pains were recurring with regularity; in none of these instances was any increase in the frequency or efficacy of the contractions observed, nor when there was hæmorrhage was there any lessening of the flow. When the uterus is in normal labour at full period of gestation, then quinine plays its legitimate part as an aid to parturition. From observations made in forty-two cases, 'in the ordinary run of every day practice, where after actual labour-pains had begun, fifteen grains of quinine were administered in one dose. 'In every case within fifteen minutes there was a decided increase in the frequency and vigour of the contractions, a rapid progress of the labour, and where there was no obstruction a speedy termination.' The labours were terminated with surprising and gratifying rapidity. Cases in illustration are given. The conclusions at which he has arrived are, that quinine increases the activity of the normal uterine contractions; the pains become more frequent and more intense, the expulsive power being greater, while the yielding of the circular fibres of the os is more prompt, the con-

tractions maintaining their proper intermittent character, the relaxation and rest in the interval being complete, showing in this respect an entirely different action from the continuous spasmodic contraction caused by ergot. It promotes permanent tonic contraction of the uterus after the expulsion of the placenta. It diminishes the lochial discharge to a normal standard. Its use is followed by less after-pains than usual in a majority of cases. It reduces the frequency of the mother's pulse, and relieves the nervous demoralisation so often seen in the first stage of labour. Given during parturition it never disturbs the brain or causes its usual unpleasant effects, even in patients who at other times are very susceptible to its influence. To sum up the conclusions:

1. Quinine has no inherent property of stimulating the gravid uterus to contraction; being inert as to any effect upon the womb in a quiescent state, and having no decided action in accidental labours at any period of gestation.

2. To its property as a general stimulant and promoter of vital energy and functional activity, and to that alone, is due its influence upon the uterus in normal parturition; producing then no action peculiar to itself, but merely increasing the power of the uterus to expel its contents by its own natural method, converting what is a defective or even pathological action into a simple physiological process.

By availing ourselves of this power, we may, by administering full doses of the sulphate of quinine at the outset of labour, favour the rapid and safe termination of what might otherwise be a tedious and exhausting work.

DEPAUL ON EXTRA-UTERINE PERITONEAL PREGNANCY.—Professor Depaul (*Archives de Toxicologie*, July, 1875) concludes a series of eight articles on the diagnosis and treatment of this condition.

Surgical interference, on account of the uncertainty of the diagnosis, can only be usefully resorted to on rare occasions before the fifth month, but after this the indications alter. It being possible that the foetus may be developed to the full time, due consideration must be given to its interests as well as the mother's. At what period should we interfere surgically? It is scarcely prudent to wait until the end of the ninth month, but rather the end of the eighth month when, the foetus being able to sustain a separate existence, the interests of both mother and child will be best consulted. This applies to cases of extra-uterine peritoneal pregnancy only, not to tubal, where the risk of rupture of the cyst is much greater.

He cites nine cases, collected from various sources, in which gastrotomy was performed, seven of the infants having been extracted living, and four of the mothers having recovered.

In certain cases where the cyst is low in the pelvis, operation *per vaginam* is less dangerous than by abdominal section. After the death of the foetus severe complications may arise, such as rupture of the cyst, fatal peritonitis, inflammation and suppuration in the cyst, with septicæmia as a consequence. Four illustrative clinical cases are given in detail.

Where the abscess tends to open by the abdominal wall, expulsion of the foetus may be facilitated by means of incision or caustic, the latter being preferred where it is feared that adhesions have not taken place between the cyst and abdominal wall.

If the abscess point *per vaginam*, an incision may equally be made to expedite the expulsion of the fetus.

The cyst may also open into the large intestine or bladder. When the abscess bursts spontaneously, whether it be by the abdominal wall or by the vagina, the openings are often narrow and insufficient, the putrid matters stagnate, and the patient's state becomes anxious. Frequent injections into the cyst should be adopted, and if the bistoury be used, great care must be taken not to incise beyond the limits of adherence between the cyst and the neighbouring parts; death has often resulted from neglecting this precaution. Where the extraction of a living child is attempted, opening the sac by incision is generally requisite; whereas, when there is no immediate hurry, the fetus being dead, and we are not certain about adhesions, the use of caustic in successive applications is safer, the gravity of the operation depending upon opening up the peritoneal cavity. Where the bistoury is employed, there is always danger of cutting down on to the site of the placenta; where caustics are used this danger is eliminated, and as it is generally impossible to extract the placenta or remove the cyst immediately, another serious risk is avoided, the placenta being allowed to come away spontaneously.

FILLIETTE ON UTERINE HÆMORRHAGE OCCASIONED BY A FIBROUS POLYPUS; TRANSFUSION OF BLOOD; DEATH DURING THE OPERATION.—Dr. A. Filliette, in the *Archives de Tocologie*, July, 1875, records a case. The patient, aged forty-nine, had a sanguineous discharge extending over three years, but objected to any examination being made until, when too weak longer to resist the effect of the hæmorrhage, she tardily consented. Her state at this time was one of extreme exhaustion, fainting occurring on the least movement. The extremities were œdematous, the patient blanched and cold.

A polypus of the size of an apple was detected on examination; it was removed, slight traction and a blunt-pointed bistoury being sufficient to accomplish the object; not a single drop of blood was lost either during or after the operation. Soup, wine, brandy, iron, and everything likely to relieve her exhausted condition were given, but frequent faintings becoming more and more prolonged, a very distressing feeling of suffocation and other evident symptoms of impending dissolution suggested the idea of transfusion, which was accordingly performed. The median cephalic vein of the left arm being opened, a trocar was inserted. The husband supplied the blood, which was received into the chamber of M. Mathieu's apparatus and injected direct into the vein of the patient, who rallied from her previous insensibility, opened her eyes, looked at the operators, cried out, 'Give me the basin, etc.,' and then fell back dead, the respiration ceasing at once. Efforts at resuscitation were of no avail.

SMITH ON THE USE OF PESSARIES IN THE EARLY MONTHS OF PREGNANCY.—In the April American supplement to the *Obstetrical Journal*, Dr. A. H. Smith has contributed an important paper showing the influence of previously existing displacement upon the retaining capacity of the uterus in the early months of utero-gestation. He disbelieves in retroflexion as an original factor in the production of early miscarriage, this condition causing, as a rule, dysmenorrhœa and sterility; retroversion on the contrary, he considers, to be the primary condition, and cites three cases in point where dis-

tinct version but no flexion existed. The employment of a modified Hodge's pessary effectually relieves this condition.

He refers to a point of clinical experience of great interest 'which has presented itself too frequently to be a mere coincidence,' that 'when patients who have previously had children have become pregnant while wearing pessaries, they have observed that the sympathetic nausea has been greatly diminished.' In some cases it has made a vast difference in the condition of the patient in this respect from that of previous pregnancies.

TRASK ON INJECTIONS OF TINCTURE OF IODINE INTO THE CAVITY OF THE UTERUS IN HÆMORRHAGE AFTER DELIVERY.—In a paper read before the New York Obstetrical Society (*American Journal of Obstetrics*, February, 1875), Dr. J. D. Trask contrasts the effects of tincture of iron and tincture of iodine (used in the proportion of one of tincture to two of water) in cases of *post partum* hæmorrhage where the ordinary means for arresting it have been tried and failed. He contends that the iron is used as a means of closing the mouths of the vessels by coagula when contractions can no longer be provoked; whereas the iodine solution excites the apparently extinguished reflex action in the uterus, and stimulates the muscular fibres of the womb to contract. Its employment is free from the evils incident to the employment of iron; its antiseptic properties are of service in counteracting the tendency to absorption of septic matter into the system after delivery. As an excitomotor agent, iodine is probably at least equally good, while incapable of causing the formation of thrombi in the uterine vessels, and thus may be used earlier than the iron.

CAMPBELL ON UTERINE DISPLACEMENTS.—Dr. H. T. Fraser Campbell, of Georgia, in the *Atlanta Medical and Surgical Journal*, discusses at some length the effect of postural treatment, combined with pneumatic pressure, in uterine displacements. The object of his report, to use his own words, is 'to establish among gynecologists generally, in this as well as in foreign countries, pneumatic pressure, as it can be evoked and utilised in the genu-pectoral position, as a constantly available and powerful instrumentality; not only for occasional use, in unusual and difficult cases of displacement, but for daily application also, in the mildest forms and degrees of uterine malposition.'

This ready method of 'self-replacement' is accomplished by the patient herself, admitting air into the vagina whilst resting in the genu-pectoral position. It should be done nightly. In many cases of early pregnancy the method seems to be of great value in relieving the many distressing symptoms caused by the increased bulk and weight of the impregnated uterus.

ROSS JORDAN ON THE DIAGNOSIS AND TREATMENT OF DISPLACEMENTS OF THE UTERUS.—In this paper (reprinted from the *Birmingham Medical Review*) the author lays stress upon the importance of diagnosing uterine displacements, in place of allowing patients to go on suffering for years without ever resorting to an examination in order to determine whether treatment will be of any service; and this can only be effected by means of a physical examination, subjective symptoms being often very deceptive. He contends that the only rational plan

of treatment is mechanical. In retroversion a Hodge's pessary will often prove sufficient; but in retroflexion an intra-uterine stem will generally be needed. He advocates the employment of Simpson's galvanic stem in cases of acute flexion, with a view to remove the atrophy of the muscular tissue at the angle of flexion.

EIDAM ON A CASE OF RUPTURE OF THE SYMPHYSIS PUBIS DURING PARTURITION.—Dr. Eidam describes this case in the *Berliner Klinische Wochenschrift*, no. 28. The patient, a multipara, aged thirty, was admitted at 5 P.M. on April 10, 1875, the membranes having ruptured. The pains were weak and far between. At 9 A.M. on the 11th, the right shoulder presenting, turning was accomplished, but delivery was not effected until 6 P.M. On examination some days later, as localised pain was complained of, a distinct rupture of the pubic symphysis was detected. A pelvic girdle was applied, and the patient progressed favourably. A month afterwards on examination the symphysis was found to be unusually thick, but quite firm. The patient was discharged convalescent.

ARTHUR W. EDIS, M.D.

PSYCHOLOGY.

MANN ON ERGOT IN THE TREATMENT OF INSANITY.—In the *New York Medical Record*, June 26, Dr. Edward C. Mann gives an account of the use of ergot in asylum practice.

Some years since Dr. J. Crichton Browne, the medical superintendent of the West Riding Asylum for the Insane, wrote an article advocating the use of ergot in the treatment of mental diseases; and since that time a few members of the profession have availed themselves of its use. The majority of the profession in America are, however, to-day ignorant of the great therapeutic value which this medicine possesses when used with discrimination in the treatment of mental diseases.

It was proved years ago by the researches of Brown-Séquard and others, that ergot possessed the power of producing contraction in the vessels of the spinal cord; and accordingly it occurred to Dr. Browne that it might possess a similar control over the vessels of the brain, and might thus be made to modify or remove the active cerebral congestion which is an attendant upon many phases of insanity. Upon thorough investigation he found that there were three varieties of insanity in which it was eminently useful, namely, recurrent mania, chronic mania with lucid intervals, and lastly, epileptic mania. Dr. Browne, and other observers who have adopted the use of ergot in the treatment of insanity, have found that in the varieties above mentioned it was almost uniformly successful in reducing excitement, in shortening the attacks, in widening the intervals between them, sometimes in preventing their recurrence entirely, and in warding off the dangerous stage of exhaustion by which maniacal excitement is so often succeeded. The way in which ergot operates upon the contractile coats of the vessels has been proved to be by its influence upon the non-striated muscular fibres and cells contained in their coats, thereby exercising a controlling power over the calibre of the intracranial vessels. In the three varieties of insanity before referred to—in recurrent mania, in chronic mania

with lucid intervals, and in epileptic mania,—we find that the lesion consists essentially in cerebral hyperæmia. We find, although the symptoms differ in these three forms of mental disease in which ergot is useful, that there are present in each form increased arterial pulsation, flushing of the face, suffusion of the eyes, dryness of the mouth, and cephalalgia. The disappearance of these phenomena in the intervals of the paroxysms, proves that they are dependent upon functional and not organic changes in the brain, in which latter case we should not expect to find any marked efficacy from the use of ergot; and, indeed, we often meet with instances in which the controlling power of ergot is after a time lost, as organic degeneration gradually follows as a sequence upon repeated attacks of mania. In epileptic mania it will be found that a combination of bromide of sodium with ergot will materially aid the action of the latter in widening the intervals between the fits, and in modifying the attacks when they occur. This combination will also often arrest paroxysms in the incipient stage. The stage of excitement which often precedes and ushers in the attack, and which sometimes succeeds it, is markedly diminished by the combination of the bromide of sodium and ergot. The bromide of sodium will be found to be preferable to the bromide of potassium, as it is pleasanter to the taste and causes less constitutional disturbance than the latter when given in large doses. Dr. Browne remarks that 'it is in epileptic mania that ergot has been found pre-eminently valuable in allaying and abolishing excitement, and in conducting to a healthier tone of mental action. In the outbursts of violent agitation, which precede or follow a fit or group of fits, which occasionally take their place, and which have been pronounced by all authorities to be of so dangerous a character, it exerts a prompt and energetic effect. We may presume that these outbursts are dependent upon a want of equilibrium in the intracranial circulation, primarily disturbed by the epileptic seizure or condition. The distension of the vessels, which succeeds their spasmodic contraction and produces coma, subsides so far as to allow the resumption of activity by the higher centres, but only in an irregular and distorted way. And we may presume, further, that the soothing and rectifying effects of ergot are due to its power of re-establishing that disturbed equilibrium.'

A thorough trial of the ergot treatment has satisfied the writer of its efficacy in asylum practice.

LEY. ON INTEMPERANCE AS A CAUSE OF INSANITY.—Mr. Ley, in his admirable report on the Prestwich Asylum, states, in reference to intemperance as a cause of insanity, that: 'In the admissions of the past year, although intemperance figures largely in the table of causation, it is probable that its influence as a producing agent of mental disease has been under-estimated. The extent to which it has acted as an immediate cause of the malady can be only partially arrived at, as many of the admissions are brought and left at the asylum without any history, and in these and other instances the cause of the mental disease has to be determined from the character and form which the malady assumes. [How is that done?] But even if all doubtful cases be excluded from our calculations, there still remains a large percentage both of males and females in whom intemperance, if not the sole cause of the insanity,

was a most important auxiliary. The greatest number of admissions in this asylum always occurs during the month or six weeks following the Lancashire Carnival, Whit-week. In the month of June last year no less than seventeen males and four females were admitted suffering from mania, induced by excessive and persistent drinking. Of these, four had attempted suicide, and had extensive wounds of the throat on admission. These instances of the direct effect of intemperance occurred, with scarcely an exception, among a class who were in receipt of good wages from regular employment, and who, therefore, had not the excuse of the half-starved and ill-clad poor. There is no disguising the fact, that among the labouring classes insanity has of late years increased by a reckless course of inebriety, favoured in a great measure by a plethora of money and an abundance of leisure. In Lancashire, as probably elsewhere, high wages and short hours of work have not been by any means an unmixed benefit to the recipients. More money has been available for the purchase of drink, and more drink, as a natural consequence, has induced greater physical and moral deterioration.

CLOUSTON ON THE PATHOLOGY OF GENERAL PARALYSIS OF THE INSANE.—Dr. Clouston, in his Morisonian Lectures on Insanity for 1873 (*Journal of Mental Science*, July, 1875), comes to the following conclusions respecting the general paralysis of the insane. 1. It is a disease of the grey or cellular parts of the nervous system. 2. It illustrates better than any other disease with which we are acquainted the tendency to that progressive degeneration which specially characterises the diseases of the nervous system; for it not only goes on steadily from bad to worse, but advances into ganglia, such as the retina and sympathetic, that have no continuity with the brain except by white fibres. 3. The disease is in all its symptoms—mental, motor, sensory, and vaso-motor—chiefly characterised by symptoms of weakness of power and want of co-ordination; it is, in fact, essentially a dementia and paralysis from the very first. 4. The stage of maniacal excitement of the disease is accompanied by such increase of temperature and symptoms of congestion of the brain as strongly point to its being the result of a process, either inflammatory or closely allied to it, not affecting the meninges only, but more especially the cortical substance. 5. The excitement of the congestive attacks is accompanied by stasis of the blood in the capillaries of the pia mater, as shown by the tendency to apoplexy and false membranes. Those false membranes seem to hold an intermediate position between the products of œdema and of inflammation. 6. The origin of the disease is usually in exhaustion or irritation of the brain-cells that regulate and control the co-ordinating centres of mental function and motion—in other words, that element of the nervous centres that has the very highest and most important function of all; this irritation or exhaustion sets up a diseased degenerative process in them, which slowly but certainly spreads to every group of cells in the nervous system with which those higher centres have direct relation. 7. So far as our present pathological facts go, we have more reason to suppose that the disease begins in the outer layer of the cortical substance of the brain than in any other part, but that it may first affect different convolutions in different cases. Dr. Clouston thinks that there are two causes which above all others produce

the disease; these are intemperance and sexual excess. The one causes irritation, the other exhaustion, of the brain. The disease prevails, however, among a class who add to these two things, great muscular exertion, namely, the coal and iron workers. The disease is more than thrice as common in Durham and Glamorgan as in the rest of England. In such a class, therefore, three of the very strongest causes of exhaustion and irritation of the brain are applied at once.

ATKINS ON THE MORBID APPEARANCES IN A CASE OF ACUTE INSANITY.—Dr. Ringrose Atkins reports (*Journal of Mental Science*, July, 1875) the case of a man aged twenty-three, who was admitted into the District Asylum, Cork, having been transferred thither from the South Infirmary, of which he had been an in-patient for a very short time for chest-symptoms. He was perfectly incoherent, knew nobody, and was unable to answer a question rationally. His respiration was hurried and shallow, his lips dusky, and cough troublesome. He only took food under pressure. He sank and died in about a week from the commencement of the mental symptoms. The body was much emaciated. The skull was very vascular. The dura mater was smooth, and during its removal a quantity of dark liquid blood escaped from the distended sinuses. A small quantity of fluid was present under the pia mater, the vessels of which were intensely congested and distended with blood. There was no lymph, and no adhesions. Both lungs were studded throughout with miliary tubercles; the left lung was highly engorged with a vomica in its apex, and the right lung was greyish.

The following appearances were observed. 1. Frontal Lobe.—Many vessels were packed with blood-corpuscles and dilated; but the majority were empty. Outside the walls, and adhering to them, in numerous cases, was a bright yellow exudation, somewhat granular; this was chiefly in vessels the walls of which were extremely thin. The outer fibrous coat of many of the arterioles was thickened and corrugated without exudation. 2. Parietal Lobe.—Many vessels passing from the pia mater to the cortex were crowded with yellowish blood-corpuscles, but many were empty. Numerous minute extravasations were seen between the pia mater and brain, chiefly where the pia mater dipped down into the sulci between the secondary and minor convolutions. No extravasations were seen in the brain itself, and the yellow exudation was less here. Many arterioles had their coats thickened, and in several minute thrombi occupied their calibre. 3. Occipital Lobe.—The same appearances were present here in greater or less degree. The cells and neuroglia were perfectly healthy. Dr. Atkins thinks that the mental derangement was due to congestion caused by the condition of the lungs. The left lung was gorged and the vessels plugged, which must in turn have produced an almost similar condition of the cerebral vessels, and hence, as a consequence, through disturbance of nutrition of the nervous tissues, the mental disorder.

HUREL ON PRISON INSANITY.—Dr. A. Hurel has analysed fifteen cases of insanity occurring in prisoners, who were on this account transferred from the central prison of Gaillon to the asylum at Eyreux (*Annales Médico-Psychologiques*, March and May, 1875). Of these fifteen, three were cases of mania, three of melancholia, three of dementia, two of

general paralysis, and one of epileptic insanity, while in three the insanity was feigned. Dr. Hurel considers them with a view of ascertaining whether the insanity can be charged to the imprisonment. As to this, he tells us that in two patients insanity was noticed on their admission into the prison; in a third it was apparent on the third day after admission. The two former were the subjects of general paralysis, the latter of epileptic insanity. A fourth, whose insanity was melancholia, with delusions of persecution, became insane in consequence of his conviction. Another showed symptoms of mania almost immediately after admission, and a sixth was in a state of senile dementia. In six cases the insanity appeared at some distance from the time of admission. One had shown signs of melancholia before condemnation; in another it may have been due to the trial and conviction. A third was a notorious drunkard, and a fourth was always addicted to vile habits and crimes. In two alone of the twelve the incarceration seemed the cause of the mental disorder. Of the whole number of prisoners, the proportion of those transferred as insane in seven years was only 2 in 1,000. M. Hurel speaks strongly of the necessity of separating epileptic persons from other prisoners, and also from ordinary insane patients, and quotes Dr. A. Foville, who thinks that they require a kind of intermediate establishment, half-prison, half-asylum.

TOXICOLOGY.

KUYKENDALL ON CANNABIS INDICA.—In the *Philadelphia Medical and Surgical Reporter* of May 29 is a communication on personal experience of the effects of cannabis Indica, by Dr. G. B. Kuykendall. He writes: A short time since I procured a new lot of the purified extract of cannabis Indica; and, being desirous of using it in the case of some neuralgic patients, I thought I would test its strength before prescribing. I had many times before tried other lots, but never experienced any effect, more than a slight exhilaration. On the present occasion I opened the jar a short time before dinner, and noticed that the extract had a fresher appearance and a stronger narcotic smell than any I had previously seen. With my pocket knife I took out, I suppose, a grain, certainly not more than that amount. It was observed to have, in a remarkable degree, that acrid tobaccoish taste common to most of the narcotic weeds. About half an hour afterwards I was at the dinner-table, and we were all laughing and jesting, and enjoying our meal with more levity than usual, I taking lead in the merriment. I was just about finishing dinner, when suddenly I felt a thrill pass through me, the room and the dining-table seemed to rise up and swing, or

float about. Then there was a sensation of lightness and dreaminess connected with everything. I had been conversing, but in the beginning of these sensations had leaned upon my elbow on the table, which attracted the attention of my wife, who asked what pained me. I answered that there was no pain, but that I experienced a peculiar kind of sensation which I hoped would soon pass away. Summoning up my will, I arose and walked into the parlour, and took a seat, and tried to compose myself; but the sensations continued to come on. For a few seconds after the first thrill, I thought all was going to pass off, but now the symptoms were increasing in intensity. I arose and went to the glass to look at myself, and to notice the appearance of the pupils of my eyes. I remember distinctly that they were perfectly natural, neither dilated nor contracted, but my face was very pale—from fear, I think, mostly, as the sensations I experienced were so peculiar that they alarmed me. Up to this time I would not believe I was under the influence of cannabis. My condition rapidly grew worse—worse, I say, for my sensations were of the most disagreeable and horrible nature possible. I felt as if reason were being hurled by violence from its throne. Sensations and states of consciousness, rather than ideas, were wildly passing through my mind. I called for an emetic. While it was being prepared, I was all the time becoming more and more restless and agitated. I arose and walked out into the hall, and then thought to myself, what is the use of my running around like a wild man, and returned and sat down in my chair, but could not be easy. The emetic was brought, and I swallowed it—nearly half an ounce of fluid extract of ipecacuanha.

By this time my condition was awful in the extreme. My own voice sounded strangely to me, and seemed to startle me when I spoke, while the voices of those about me sounded as if obscured by a gauze or veil over my senses; the sounds seemed far off, dreamy and unreal. I was beginning to have a sort of double or even triple consciousness. It seemed as if I were living three lives at once. Anything spoken to me immediately seemed to have been an age ago. The few movements I made were governed by the will, and yet they seemed automatic, as I could not feel myself move. Indeed, I seemed to have lost my body and become all dreamy imagination. I moved occasionally, but had no physical sense of doing so. After swallowing a quantity of warm water, I unbuttoned my vest, but did not seem to touch the buttons, and yet I must have had some sense of feeling, for I did not watch the movements of my hands. I saw with my eyes; but nothing was natural. I looked at the wall and the objects around; an impression was made upon the sensorium, and the visual impression seemed hurried off at lightning speed, then immediately the same impression was made with some different phase, while an age almost seemed to intervene between these changing states of consciousness. A moment seemed an eternity; the most terrible impression came over me. My mental states and sensations seemed to move in circles. Rapidly, smoothly, and noiselessly, I seemed to be carried down a psychical maelstrom. The voices about me sounded in my ears as a dull, dreamy droning, although I understood all that was said. Dissolution seemed imminent. I still could get out, by great effort of the will, as it seemed to me, short sentences; but when I spoke only three words, before the third was uttered the first seemed

to be far in the dim distant past. When I spoke, I seemed as if started from a dream; a flash of light came before my eyes, and everything seemed to rise up suddenly before me. I remember that the floor seemed to me to be sloping up before me, and pitching off behind. I now laboured fully under a triple consciousness, two dreamy and unreal, and underlying these, apparently, was my real self, obscured by the intoxication upon me. I seemed to pass successively from one state of consciousness to another. When in one state, I remembered the successive changes of sensation in that state that had occurred previously. Noise or movements seemed to transfer me immediately to another state of consciousness. In this new state, the recollection of the sensations in the other state were dim and soon forgotten, while I seemed to remember back in the line of consciousness in which I then was.

Through all these wonderful psychical phenomena, I preserved a good degree of rationality. I remember distinctly to have reflected, 'What is my condition?' 'How long is it going to last?' I told the attendants to get mustard and warm water. When they were going to give me lemonade, I tasted it, and said, 'It is not sour enough; put in citric acid, it is the acid that is the antidote to the hasheesh.' During all this time I was sitting stupidly in a chair, before the stove, making but few movements. I lost all correct idea of time; a moment seemed an age; I thought they never would get the mustard and water for me. After drinking the mustard mixture I called for warm water, and thought they would never get it ready, and called for it, as I thought, about once every fifteen minutes, supposing they had forgotten to bring it. My wife says I spoke incessantly, repeating my request as fast as I could. As I recollect now, it seems to me I called only three or four times for anything, and then at long intervals. I still seemed to be sinking down into the maelstrom, and was nearing the apex below, when suddenly I gave a retch, and began to vomit. While in the very act of straining to vomit, I felt more natural. The vomiting over, I felt I was about gone, and said, as it seemed to me, with an awful effort, 'Put me in bed; I shall know nothing in a few minutes more.' At one time I really thought I was entering the world beyond, and was wondering how things would appear, when something changed the current of my ideas. Just as I started to bed I had reached the climax of wretchedness. A few minutes before I had taken some lemon-juice, which they brought me instead of the citric acid solution I had called for, and now the symptoms seemed to begin to abate. The revolving panorama of sensations seemed to move more slowly, and each revolution appeared to bring me back, up, more to the light, and to myself again. I was now in bed, had walked from the kitchen, but did not feel the floor; with a feeling of relief, I said, 'I shall get all right again.' My hands now began to become cold, and then my feet, and I requested to be kept warm, and asked to have my hands rubbed. From this on I dozed in a dreamy, intoxicated manner; for a few seconds I lost myself in sleep, and then started up; still I had no correct idea of time; my hands were still cold, and I asked the attendants to chafe them, and then dropped into a doze, and after, as it seemed to me, half or three-quarters of an hour, I aroused and repeated the request. Those who were attending me say I was incessantly repeating my request. They put warm bricks to my feet, and

I immediately dozed off again, and in less than half a minute asked them to put something warm to my feet, saying I was nearly frozen. I was reminded that it had already been done a moment before. I remembered the circumstance, but it seemed to have been at least two or three hours before. From this on, the symptoms of intoxication gradually abated. After dark, at seven o'clock, I could converse very readily, but time dragged very slowly. Towards morning I slept somewhat more naturally, but was nervous, and felt aching in my back and neck, and soreness of my sides, from vomiting. Next morning my appetite was poor, my head ached, and I felt dull all day—much the same, I imagine, as a man after a drunken spree.

During the whole operation of the medicine the pupils of my eyes were perfectly natural, and after the first few minutes the colour of my face was the same as usual. My pulse was at first rapid and strong, afterwards not so strong, but faster than common; my hands and feet were cool, from the end of the first to the middle of the third hour. At no time was there any tendency to spasmodic movements of any kind, no twitching of the muscles; the disposition was rather to lie inactive and quiet. I was about six hours under the influence of the drug, but the climax of the symptoms was reached in about an hour and a quarter. Had the emetic and lemon-juice not been taken, the effects of the poison might have been more intense and prolonged.

Taking the drug as I did, just before dinner, it had time to be well spread over the mucous coat of the stomach, and when the process of absorption began with the meal, the whole of the medicine was suddenly thrown into the circulation. The same amount of the cannabis taken two hours after a meal, would not likely have produced so much effect. My experience with hasheesh leads me to think it a very powerful drug, but extremely uncertain in strength, as found in the shops. Used in large doses, or in improper cases, it is capable of doing serious injury to the nervous system; while in those cases to which it is suited, it is a remedy of questionable value.

J. MILNER FOTHERGILL, M.D.

SMITH ON OPIUM-POISONING.—At a meeting of the New York Medical Society (*New York Medical Journal*) Dr. Andrew H. Smith read a paper on poisoning by opium and its treatment. He brought out strongly the fact that the number of the respirations is not always an index of the amount of narcosis, and gave an idea as to what extent belladonna might serve as a physiological antidote. In poisonous doses of opium the stage of excitement is usually limited to a short time, if not entirely wanting, and to it succeed dizziness, nausea, and sometimes vomiting. The face is at first dusky, but by degrees becomes pale. The pulse at first is bounding, but in a short time sinks below the normal rate. Convulsions may occur, but they are most likely to do so in children. The intellect is completely in abeyance, though it is usually possible to arouse the patient till the coma is profound. Delirium occasionally manifests itself, though it is not characteristic, as in poisoning by belladonna. The narcotic influence is exerted, partly by pressure on the brain from paralysis of the vaso-motor nerves, and partly by the direct influence of the drug on the cells of the brain. The effect of opium in contracting the pupils is due to its central action on the nerve supplying the pupil,

and in this respect it differs from belladonna. Belladonna acts on the periphery of the nerves, as proved by applying atropia to the eye. Morphia applied in a similar manner has no action whatever.

It has been supposed that the respirations were a criterion of danger, but latterly evidence has been accumulating which proves that they cannot be relied on, as is evident from the cases reported. When death approaches, the temperature falls; and the pulse, which earlier was increased in frequency, decreases. If the patient suffer from peritonitis, the pulse sinks below what it was before the opiate was administered, but does not do so in proportion to the respirations. There is no specific lesion in opium-poisoning. Congestion of the brain is usually found, and sometimes there occurs hyperæmia of the mucous membrane of the stomach; but when this latter condition is found, it can be attributed to the alcohol in the laudanum. The diagnosis rests mainly between apoplexy, depressed fracture of the skull, uræmia, and poisoning by alcohol. In apoplexy, there are hemiplegia, pulsation of the carotids, and inability to rouse the patient from the coma. The same is true of depressed fracture, with the additional fact of injury found on examination of the head. In alcohol-poisoning, the patient, when aroused, manifests anger, and in the breath there is the alcoholic odour. This may, however, and does frequently, complicate poisoning by opium. In uræmia, the urine is the main reliance for diagnosis, but in this and the other cases there is not the contraction of the pupils which, in poisoning by opium, continues till near the close of life.

The treatment resolves itself into the evacuation of the stomach; the administration of belladonna and such stimulants as coffee; keeping up some irritation, such as walking, the faradic current, and the cold douche, and careful attention to respiration to prevent its flagging. The administration of oxygen gas has proved a most valuable aid in this latter respect. It seems, moreover, to have a more extended influence than would at first be supposed; and this is caused, in all probability, by accelerating capillary circulation, and possibly by aiding in the destructive assimilation of the poison. In regard to the evacuation of the stomach, if the patient be seen early, mustard, sulphate of zinc, or sulphate of copper, may be given to cause vomiting; but if this fail to act soon, or if it have been some time since the taking of the drug, the stomach-pump must be used. The emetics may be increased in their efficacy by kneading the epigastrium from time to time. Belladonna has long been supposed to have an action antagonistic to opium, from its effect on the pupil, but much obscurity attends its use: 1. from the amount required to act as an antidote; and, 2. from the lack of knowledge of the amount of opium taken into the system. It is now known that belladonna, up to a certain point, has an effect antagonistic to opium: the respirations are quickened, and the circulation is increased. Beyond this point it deserts us, and goes over to the enemy, increasing the prostration and complicating the case. It is safe to give from $\frac{1}{10}$ to $\frac{1}{5}$ of a grain of atropia hypodermically, and supplement it by the administration of a strong infusion of coffee. A dose of atropia larger than this is given with risk, as it is impossible to tell not only how much of the opiate has been taken, but also how much of it is absorbed and exercising its influence. The patient should be kept continuously irritated, either by walking, or, if quite

unable to walk, by the faradic current. Pain exerts a protective influence on the system, and in cases of spasmodic pain, where opiates have been given, it is occasionally found that during the continuance of the pain but slight influence of the anodyne is detected, whereas, when the spasm ceases, dangerous narcotism may and often does supervene.

The dangerous sequelæ of opium-poisoning, when recovery is being established, are, first, a relapse; and, secondly, pneumonia. The pneumonia is probably caused by the state of the blood in the lungs. It has been supposed that the respirations are an index of danger after the administration of opium, but, though this is true as a rule, it is becoming known now that there are many exceptions to it, and that great danger may be impending when the respirations are either normal or above the normal rate.

Dr. Smith gave notes of the following cases.

The first case was a patient suffering from puerperal peritonitis. When seen, she was in a profoundly comatose state, cyanosed, but the respirations averaged about eighteen during the minute. Under the use of oxygen gas the patient soon rallied, but died eventually of pneumonia.

The second case was in a patient aged forty. Magendie's solution was administered every two hours, in ten-minim doses; after eight or ten hours the respirations sank to ten per minute, then rose to fifteen, and again dropped to twelve, and then ten; afterward they rose to twenty-two per minute. The patient at that time was cyanosed, and in a state of coma; oxygen gas was administered, and soon afterward the patient passed out of the narcosis.

The third case was communicated by Dr. J. J. Reid. It occurred during his service at Bellevue Hospital. The patient was taken into the hospital ward suffering from narcosis; the respirations were about five or six per minute, and the coma profound. The cold douche was used, and the respirations rose to eighteen or twenty per minute, and continued so for three or four hours, when the patient died.

The next case showed the good effect of oxygen gas: the respirations were five in three minutes, but no difficulty was found in arousing the patient; after the administration of the gas he rapidly recovered.

The fifth case occurred at St. Luke's Hospital. The patient was found in a comatose state in Central Park, with a respiration averaging one in two minutes; after two hours, oxygen gas was given, and in three or four hours he had recovered from the narcosis. He took the drug twelve hours before being discovered.

The sixth case was very much improved by oxygen gas, but afterward developed pneumonia and died.

The seventh case had increased respiration, and died from the narcosis.

The oxygen gas given in the above cases proved more beneficial than any other agent used in rousing the patient from the lethargy. The method of administration was to fill an India-rubber bag with the gas, and then introduce the inhaler into one nostril, leaving the other free to receive atmospheric air.

Dr. Baylis read a case of opium-poisoning, which was of interest from the large amount of the narcotic taken. During a period of three and a-half hours the patient took five grains of morphia, and six hours after he took the last dose of morphia, narcosis set in. In this man there was pulsation of the carotids, a rare symptom in opium-poisoning. The respirations numbered two per minute. Sulphate of atropia was given in one-fortieth grain

doses hypodermically, and in forty-five minutes the pupils began to dilate; at the expiration of an hour-and-a-quarter this dilatation was complete. Oxygen gas was administered, and in eighteen hours the patient had recovered. Dr. Baylis noted as strange that when the patient rallied from the coma there was perversion of the intellect, but this was explained by Dr. Smith to be due to the atropia administered.

Dr. Joel Foster related a case where twenty-five grains of morphia were taken by an officer in the navy, and the patient afterwards recovered.

Dr. Peaslee narrated the case of a young woman who took about thirty grains of morphia, and afterwards recovered completely.

Dr. Smith, during the reading of his paper, said that Dr. Mary Putnam Jacobi anticipated the observations in regard to the effects which belladonna exercises in the system upon opium, made by a commission appointed recently in England.

RENAUT ON CHRONIC LEAD-POISONING.—Chronic lead-poisoning is produced when the lead, constantly absorbed into the organism, cannot be eliminated in proportion to its introduction, and partly fixes itself in the tissues in a state of combination with the albuminoid substances.

The slow saturation of the animal economy by the metal renders the individual saturnine, and prepares in him a fresh ground, containing a reserve of lead, which, under the influence of accidental causes, may pass back in a notable quantity into the blood and bring on accidents analogous to those of acute poisoning or presenting special characteristics. The first effects of lead impregnation are, production of saturnine anæmia (hypoglobulia, with augmentation of the size, and loss of plasticity of the corpuscles, Malassez), polycrotism of the pulse (Lorrain and Marey), plumbic colouring of the skin, colic, dyspepsia, acute or chronic saturnine asthma then come on; encephalopathia, disturbances of sensibility, ataxy (Vulpian and Raymond), disturbances of hearing and sight, paralysis, contractions, tremblings, arthralgias, etc. The accidents which may be characterised as accidents of elimination are renal lesions, albuminuria. The predominant phenomenon of chronic saturnine intoxication is its action on nutrition, the arrest of the nutritive changes bringing on saturnine cachexia. The influence of this intoxication does not only affect the individual; it also makes itself felt in the vitality of the species. M. C. Paul has demonstrated that it induces abortion, or the production of non-viable or feeble children. M. Roque has ascertained that a considerable number of idiotic or epileptic children were the offspring of saturnine subjects, in whom saturnism alone could be cited as the cause of decline. The influence of saturnine intoxication on the production of gout and general paralysis is now established; its antagonism with tuberculosis is strongly contested. The different treatments of lead-poisoning pursue two different objects; either the neutralisation of the lead introduced into the economy (sulphur, iodide of potassium) or its elimination. Opium is useful by combatting the spasm of the capillaries. According to an analysis of M. Renaut's work in the *Archives Générales de Médecine*, for July, 1875, at the same time that the author gives a detailed clinical exposition of the accidents of lead-poisoning, he has set himself to furnish the explanation of these accidents, in accordance with the most

recent data of pathological anatomy, physiology and medical chemistry. These researches give quite a special interest to his work.

PALMER ON THE DETECTION OF OPIUM AND DHATURA.—Surgeon-Major W. J. Palmer, in a highly interesting report of the work performed in the Chemical Department (Calcutta) during the year ending March 15, 1875, including a vast field of experience, has the following paragraphs.

Detection of Opium.—The value of amyl alcohol as a solvent for separating morphia from the purified extract obtained by Stas's process, after ethyl ether has been used to extract the narcotine and porphyroxin, is scarcely yet recognised as fully as it deserves. Its use facilitates the separation and isolation of morphia to such an extent as renders it possible to obtain reliable evidence of the presence of this alkaloid in cases where the quantity is so small that no decided or positive opinion could be formed without its aid; morphia being almost insoluble, or soluble to such a very limited extent, in the ethyl ether ordinarily used, as to render it almost impossible to detect its presence when this fluid alone is relied upon for its separation.

The merits of the porphyroxin colour-test for opium being under discussion just now, its value has been carefully inquired into in each of thirteen cases which have come under observation in this department during the year. In most of the cases the colour has not only occurred, but the depth of colour developed has appeared to bear a proportionate relation to the quantity of the other constituents, viz., meconic acid, narcotine, and morphia, subsequently found in the same case. In one solitary case, however, where both morphia and meconic acid were undoubtedly present, no porphyroxin coloration could be induced to manifest itself. Though its presence, therefore, corroborates the conclusion arrived at from the detection of the other constituents, and also affords grounds for an approximate estimation of the quantity of such other constituents, its absence in any given case does not appear to justify the conclusion that opium is not present. My own opinion, formed after some experience in the Opium Department, is, that the colour-forming material exists in much greater abundance in Indian than in European opium, and therefore that this coloration is of much more value as a test for the former than for the latter.

Detection of Dhatura.—It has been recently stated that the spermoderm or husk of the dhatura seed, as it exists in drugged food, as boiled rice or baked flour-cakes, although liable to be confounded with husks of wheat or leguminous food-grain if examined by the naked eye only, may, if examined under a magnifying power of sixty diameters, be readily distinguished from them by its colour and very beautiful structural characters. This statement, though perfectly true so far as it goes, appears to be liable to lead to very grave error; for no mention is made in the paper of the testa or covering of the capsicum-seed, which resembles that of dhatura so closely, both in colour and structural arrangement, as to render it extremely difficult, if not quite impossible in some cases, for the most experienced observer to distinguish one from the other, even with the aid of any magnifying power whatever. Capsicum-seeds are so frequently found mixed with the food of inhabitants of Bengal and the Upper Provinces, that little or no reliance is placed in this department upon

the evidence afforded by the above-mentioned characters, unless such evidence be corroborated and confirmed by the co-existence of the recurved embryo peculiar to, and characteristic of, the genus *dhatura*, or by the peculiar physiological action of a prepared extract on the pupil of a cat's eye; either of which characters, if present, affords a sufficient safeguard against the possibility of mistaking portions of harmless capsicum-seeds for the poisonous *dhatura*.

OPHTHALMOLOGY AND OTOLOGY.

LADREIT DE LACHARRIÈRE ON MÉNIÈRE'S DISEASE.—In the first number of the *Annales des Maladies de L'Oreille et du Larynx*, Dr. Ladreit de Lacharrière gives a concise *résumé* of Ménière's disease, and reviews the opinions of some of the authorities on the subject. He believes that the disease is always characterised by lesions of the labyrinth, and that those affections which have not their seat there, although they closely resemble it in their symptoms, can always be distinguished from it. He divides the symptoms into the transient, under which he places the syncope, the vomiting, and the headache; the more persistent, including therein the vertigo and the tinnitus; and the constant, which is the deafness. In relation to the last symptom, he says that when all the other morbid phenomena have disappeared, the deafness generally persists to a considerable degree, though possibly not always so complete as at first.

Among the diatheses, the author thinks that the syphilitic and scrofulous play an important part in Ménière's disease, as he has frequently seen the affection of the labyrinth appear at the same time as the tertiary symptoms of syphilis, and he therefore thinks there is a connection between them. Moreover, he adds, syphilis and scrofula are constantly showing themselves in affections of the mucous membranes and periosteum, and are very frequent causes of the diseases of the ear. As other causes, he mentions injuries or concussions to the head, causing osseous lesions, purulent catarrh of the middle ear, and polypus of the ear.

The diagnosis of the affection is not difficult when the symptoms appear suddenly, when it is remembered that, being an affection of the labyrinth, the deafness must be more or less complete, and that three symptoms are always present—namely, deafness, tinnitus, and vertigo. Where deafness and tinnitus occur without vertigo, he says the cause of these phenomena will always be found in lesions of the middle ear. Where vertigo and tinnitus are complained of, but the hearing is intact, a lesion of the middle ear, cerebral congestion, and epilepsy ought to be looked for. But where the three symptoms are present, without sufficient lesion of the middle ear to explain them, a lesion of the labyrinth is to be assumed. Dr. Ladreit de Lacharrière also looks to the character of the tinnitus, and avers that the patient suffering from affection of the cavity only never complains of the musical and bell-like bruits, which are spoken of by those suffering from Ménière's disease. Further, when the deafness, as determined by the tuning-fork, is slight—not differing much from that of the sound side—he thinks the observer may rest assured that the disease is limited to the organs of transmission.

The progress of the affection, according to his experience, varies. In the cases where the onset has been sudden and violent, the morbid phenomena pass off by degrees, but deafness always remains to a variable extent. Where, on the contrary, the disease has progressed slowly but regularly, the deafness remains complete.

The treatment is not so hopeless, according to Dr. Ladreit de Lacharrière, as is generally believed in this country. He has, he says, frequently had the satisfaction of ameliorating the state of patients who have come under his care. His treatment is etiological. If inflammatory affection of the labyrinth be supposed to be present, antiphlogistics are indicated; while if syphilis have probably been the cause, mercury, iodine, or iodide of potassium is tried.

BERTHOLD ON EXAMINATION OF THE RETINA, THE TYMPANIC MEMBRANE, AND THE LARYNX.—Dr. Emil Berthold, of Königsberg, gives, in the *Berliner Klinische Wochenschrift* for June 21, a description of a simple method, by means of which two observers can simultaneously examine the retina, tympanic membrane, or larynx.

In examining the fundus oculi the indirect image is obtained by one observer in the usual way, a concave mirror being used in preference to the plane or to the non-silvered glass plates of Helmholtz. The second observer, standing at the side of the observed eye, looks through a concave mirror, of from fifteen to twenty inches focus, at the image in the mirror used by the first observer. It is necessary that the opening of the first observer's mirror should be small, so that the opening interferes as little as possible with the image seen by the second observer. The corneal reflex seems to be the difficulty to be overcome, as the first observer must hold the object-lens in such a position that the reflex does not interfere with either his own or the second observer's view of the image. Dr. Berthold says a little practice soon sets aside this difficulty.

The examinations of the larynx and the tympanic membrane are conducted in the same way; but with them it is easier, as there is no disturbing reflex. The examination of the *membrana tympani* can be made either by artificial light or by day-light. If by the latter, the mirror which reflects light directly on the membrane ought to have a focus several inches greater than the distance between the mirror and the membrane, by which means the second observer will see a somewhat enlarged image of the membrane in the mirror without having to use a second mirror.

W. LAIDLAW PURVES.

GIRAUD-TEULON ON DEFECTS OF VISION IN CONNECTION WITH MILITARY SERVICE.—The *Bulletin de l'Académie de Médecine*, June 15 and following numbers, contains a very severe and long criticism by Dr. Giraud-Teulon upon the present methods of examination, and upon the mode of testing the vision of recruits in the new French army. In order to make his criticisms more clear, Dr. Giraud-Teulon explains step by step the various methods of investigation which are employed in civil practice, and compares with these the proceedings of the military boards as carried out in accordance with instructions from the minister's bureau. As the French army, as reorganised, consists of an active force, of certain reserve forces, and of volunteers under special circumstances, Dr. Giraud-Teulon contends strongly that a hard and fast limit of vision should not be insisted upon for all these different grades of

the service, inasmuch as a recruit whose vision is too imperfect to qualify him for active service as a combatant may yet be eligible for duty of another kind and in other situations; whereas, according to the instructions now issued, he is rejected altogether. And in the various grades of volunteers other considerations arise which are of great importance. In cases of emergency and in great patriotic crises, the majority of these volunteers would be drawn from the cultivated and the highly educated classes, and modern statistics show very clearly that in proportion to the intellectual power of a community so is the frequency of myopia; and if a strict limit were insisted upon for the vision of volunteers, the army and the country would be deprived of very much useful and intelligent assistance. The Germans understand this, and the consequence is that they are able to make a boast of the number of spectacles which are worn in their ranks. So evident is it that myopia is more frequent in schools than elsewhere, that a very large proportion of their officers and the educated men within the ranks wear glasses of some kind, and 'no one,' says Dr. Giraud-Teulon, 'can doubt their intelligence or their efficiency.' Accordingly, he insists strongly that France should not deprive her army of such an intellectual contingent by any arbitrary rules as to the amount of vision.

The instructions to the medical boards are to the effect that recruits suffering from myopia $\frac{1}{4}$, or from amblyopia, so that their visual acuteness is diminished to one-fourth, are altogether ineligible; and Dr. Giraud-Teulon proceeds to show that such rules are inexact and unscientific, inasmuch as it can be proved that loss of vision is not by any means in proportion to the degree of the error in refraction. In order to investigate such cases satisfactorily, so as to eliminate fraud and to come to any reliable conclusion, it is essential that much more time should be devoted to the examination of a recruit than can be given under the present arrangements, and it is absolutely necessary that there should be attached to each board of inquiry an additional member who should also be a skilled ophthalmoscopist. Dr. Giraud-Teulon divides his remarks under two headings, the first have reference to the defects of vision owing to errors in the refraction, and the second to the consideration of all the varieties of amblyopia; and as regards these he insists that the present method of examination by test-types, etc., is unsatisfactory, unless it be supported by an examination with the ophthalmoscope. The use of this should be compulsory, and not, as at present, merely allowable.

ARLT ON THE ORIGIN AND TREATMENT OF PURULENT OPHTHALMIA.—In the *Wiener Medizinische Zeitung*, May 25, Professor Arlt brings to an end a series of papers upon purulent ophthalmia, and in a short *résumé* thus sums up the conclusions at which he has arrived. Although purulent ophthalmia very commonly appears amongst the members of communities, yet it not unfrequently attacks the eyes of individuals amongst the poorer and lower classes, who are already suffering from any of the milder forms of ophthalmia; it matters little what the nature of this may be, whether it be granular or trachomatous, or any other variety of the inflammation; it may appear after a long or a short interval, and it may lead to rapid destruction of the eyesight by invading the cornea, or to its slow and gradual extinction by causing trichiasis and entropion. In

many cases minute greyish bodies may be seen on the under surface of the upper lid, and especially in the mucous membrane above the lid. The ophthalmia is generally acute if it be caused by inoculation from the genital organs, but it is usually chronic when it spreads from eye to eye, or when it is brought about by exposure to draught. The activity of the contagious matter depends much upon the concentration of the material, and upon the length of time during which the conjunctiva is exposed to its influence; its power is favoured by heat and retarded by cold. The occurrence of one single case within a community may lead to the appearance of an epidemic, the contagion being conveyed as much by the air as by all kinds of instruments and utensils, more especially when the weather is warm and moist. It appears that the disease may have its origin in atmospheric influences alone, such, for instance, as sudden changes of the weather, and if the air be charged with dust or smoke. According to Professor Arlt, it is not certain that purulent ophthalmia is more rife amongst military than in civil communities, nor does it appear to him conclusively shown that the disease had its origin in Egypt, inasmuch as Egypt was esteemed by the Greeks and Romans as a very healthy country, and the assertion that Cyrus applied to Egypt for the aid of physicians does not prove more than that the Egyptians in those days were a cultivated people, and were in a position to afford the assistance which was asked. There is no reason to suppose that there is any change of structure in the eyes of scrofulous subjects which should render them especially liable to the disease.

In conclusion, as regards treatment, Professor Arlt is quite at a loss how to suggest any safeguards against the disease; for, although we look upon it as contagious, we cannot isolate all or any who have been exposed to it, and it very frequently happens that those who have been exposed are utterly unaware of the fact, and but too often unwilling to submit to any treatment until the disease is far advanced, and according to our present knowledge it would be quite impossible for medical men to examine the eyes of all of those under their care and who may in any way have exposed themselves, or whose eyes may at any time become attacked.

DEZANNEAU ON IRIDECTOMY AS AN AID TO THE EXTRACTION OF CATARACT.—The *Bulletin Général de Thérapeutique* (May 15 and 30) contains an elaborate analysis of one hundred and fourteen operations for extraction performed by Dr. Dezanneau, from the results of which he draws certain practical conclusions as to the value of iridectomy as an adjunct to operations for the removal of cataract. In every instance the pupils were dilated with atropia, on the ground that not only was the iridectomy rendered easier, but the removal of the lens was thereby facilitated. With the exception of one case, and this a cause of regret to Dr. Dezanneau, no anaesthetics were employed. The eyelids were separated by means of a common retractor, and the fixing forceps was only made use of during the section of the cornea, the excision of the iris being accomplished without any other aid than that of the retractor. The excision was always made upwards, and very freely. The section of the cornea which Dr. Dezanneau performed in all his cases, and which he strongly advocates, is a section exactly at the sclero-corneal junction, so as to make a flap which shall embrace about the upper-third of the

cornea, and exactly parallel to the plane of the iris. This section is all the better if there be a small conjunctival flap also. At the third stage of the operation, most scrupulous care is taken to remove all *débris* of lenticular matter, but without using instruments within the eye. This is brought about by gentle friction and manipulation. Subsequently to the operation the patients were confined to bed for one day, and a compressive bandage was employed for one week; the eyes were not examined at all until the fourth or fifth day. As the result of one hundred and fourteen operations, complete success followed in eighty-eight, in seventeen there was but a partial success, and in nine the vision was not improved; in no single instance was the eye lost. By complete success is meant the ability to read ordinary type for any length of time, with the aid of proper glasses; and by incomplete success is meant the power of seeing all large objects, but without the power to read or write. As regards the value of iridectomy, Dr. Dezanneau considers that it does not render the operation more dangerous by causing hæmorrhage into the anterior chamber, or by facilitating any loss of vitreous humour; nor does it favour the formation of secondary cataracts, with all of which faults it has been reproached. On the other hand, an iridectomy appears to ward off, or at least to modify exceedingly, any subsequent inflammation. If the excision of the iris be complete and cleanly done, it is not the cause of imperfect healing of the corneal wound; and the results of extractions in which it has been performed are in no way inferior to those obtained by the old method. To use Dr. Dezanneau's words, 'Iridectomy adds no serious difficulty to the operation for extraction; on the contrary, it facilitates the removal of lenticular matter in many instances, and without it some cataracts could not be removed at all; while it almost certainly protects the eye from grave inflammatory troubles which would otherwise compromise the result of the operation.'

REPORTS OF FOREIGN SOCIETIES.

ACADEMY OF MEDICINE IN PARIS.

June 22. *Cholera*.—A discussion on cholera, which had been opened in the Academy, was resumed. M. Tholozan said that the question now raised, however it might be settled, must throw some light on the origin of cholera. Facts were grouped to gain ideas; the mass of facts on the etiology of cholera was misread; for it was still disputed what a cholera epidemic was; how many had occurred in Europe; what was a primary and what a secondary epidemic. It was thought, before his enquiries were published, that Asiatic cholera could not reproduce itself in Europe, and that we must trace even secondary outbreaks to India. He did not find one of the last five cholera

epidemics coming direct from India. Two sprang up in Europe, two in Persia, and one in Arabia. It was useless to say that these epidemics were not primary, but were derived from India, for on tracing the history of every modern epidemic in India there was no such thing to be met with there as a primary epidemic; all were secondary, all derived from pre-existing sources. How cholera arose in India was still questioned. Was it engendered *ab ovo* in every new epidemic; or did these terrible events result from germs left from a preceding epidemic? Cholera, like plague, yellow fever, small-pox, scarlatina, and measles, had the fatal power of contagion, and of becoming epidemic. No one now maintained that measles, scarlatina, or small-pox were produced by vicissitudes of climate, by errors of digestion, or the causes we call common; an infecting particle was necessary to cause them. We must admit a specific germ of the same kind for cholera also, or reverse all the laws of pathology. Could cholera depend on a specific cause out of India and there be the product of common causes only? Because this disease originated in India long since, it was supposed to be continually arising there *de novo*. It was an error to suppose that cholera commonly arose in India. In India the germs of cholera had never been absent from the times of remote history; they were roused into activity after longer or shorter periods of dormancy, just as occurred with the ordinary zymotics in Europe. In India the germ of cholera was sometimes sterile; it might be fertile in places out of India, and set up centres of diffusion as powerful as any watered by the Ganges. This variation of epidemic intensity was as necessary as is the fact of contagion to explain the spread of measles and scarlatina as well as of cholera. Dr. Cunningham's recent reports showed the disadvantages of restrictive measures in India. Cholera was already endemic in parts of Russia; yet barriers found useless in the West were again to be enforced in the East, at least, if some conclusions of the late Sanitary Conference at Vienna were to be literally observed. The doctrine of contagion followed too exclusively led to narrow views, and shut out facts which it could not explain. This doctrine must be enlarged so as to combine with the germ theory the idea of epidemic influence to explain all the phenomena. These two ideas probably corresponded to a single fact or to one series of phenomena proceeding from the same source; the essence of these pathogenic facts was hidden, and could not therefore be comprehended in a single conception.

June 29. *Cholera*.—The discussion on cholera was continued by M. Briquet. He warmly acknowledged the value of Dr. Tholozan's contributions to the history of plague and cholera, specially of the facts which his official position in Persia had enabled him to gather on the etiology of cholera in India which supplied some of the keenest wants of science. He was surprised at much that M. Tholozan had said, and would adduce facts to show that India was the birth-place of cholera, that it had existed there from time immemorial, and that before 1817 it was unknown elsewhere. He doubted if it were possible to originate epidemic cholera in temperate climates, or that our summer cholera could ever be transformed into an epidemic as M. Guérin supposed. Vanderhayden told us that in 1645 cholera appeared in Holland when that country was in relation with the Moluccas, but it did not spread. The extension of commerce after the peace of 1814 brought it from

India. He believed each epidemic in India to arise *de novo* and not, as Dr. Tholozan maintained, to result from germs left by a previous epidemic; yet he admitted that cholera was always present in India in the sporadic form. If the conditions which would give rise to cholera existed nowhere but in India, it followed that any epidemic must be derived thence. There were direct proofs that the epidemics of 1819, 1830, and 1846 started from India; so far all authorities concurred. M. Briquet had elsewhere shown how local outbreaks, with winter pause and summer recrudescence had followed the epidemics of 1830 and 1846: M. Fauvel had done the same for the epidemics since 1850. It was not known how long an epidemic might retain its activity, so that it was necessary to guard against the possibility of fertile germs still lingering; but we must not neglect the ordinary channels of importation; these, since the close approximation of Russia to India, were no longer chiefly identified with ocean traffic. The highway by Russia was now as dangerous as was that by England.

REVIEWS.

Physiological Diagrams, containing 240 Coloured Figures, Illustrative of a Description of the Human Body, its Structure and Functions, designed for the Use of Teachers and Schools and Young Men destined for the Medical Profession, and for Popular Instruction generally. By JOHN MARSHALL, F.R.S., F.R.C.S. Third Edition. Revised and enlarged. London: Smith, Elder & Co. 1875.

The title of the above work, though somewhat a long one, is necessary to show fully the object and scope of the work itself. The high excellence and minute exactitude with which Mr. Marshall's large diagrams were executed, rendered such a work as the one under notice indispensable to the private student, and to those who had neither the means nor the convenience necessary for the study of life-sized diagrams. To meet this want, the illustrations in this set of drawings have been made on a scale of one-sixth of the original size, so as to bring them within the compass of a handy book of reference. We can speak in high terms not only of the excellent manner in which the task has been accomplished in an anatomical point of view, but also to the high artistic merits of the work, which is as valuable to the student of art as it is to the student of anatomy. The price also brings these life-like studies within the reach of many who could not otherwise have the benefit of Mr. Marshall's *magnum opus*.

The reduced work contains many plates which are not in the original, whilst the scientific descriptive portion of the work has been brought up so as to include the most recent discoveries in the anatomy of the human frame; and, as all the plates have been re-engraved, all the distinctness of outline which is essential to the illustration of the human body has been secured. The work, being intended for the art as well as the medical student, contains only those parts of the anatomy which can be placed on the drawing-room table in the most mixed society without fear or reproach. We can cordially recommend this edition of Mr. Marshall's *Physiological Diagrams* not only to the medical student and artist, but also to the general public.

On Paralysis from Brain-Disease in its Common Forms. By H. CHARLTON BASTIAN, M.A., M.D., F.R.S. Pp. 335. Woodcuts. Macmillan: 1875.

This volume is a revised and enlarged reprint of lectures published in the *Lancet* last year. It is a readable and instructive monograph on the somewhat restricted subject of hemiplegia. The various causes of this form of palsy are first enumerated, with due reference to the blood-supply of the several parts of the brain, illustrated by the figures of Ecker and Duret. A remarkable case of hemiplegia due to hysteria is given at length in this chapter. The phenomena of the apoplectic state are then discussed, together with the various changes in the condition of the affected muscles, in the power of speech, and in other functions which are its sequelæ. The subject of aphasia, as one might expect, is particularly well treated. Dr. Bastian adheres to his suggestion of restricting this term to loss of power both of speaking and of writing, using the words 'aphemia' and 'agraphia' to denote one of these defects without the other. Perhaps the most interesting chapter of the book is that on regional diagnosis in disease of the brain. The symptoms which point out lesion of the pons, the crura cerebri, the thalamus, and the corpus striatum respectively, are carefully analysed, and then the scarcely less difficult symptoms which denote hæmorrhage into the ventricular cavity, lesions of the hemispheres, and, lastly, of the cerebellum. Then follow some practical remarks on prognosis in apoplexy and hemiplegia, and a few words on treatment complete the volume. The woodcuts, taken from Marshall, Turner, and Ecker and Duret, serve to illustrate the anatomy of the brain. The only improvement we would suggest in a second edition is compression.

MISCELLANY.

THE Committee of the French Association for the Advancement of Science, which meets at Nantes on August 19, have issued a list of some of the French men of science expected to be present. Among the subjects which will be brought before the Association are 'Researches on Prussic Acid,' by M. Claude Bernard; an important paper by M. Pasteur on Beer; an account of the work relating to the meridian of France, by Commandant Perrier; and a new rhinoplastic process, by Dr. Ollier. Among those expected to be present are, MM. Dumas, Claude Bernard, Pasteur, H. St. Claire Deville, De Quatrefages, Levasseur, P. Broca, E. Caventou, L. Lefort, E. Moreau, Trélaud, Verneuil, and other eminent scientific Frenchmen.

LOCUSTS AS FOOD.—At the last meeting of the Entomological Society, Mr. Charles V. Riley, State Entomologist of Missouri, exhibited sundry insect pests that do so much damage in the State, including the army worm (*Leucania impuncta*), and the Rocky Mountain locust (*Caloptenus spretus*), and entered at some length into the habits of the latter insect, and the vast amount of destitution caused by it; stating that in a short period it devoured almost every living plant, leaving nothing but the leaves of the forest trees, and converting a fruitful country into an absolute desert. Having noticed that hogs and poultry grew excessively fat from devouring the locusts, and considering that the use of them as food for man would tend to relieve some of the distress occasioned in the devastated districts, he had caused a number of them to be prepared in various ways, and they were found to be well suited for food, especially in the form of soup.

BRITISH MEDICAL ASSOCIATION.—The fifty-third annual meeting of the British Medical Association was held in Edinburgh last week, under the presidency of Sir Robert Christison, Bart.; and was very largely attended by members from all parts of the kingdom. In addition to an interesting and highly instructive address from the president, on the University of Edinburgh and Medical Education, addresses were delivered, in Medicine, by Dr. Warburton Begbie; in Surgery, by Professor Spence; and in Physiology, by Professor Rutherford. Numerous papers were also read in the sections into which the meeting was divided, viz. Medicine, Surgery, Obstetric Medicine, Public Medicine, Physiology, and Psychology. The Presidents of Sections were: Medicine, Dr. R. Quain, F.R.S. (Dr. W. T. Gairdner, Vice-president, acting in his unavoidable absence); Surgery, Professor Lister; Obstetric Medicine, Dr. Matthews Duncan; Public Medicine, the Right Hon. Lyon Playfair, M.P.; Physiology, Dr. Burdon Sanderson, F.R.S.; Psychology, Dr. Lowe. Among other business, a committee was appointed to investigate the action of anæsthetics; and it was determined to take measures for promoting legislation for the restraint and cure of habitual drunkards. The meeting of the association in 1876 is to be held at Brighton.

SCIENCE IN ABERDEEN.—Professor Struthers has been delivering a gratuitous course of Saturday evening lectures on anatomy and physiology at Mareschal College. They have been very largely attended by both sexes, and particularly by that portion of the community, comprising all classes, whose opportunities for instruction in scientific subjects has been necessarily restricted. A beautifully illuminated and handsomely mounted address was recently presented to Dr. Struthers by the Dean of Guild of the city on behalf of a large number of subscribers, as a mark of their appreciation of his disinterested labours. The Aberdeen School Board had been stimulated to resolve to introduce some physical science into the Grammar School. They propose to have a course of elementary chemistry and elementary physics, and also one of botany. The Mechanics' Institution of Aberdeen, now aided by a munificent bequest from the late Dr. Neil Arnott, himself an Aberdonian, is also doing valuable work in the way of disseminating systematic knowledge in various branches of physical science.

ABORTION IN AMERICA.—In an article in the *Canada Lancet*, June 1, Dr. A. A. Andrews sums up as follows. The crime of feticide is fearfully prevalent, and rapidly increasing, and corrupting and debasing the country both morally and physically. It is worse than typhus or small-pox. How are we to restrain it? We cannot attack it in the public press; delicacy forbids that. Our assaults in the medical press would not reach those who need the instruction and warning. The pulpit is out of the question. Where is the clergyman who would dare preach a sermon upon the text, 'Thou shalt do no murder,' and make special, distinct, intelligible application of his text to this species of murder? I had for many years noted and wondered at the fact, that of the married women who sought my co-operation nearly all were Protestants. Being myself a Protestant, and not ready to acknowledge any marked moral inferiority in my co-religionists, I was for a long season puzzled, but I think the solution is this. The pulpit is debarred; but the Roman Catholic priesthood have in their confessional an opportunity of instructing and warning their flock. Protestant women do not go there, but we, and we only, have the private confidential ear of the whole sex, and it is, I conceive, our duty to lose no opportunity of diffusing the information we possess in this regard. Let us purify the moral atmosphere. Let us make the whole sex know that it is murder, when the embryo is but four weeks old, as completely as if the nine months of foetal life had been reached or passed. We have a duty to perform, and we have countless opportunities of doing it.

THE HÔTEL-DIEU OF PARIS IN THE OLD TIMES.—M. Maxime du Camp's elaborate work on *Paris, ses Organes, ses Fonctions, sa Vie*, just completed, contains a striking description of the state of the Hôtel-Dieu hospital in the time of the Grand Monarque, Louis XIV. It seems that the institution contained 2,800 patients, heaped in fours, fives, and even sixes on the same bedstead, in wards where the wet linen was hung to dry. When, in 1785, the delegates appointed by the Academy of Sciences, with which Louis XVI. had taken counsel on the subject, visited the former leper hospital, they found 3,418 patients in 1,219 beds, some even being placed on the testers of the beds. The wounded in war, fever patients, those who had undergone operations, women in child-bed, maniacs, patients labouring under loathsome skin-diseases, small-pox cases, and consumptive patients, all massed together in the most abominable confusion, died side by side on the same pallet. The dead were allowed to remain for hours by the side of the dying; operations were performed in the general ward, on the bed used in common with other patients; and it is said that, when the coverlid thrown over all this living corruption was lifted up, a perceptible lye ran away. Louis XVI. was touched by this misery, and it was decided that the Hôtel-Dieu should be suppressed, and that four hospitals should be constructed, placed in the outskirts of the city, and amongst trees. Even the funds necessary for the execution of this project were forthcoming, but were used by the minister Loménie de Brienne to stave off some other pressing want, and the Hôtel-Dieu remained what it had always been—a charnel-house—until the Revolution.

THE PHENOMENA OF OLD AGE.—M. Chevreul, himself one of the oldest of the French academicians, being, we believe, in his seventy-fourth year, lately communicated to the Academy of Sciences his conclusions on this subject. He does not entirely share the opinion advanced by Professor Lordat, of Montpellier, that the intellect, the soul, the spirit, retains its faculties without ageing, consequently enjoying insenscence. M. Chevreul admits, in principle, that the intellectual faculties become weaker with age; but he does not allow that it is demonstrated by observation that the weakening of the intelligence should be in proportion with the visible weakening of any special organs; and he thinks that acquired knowledge, in the department of the sciences belonging to natural philosophy, far from being weakened by age, gains in generality and precision. A writer in the *Gazette des Hôpitaux* for July 6, commenting on these opinions of M. Chevreul, agrees with him that acquired knowledge gains generality with age. The brain of the old man is like the intelligence of the peoples of antiquity, who for the first time applied their attention to the totality of created things. The brain of the former and the intelligence of the latter are only impressed by general views; the one sees the details through a distant prism; the others do not yet know them. The precision claimed by M. Chevreul is more difficult to grant him, since he admits, amongst the discomforts of old age, weakening of the hearing, sight, muscular flexibility, etc. Amongst senile infirmities, M. Chevreul accords particular attention to forgetfulness of proper names. According to him this amnesia comes from the fact that the totality of the attributes which characterise a noun have not been sufficiently defined in the mind of the person who forgets. The amnesia of faces, which generally comes on after that of names, would be due to the weakening of the sight, which interferes with the recognition of the person spoken to. In order to correct this annoyance, M. Chevreul recommends that every opportunity of bringing together before one's eyes the two persons whose faces we confuse together should be taken, so as to look for a differential characteristic, in the same way as a naturalist does. This method of repairing the irreparable havoc of years is simple in its conception, but might sometimes be difficult of realisation.

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

A CASE OF TOTAL EXTIRPATION OF THE LARYNX WITH THE HYOID BONE, AND A PORTION OF THE TONGUE, PHARYNX, AND CESOPHAGUS. BY B. VON LANGENBECK, PROFESSOR IN THE UNIVERSITY OF BERLIN.*

Gentlemen,—The preparation which I beg to lay before you is worthy of attention on account of the unusual extent to which the cancerous degeneration has reached in the larynx and beyond it. It was necessary on this account to remove the whole larynx with the epiglottis, the hyoid bone, and the posterior third of the tongue, as well as the anterior and lateral portion of the pharynx with the pharyngo-palatine arch, and a small part of the cesophagus. I will give first a brief statement of the history of the disease.

A master smith named Krause, of Brandenburg, aged fifty-seven, was admitted into the hospital on November 29, 1874, with violent dyspnoea, threatening suffocation, attacks of cough attended with a whistling sound, and a cyanotic tint of the face. It was impossible to obtain the anamnestic circumstances of the disease from the patient himself; and we only learned that he had been a healthy and strong man up to about four years previously, when he suffered from hoarseness and difficulty of breathing, and that for some time he had been treated in Berlin by cauterisation of the larynx. Laryngoscopic examination, which was very much impeded by the difficult respiration, showed ulceration at the anterior commissure of the vocal cords and a defect of the left arytenoid cartilage. The evening temperature was 38.2 Cent. (100.76 Fahr.)

On November 30, tracheotomy was performed, under chloroform. The upper rings of the trachea were ossified, and were divided with difficulty; and after the trachea had been opened, the introduction of the cannula was hindered by incessant and long-continued paroxysms of cough. By these, a quantity of thin purulent sputa was expectorated, and the breathing was considerably relieved. Some infusion of ipecacuanha, with morphia, was given.

The tormenting paroxysms of cough, with abundant expectoration of purulent sputa and acute fever, continued until December 10. The fever then ceased, the sputa became mucous, and the operation wound healed, leaving at the end of December only the fistula in which the cannula lay.

An examination made at this time revealed distinct enlargement of the larynx, and tenderness on pressure. The lymphatic glands in the right inframaxillary region were swollen. Nothing abnormal could be detected on inspection of the mouth and

fauces; with the finger, the epiglottis was felt to be swollen. The laryngoscope showed a remarkable œdematous swelling of the epiglottis and of the ary-epiglottic ligaments, so great that it was impossible to obtain a view of the cavity of the larynx and of the rima glottidis.

Extirpation of the larynx was urgently recommended at this time; but the patient refused to submit to the operation, and left the hospital on January 11, 1875.

On July 1, Krause was re-admitted. Breathing had been carried on with perfect freedom through the tracheal tube; but lately there had been increasing difficulty of deglutition, so that the patient was now only able to take fluid food. The larynx, so far as could be ascertained by palpation, was swollen, widened, without distinct outline, and hard. On both sides of the neck, infiltrated inframaxillary glands could be felt.

On pressing down the tongue, a yellowish red nodulated mass was seen to project behind the root, which we were inclined to regard as the diseased epiglottis. Laryngoscopic examination was impossible, in consequence of the masses of mucus which filled the pharynx and completely closed the upper opening of the larynx. In this region the finger felt a ragged nodulated swelling, which prevented the finger from penetrating further into the pharynx. The patient's general condition and strength were satisfactory.

Extirpation of the larynx was performed on July 21. The patient having been narcotised by chloroform administered through the tracheal fistula, the cannula was removed, the opening in the trachea was enlarged downwards, and Trendelenburg's tampon-cannula was introduced and fixed into the trachea by pumping air into the India-rubber bag. Anæsthesia was kept up to the end of the operation by administering chloroform through a tube introduced into the cannula.

I performed the operation in the same way as I had devised in 1854 in a similar case, in which, however, operative procedure was finally abandoned.

A transverse incision was made through the skin, two centimetres (0.8 inch) above the hyoid bone, from the inner edge of one sterno-mastoid muscle to that of the other. From the centre of this incision, another was carried in the middle line, over the larynx, close down to the tracheal fistula, the upper cicatrix of which, however, was not divided. The skin was then turned back in two flaps, and the larynx (thyroid cartilage) was laid free. The infiltrated lymphatic glands, with the right submaxillary gland, were then extirpated; the mylo-hyoid, digastric, and hyo-glossus muscles were cut through above the hyoid bone, the lingual artery was exposed and tied; the glands were then removed on the left side, and the left lingual artery was tied. The operation was considerably impeded by the unusual shortness of the patient's neck, and by the fusion of the soft parts with the larynx, probably induced by the long retention of the cannula. The stripping off of the soft parts from the thyroid and cricoid cartilages could only be imperfectly accomplished; and the intention of dissecting off the pharynx and the upper end of the cesophagus from the larynx had to be abandoned, as the cancer had invaded the first-named of these parts.

It being then impossible to preserve the anterior wall of the pharynx and cesophagus, we proceeded to lay open the fauces. The larynx being drawn for-

* Read before the Medical Society of Berlin, July 28. *Berliner Klinische Wochenschrift*, August 16.)

wards and downwards by a sharp hook fixed in the hyoid bone, the point of the tongue was drawn out of the mouth by means of a thread passed through it, and the root of the tongue was cut through about four-fifths of an inch above the hyoid bone. The superior thyroid arteries were then tied, and the lateral wall of the pharynx cut through. Finally, the pharyngo-palatine arches, which were stretched forwards by the strong dragging of the larynx, were divided. The external carotid artery, which was drawn forward with the lateral wall of the pharynx, was then laid bare on each side, tied in two places, and cut through between the ligatures. The lingual and hypoglossal nerves were also exposed and divided.

The larynx now remained connected only with the trachea; and the latter was divided close below the cricoid cartilage, so as to leave the tampon-cannula in the tracheal fistula.

The anterior cervical region, from the chin nearly as far as the manubrium sterni, showed now a large opening, at the bottom of which the spinal column, covered by the posterior wall of the pharynx and œsophagus, lay exposed. The skin of the neck, which had been divided by the transverse incision, was turned over in two flaps, like a collar. The trachea sank downwards, so that the cannula lay close above the sternum. At the upper end of the wound were seen the velum palati and the broad wounded surface of the tongue. On inspection through the mouth, the anterior part of the tongue was seen to be quite pale; it had receded from the lower jaw, and was completely immovable.

The muscles divided and removed in the operation, besides the small laryngeal muscles, were the sterno-hyoid, sterno-thyroid, crico-hyoid, and mylo-hyoid, digastric, genio-hyoid, stylo-hyoid, and stylo-glossal; the stylo-pharyngei, glosso-pharyngei, and palato-pharyngei. Forty-one ligatures were applied to vessels, viz., to the external maxillary, lingual, superior thyroid, external carotid, and laryngeal arteries; and both hypoglossal and lingual nerves were divided. Along with the infiltrated lymphatic glands I had removed both submaxillary glands, fearing that these glands, which were apparently somewhat enlarged, might become diseased.

Notwithstanding the extent of the wound and the length of the operation, which lasted two hours, there was comparatively little exhaustion. The patient's appearance was good; pulse 80, full and strong; temperature 36.8° Cent. (98.25° Fahr.). I believe that this is mainly to be ascribed to the circumstance that complete chloroform-narcosis was steadily kept up by the help of the plug in the trachea from the beginning to the end of the operation; that we were able to completely prevent the flow of blood into the air-passages; and that, the operation being performed by careful anatomical dissection without any bruising or laceration of the parts, we were able to tie the great vessels before dividing them.

After the operation was completed, and the patient had awakened from the anæsthesia, some Hungarian wine was given to him through an œsophageal tube, the tampon-cannula was removed and an ordinary strong tracheal cannula substituted. In order to prevent the mucus, which was abundantly secreted by the remaining part of the fauces, from coming into contact with the cannula, a compress soaked in a solution (one-third per cent.) of salicylic acid was placed round the neck so as to cover the wound. I abstained from attempting to unite the wound in

the cervical integuments by sutures, fearing that the stretching of the parts would favour the burrowing of the secretions from the wound between the divided cervical fasciæ. The flaps of skin on the two sides of the neck were therefore simply laid down in place, and supported by the above-mentioned salicylised compress.

July 22. The patient had vomited twice since the preceding evening (after-effect of chloroform); in other respects his condition was good. Pulse, full and strong, 80; temperature, morning 38.6° Cent. (101.48° Fahr.); evening, 39.8° Cent. (103.64° Fahr.). He was fed three times daily through the œsophageal tube, and had nine eggs, milk, soup, and about a pint of Hungarian wine in the day.

July 23. There was abundant expectoration of thin mucus through the cannula. Temperature, morning, 38.6° Cent. (101.48° Fahr.); evening, 39.4° Cent. (102.92° Fahr.); pulse, 80.

July 25. The patient passed a good night. Since the preceding day there had been diarrhœa, for which fifteen drops of tincture of opium were ordered. The temperature and pulse were as on the 23rd. On account of fœtor, the cavity of the mouth was several times washed out with salicylised water. By means of a large sponge, which was pressed above the cannula against the posterior wall of the pharynx, overflow into the trachea was prevented, and the mouth and fauces were carefully wiped with a solution of salicylic and boracic acid.

July 26. There was still abundant purulent secretion; but respiration was perfectly free and quiet. Pulse full, strong, regular, 80. Evening temperature, 38.2° Cent. (100.76° Fahr.).

July 28. The patient's general condition remained good; he was free from fever.

In the preparation, the anterior wall of the œsophagus and pharynx is cut through, the larynx is cut away from behind, and the hyoid bone sawn through in the middle. The cancerous degeneration has so completely involved the upper division of the larynx, the epiglottis, and the hyoid bone, that it is difficult to recognise the individual parts. The inner surfaces of the cricoid and thyroid cartilages, as far as the laryngeal pouches and the inferior vocal cords, are free. The morbid change begins close above the laryngeal pouches, and, in the form of modulated masses, completely fills the whole upper part of the laryngeal cavity. The arytaenoid cartilages and the ary-epiglottic ligaments are completely lost in the tumour. The epiglottis is recognisable in a somewhat separate mass, in which some fragments of the œsophagus can still be recognised. The hyoid bone is surrounded by the swelling, which has grown upwards into the base of the tongue.

The anterior surfaces of the thyroid cartilage and the ring of the cricoid cartilage have remained quite free from disease. The tongue was divided in front of the papillæ circumvallatæ, and the cut surface shows healthy tissue. The removed larynx, hyoid bone, and tongue are about 4.4 inches long, of which 1.2 inches belong to the tongue.

You are aware, gentlemen, that after Czerny had demonstrated by experiments on dogs the possibility of extirpating the larynx (*Wiener Medizinische Wochenschrift*, nos. 27 and 28, 1870), the first extirpation of the larynx in man was performed by Billroth. On December 31, 1873, he removed the larynx from a schoolmaster, aged thirty-six, on account of diffuse epithelial cancer. A part of the two upper tracheal bags, and the whole of the cri-

coid, arytaenoid, and thyroid cartilages were removed, and a third of the base of the gullet was taken away. The œsophagus and pharynx, the anterior and greater part of the epiglottis, and the hyoid bone, were preserved. The patient was dismissed cured on March 2, 1874, able to speak intelligibly by means of an artificial larynx (Dr. C. Gussenbauer, in *Archiv für Klinische Chirurgie*, Band xvii. 1874).

The second operation, for partial extirpation, was performed by Heine, of Prague, in a case of stenosis of the larynx. How much of the larynx was removed I do not know; and in regard to this I must refer you to the forthcoming transactions of the fourth German Surgical Congress, held in April of the present year, at which the patient operated on by Heine was shown.

A third operation of this kind was performed on August 12, 1874, by Dr. Moritz Schmidt, of Frankfurt, who removed the cricoid, thyroid, and arytaenoid cartilages from a cattle-dealer, aged fifty-six, on account of carcinoma of the larynx, producing narrowing and symptoms of suffocation. The patient died of collapse on the fifth day after the operation.

With regard to the steps of the operation, I must inform you that Billroth and Schmidt made a longitudinal incision upwards from the hyoid bone, and removed the larynx by cutting through the trachea from below; while I made a T-shaped incision, freed the larynx from its connections above by careful dissection, and divided the trachea last of all. I would recommend my method also in cases where the larynx alone is to be removed, and the epiglottis, hyoid bone, and tongue, are to be preserved. By performing extirpation from above, it becomes possible to expose and tie the principal arteries before dividing them, so as to reduce the loss of blood to a minimum, and to prevent the escape of blood into the trachea, even when one operates without plugging the trachea, or when the plug is spoiled. I must, however, attach the greatest importance to the plugging of the trachea; and it is advisable always to have at hand several of Trendelenburg's tampon-cannulæ, in case that one or other of them should fail.

In order to be able to carry out the plugging as quickly as possible, it is advisable to perform the tracheotomy before proceeding to extirpate the larynx. Indeed, in most cases it will be possible to wait for the cicatrization of the tracheal fistula before proceeding to the principal operation. The advantage is gained by this, that the trachea, being united to the skin in the region of the fistula, does not sink downwards as is otherwise the case, and that the process of stitching the skin of the neck to the trachea may be omitted.

In the cases operated on by Heine and Billroth, an artificial larynx was fitted on soon after the operation. In my patient, the large traumatic cavity, extending far beyond the limit of the larynx, will render this impossible, and it will be necessary to wait for the cicatrization of the wound. How this will take place if the case continue to make favourable progress, and whether, in the perfectly immovable state of the remnant of the tongue, the power of swallowing may return, I am not able to foresee.

TWO CASES OF COMPLETE TRANSPOSITION OF THE VISCERA. BY DR. SCHEELLE, OF DANTZIG.*

CASE I. Total Transposition of the Viscera. Insufficiency and Narrowness of the Aortic Orifice, very probably Congenital. Thoracic Portion of Spine straight, not convex towards the left. Right-handedness.—Alfred G., aged four and a half, came under my care on December 28, 1871. The child's father, a ship captain, is a man in excellent health; the mother is an extremely blooming and powerful woman. His three sisters are vigorous and healthy. The grandparents are not alive. In no member of the family can the existence of an anomaly in the position of the viscera be ascertained. The mother is said to have enjoyed perfectly good health during her pregnancy. The boy himself was born four weeks before full time. At first he was very weakly and slender, but gradually filled out. At the age of a year and a half, it was stated, he suffered for some time from diarrhoea. In the winter of 1870-71 he had 'catarrhal fever,' but during the summer of 1871 was cheerful and healthy. His mother frequently noticed that he was 'quite out of breath' after active playing and making much noise. His parents did not notice that the boy ever used the left hand by preference in eating, playing, throwing, or striking. There was nothing remarkable in his mental development, but he was said to be very easily irritated, and to then become at once very short-breathed.

On December 26 he was attacked with vomiting, and pain in the head and belly, to which diarrhoea was soon added; these symptoms were ascribed to indigestion, in consequence of a Christmas feast. The touch could detect no increased heat; the pulse was much quickened, the tongue moderately coated.

In the beginning of January a rather violent cough set in, occurring in paroxysms, being especially frequent in the evening and night, and giving the child much uneasiness. During the paroxysms, a profuse cold sweat broke out on the forehead and face, and the child became very short-breathed. This led the parents to send for me, and induced me to make a careful examination of the child.

The examination revealed a complete inversion of the viscera, with rather considerable narrowing and insufficiency of the aortic valves. The gastro-intestinal catarrh had probably produced much disturbance of the compensation power of the heart. When the child had recovered under treatment, I made the following note of his condition.

February 6, 1872.—The child is of slender build, well nourished. The expression of his countenance is anxious. The face is pale; the mucous membranes, as far as they can be seen, are pale and cyanosed. There is no cyanosis of the hands and feet; no cedema. The temperature is not raised (96°-8° Fahr.); the pulse is frequent (118-120) moderately full. The pulse-wave is high, almost jerking; tension rather considerable. The carotids in the neck throb much, and there is a distinct thrill in them.

In the chest, a strong pulsation is at once felt on the right side. At the same time, the regal third, fourth, and fifth costal cartilages, and the base of the sternum show a marked bulging forwards. The

* *Berliner Klinische Wochenschrift*, July 12 and 19, 1875.

pulsation extends from the third to the sixth intercostal space. In the sixth intercostal space, 1½ centimètre outside the right nipple-line, the apex of the heart is distinctly felt. The hand laid in the bulging portion of the chest is rather forcibly raised, especially in the direction of the apex of the heart, to the right, outwards, and downwards. The impulse of the apex is high, moderately extensive, rather resistant. *Fremissement* cannot be perceived. To the left of the sternum, pulsation can neither be seen nor felt in the cardiac region. On pressing with the points of the fingers in the jugulum, the arch of the aorta is distinctly felt. It cannot be followed towards the right, but can be traced towards the left beneath the origin of the sterno-cleido-mastoid (innominate artery).

The percussion-sound above and below the clavicles on both sides, is full and moderately clear. On the right side, dullness begins in the second intercostal space; it is intense over the third rib, at a point corresponding to the commencement of pulsation; extends in the third and fourth intercostal spaces, on the right, towards the nipple-line; and passes about two centimètres beyond this in the sixth intercostal space. At the seventh rib, in the nipple-line, the dullness is bordered by a loud, deep, tympanic, pulmonic sound. The dullness extends to the left as far as the sternum, and passes a centimètre beyond the left border of this bone. On the left side, there is a loud clear percussion-sound in the cardiac region. On tracing out the limits of the dullness on the right side, it assumes the form of a triangle, the apex of which lies in the sixth intercostal space outside the nipple-line, and the base is formed by a line drawn a centimètre outside the border of the sternum, from the sixth costal cartilage to the junction of the third costal cartilage with the sternum. On the left side of the thorax, slight dullness begins in the parasternal line at the fifth, and becomes more intense at the sixth rib. Its limit can be followed in a tolerably straight line towards the left. Intense dullness in the parasternal line reaches four centimètres, and in the nipple-line two centimètres, beyond the free border of the ribs, and ends in the axillary line at the edge of the ribs. Towards the right, the dullness extends 0·8 beyond the sternum, and passes upwards, without having any defined limit, into the cardiac dullness described above. The outline of dullness, when marked out, represents the form of a very extensive liver-dullness, the greatest vertical diameter, corresponding to the great lobe, lying in the left hypochondrium. This relation of parts can be distinctly confirmed by palpation. The whole of the free border of the liver is felt, slightly rounded, and gradually lessening towards the right hypochondrium. *Fremitus* is distinctly perceived over the dullness, so far as the lungs extend.

On the right side of the chest, below the region of the heart's apex, at the seventh rib, the percussion-sound of the stomach commences. It extends to the right along the last costal cartilages, and passes downwards into the intestinal sound. With great care, a semilunar space can be distinctly marked out by percussion.

Below the right axilla, at the ninth rib, the pulmonic sound passes into a moderately intense dullness, which, from its being bounded by the course of the ninth rib, and in front by a line drawn from the right sterno-clavicular articulation to the point of the eleventh rib, is recognised as splenic dullness.

The free edge of the spleen cannot be felt during deep inspiration.

At the apex of the heart, in the sixth intercostal space on the right side, along with the systolic sound, a systolic murmur and a diastolic sound are heard. At the juncture of the third rib with the right border of the sternum are heard a systolic sound, a weaker systolic murmur, and a diastolic sound with a prolonged loud diastolic murmur.

In the second left intercostal space (region of the aorta) the same is heard; but here the systolic murmur exceeds the diastolic in intensity. In the second right intercostal space (pulmonary artery) the murmurs are much weaker; the diastolic sound is fairly loud. At the base of the sternum are heard a systolic sound with a short systolic murmur, and a diastolic sound with a prolonged diastolic murmur. In the region of the carotids, a loud systolic murmur is heard, but nothing during the diastole.

Over the brachial artery at the bend of the elbow and over the femoral artery, arterial murmurs are heard. Behind, the systolic murmur is heard distinctly along the right of the spinal column so far as the lumbar vertebræ; the diastolic murmur is here much less distinct than in front. To the left of the spinal column, the systolic murmur is almost lost. No difference can be felt as regards the time and quality of the pulse-wave, between the radial and crural arteries (an examination with the sphygmograph and cardiograph was made; but, as the instruments were defective, the result is omitted). There was no evidence of abnormal dilatation and pulsation of the intercostal, internal mammary, epigastric, and other arteries.

In other parts of the chest, there is no anomalous dullness. In the dependent parts of the lungs posteriorly, on both sides, moderately abundant moist râles of medium fineness are heard. The breath-sound everywhere is sharp and puerile.

There is moderately intense dullness in the right hypogastric region. (Later experiments with enemata led to the conclusion that the sigmoid flexure and the rectum lay in the right hypogastric region).

The scrotum is wrinkled; the right half of the scrotum appears the more voluminous; the right testicle is a little larger than the left.

The spinal column is quite straight, and shows no lateral deviation in the interscapular space. The circumference of the left half of the chest, however, is less than that of the right, the former being 10·6, the latter 11·8 inches.

The boy is right-handed; he always uses the right hand in eating, striking, etc. Both extremities are more powerfully developed on the right side than on the left.

From the preceding details of the physical examination, a complete transposition of the viscera in general can be easily diagnosed. Not only does the heart lie in the right half of the chest, but the great vascular trunks are also transposed. The innominate artery can be felt behind the left sterno-clavicular articulation. Both palpation and percussion give evidence of heterotaxis of the organs lying below the diaphragm. From analogy, and from comparison with other previous observations, it may be assumed the heart is transposed in all its parts, and that the pulmonary artery is to be sought on the second intercostal space on the right side.

It further appears from the increased area of cardiac dullness, the dullness at the base of the sternum, and the increased diastolic sound over the

pulmonary artery, that not only the aortic ventricle, but the whole heart, is in a state of excentric hypertrophy.

Finally, the existence of an affection of the valves of the heart is proved by the existence of murmurs audible over the orifices. The accurate determination of these is very difficult, especially as, in cases of anomaly of position, unexpected irregularities in the septum and valves frequently occur, and hence the significance of auscultatory signs is much obscured. In the mean time, I think, there are sufficient grounds to justify me in assuming the existence of narrowing and insufficiency of the aortic valves, viz:—

1. The hypertrophy of the systemic division of the heart. The direction of the increased impulse follows the apex, which is displaced downwards and outwards, and the apex beat is resistant and high.

2. The systolic and diastolic murmur, which is heard in greatest intensity over the aortic semilunar valves, *i.e.*, at the sternal end of the third right rib.

3. The condition of the carotids, the throbbing and thrill, and the absence of diastolic sound in them.

4. The propagations of the systolic murmur into the carotids.

5. The condition of the peripheral arteries.

The sum of these physical phenomena places the diagnosis beyond a doubt. I had also the opportunity of showing the case to Professors Leyden (of Strassburg) and Baum (of Göttingen), as well as to several colleagues of this and other places. It seems, however, incumbent on me, as I am not able to adduce the result of a *post mortem* examination, to give still more accurate grounds for diagnosis *per exclusionem*.

There are only a relatively small number of cases of congenital malformation of the heart, which, latent for a long time, come accidentally under the notice of the practitioner. Among these are,

1. Permanence of the foramen ovale—defect of the septum of the ventricles.

2. Narrowing of the aorta at the insertion point of the ductus Botalli.

3. Narrowing of the orifice of the pulmonary artery.

Almost all other cases are rarely viable, on account of the greater malformations and defects, or come at once under notice in consequence of the presence of symptoms of severe disturbance of the circulation.

1. Permanence of the foramen ovale is not only a rather frequent occurrence in a normally placed heart, but has been noticed in several cases of transposition of the viscera (B. Schultze, Valleix, and Schrötter). If this arrest of development produce general symptoms, these are always the phenomena of cyanosis in its highest grade (*morbus cæruleus*). Far more often, this occurs with simultaneous defect in the ventricular septum (Boyer, De Bary, Martin Breschet, Virchow). In Virchow's case there was also general dropsy. The auscultatory phenomena in open foramen ovale, when they exist, are, as a rule, exquisite systolic murmurs (B. Schultze, Wolfshofer, Schrötter). The murmurs, however, are not propagated into the carotids, and are not capable of causing the diastolic sound to be lost. I find, however, no record of a diastolic murmur in the cardiac region.

2. The auscultatory phenomena in this case, their wide extent, and their propagation into the carotids,

might indeed be explained by a congenital narrowing of the aorta at the isthmus, complicated with relative insufficiency of the aortic valves. But then there is an absence of the collateral dilatation of the intercostal, internal mammary, epigastric and other arteries, so characteristic of this form. Further, there is an absence of the difference between the systemic arteries above and below the narrowed part in relation to breadth, synchronism, and the form of the pulse-wave, such as I have seen and described in a case in Leyden's clinic.

3. Narrowing of the pulmonary artery must be excluded, since it exerts no influence on the occurrence of the phenomena in the systemic arteries. Besides, in affections of the pulmonary artery, murmurs are not propagated to the carotids; and, finally, there is in them no ground for absence of the diastolic sound.

The condition of the systemic arteries unmistakably indicates an affection of the aortic valves—namely, insufficiency. The diagnosis of insufficiency and narrowing of the aortic orifice is then decisive, as the explanation of all the symptoms.

One question yet remains to be answered. Is this affection of the valves congenital?

There is a preponderance of reasons for believing that it is so. There is no record of the child having suffered from endocarditis. In the winter of 1870-71, it is said, he suffered from 'catarrhal fever;' but, although he has been confined to bed for a long time, cyanosis, oedema, etc., have not been observed. In the earliest years, congenital malformations of the heart, compatible with life, produce relatively little trouble, while the presence of endocarditis can scarcely be overlooked, on account of the pain and disturbance of function. The practitioner who previously treated him, on being questioned by me, could not remember that the child had had any disease of the kind.

The assumption that the defect is congenital, is further supported by the circumstance that in transposition of the viscera there is, if we may use the expression, a certain predisposition to malformations of the heart. Anomalies of this kind have been observed in nine out of above 100 cases recorded by various observers. In eight the foramen ovale and septum ventriculorum, in one the pulmonary orifice, were implicated. The aortic orifice has hitherto not been found diseased in transposition of the viscera; and congenital abnormality of this part is very rare. And this was indeed the only ground which opposed the assumption of the congenital condition in my case. The great probability of the above-mentioned presumption, however, cannot be denied.

CASE II.—*Complete Transposition of the Viscera; Incipient Cirrhosis of the Liver; Deviation of the Spinal Column to the Left in the Intrascapular Region; Right-handedness.*—The subject is S., a master painter, aged thirty-four. His parents are alive and healthy. Neither in them nor in the man's three children, who are alive and healthy, is there any anomaly in the position of the internal organs; and his mother does not remember any disturbance during her pregnancy. When young, he suffered many times from intermittent fever; and he acknowledges that he has been addicted to drink. For three years he has suffered from a more and more increasing difficulty of digestion, a sense of fulness in the epigastrium, constipation, and occasional

vomiting, especially after eating fat and hard food. In the summer of 1873, he had a severe attack of hæmatemesis. After that time he remained pretty well, especially after the use of Carlsbad waters. His bowels are generally constipated. He has lately complained of occasional pain in the neck, and hoarseness. He has a little cough and expectoration. He denies having fever or night-sweats, or that he has become thinner.

November 9, 1873.—He is a small feebly built man, with a pale countenance; the mucous membranes, as far as they can be seen, are pale; he is free from fever, but complains of a sensation of pressure in the epigastrium after taking solid food, constipation, and dryness of the throat, with hoarseness. His muscles are scanty and flabby; the panniculus adiposus is moderately developed. His neck is thin and long; neither the sight nor touch can detect any anomaly in it. His voice is deep—rather rough. He has intense pharyngitis granulosa. The chest is narrow, relatively short, slightly distended at the lower part; the range of motion is small. The right half measures 43 centimètres, the left 41. The respiration is costo-abdominal. There is no dyspnoea. The pulse is regular, of moderate fullness.

The epigastric region and the left hypochondrium are much distended, and a strong resistance is here felt. Palpation detects an even smooth tumour occupying the whole of the left hypochondrium, and extending to the left, without defined limits, into the splenic region. Towards the right it is sharply defined, and ceases about 0·8 inch outside the right upper line. On tracing out the tumour by palpation in the epigastrium and left hypochondrium, the form of an inverted liver is presented. Percussion shows this condition still more accurately. There is intense dullness over the whole "semilunar space." The dullness extends in the left anterior and lateral thoracic wall, nearly a handbreadth beyond the free edge of the ribs.

A close examination of the chest gives the following results. In the fifth right ulcerated space, in the region of the nipple, pulsation is scarcely visible, but is distinctly felt. On the left side, the apex-beat is absent. The pulsation on the right is easily recognised as the apex-beat of the heart, transposed to the right. Corresponding with this, percussion on the left side shows absence of cardiac dullness, while this is perceived, on the right, from the fourth rib in the right parasternal line. The cardiac dullness on the right does not reach to the left beyond the right sternal line, and passes downwards into the dullness of the smaller lobe of the liver, which is swollen. At the point of the apex-beat, in the fifth right intercostal space, two clear distinctly accentuated heart-sounds are heard. On the left, in the cardiac region, the heart-sounds are much more feeble, being evidently transmitted. There is a clear sound over the second intercostal space on both sides. The innominate artery cannot be felt.

In the left lateral wall of the chest, percussion detects an enlarged spleen with the greatest distinctness. On deep inspiration, the sharp edge of the spleen can be felt quite plainly.

The right hypochondrium is occupied by the stomach, and gives a loud, deep, tympanic stomach-sound.

Behind, there is a disposition to projection of the scapulae. In the intrascapular space, the spinal column shows a distinct curve, with the convexity towards the left.

Physical examination of the lungs detects no evident disease of these organs. The fremitus is somewhat more distinct posteriorly and laterally on the left side than on the right.

Percussion of the abdomen shows that the sigmoid flexure and the rectum lie to the right side; at least, there is intense dullness in the ileo-cæcal region.

The right half of the body is more powerfully developed than the left. This is consonant with the fact that the man has always used the right hand in his occupation.

The diagnosis in this case of complete transposition of the viscera is not difficult. The enlargement of the liver, and the splenic tumour, taken in conjunction with abundant hæmatemesis, leaves no doubt, although ascites and icterus are absent, that the assumption of chronic interstitial hepatitis is correct. I had an opportunity of showing the man to my friend Dr. Kohts of Strassburg, and to other medical men in this place; and the correctness of the diagnosis was confirmed by all. In the first case, the existence of the irregularity of structure was more accurately confirmed by the presence of the abnormal pulsation in the right half of the chest; and in the second, by the presence of the greatly enlarged liver in the left hypochondrium.

Medical literature is not deficient in cases of transposition. The first comprehensive collection was given by Wenzel Grüber in 1865, in Dubois-Reymond and Reichert's *Archiv*. He collated seventy-nine cases from literature, and assumes that there were still other cases which were not accessible to him, so that the total number would be about 100. Grüber indicates accurately the sources of his information. Since Grüber wrote, the cases have been made known by the following authors.

Scharlau (*Monatsschrift für Geburtskunde*, October, 1866). Preparation of a new born child.

Duroziez (*Gazette des Hôpitaux*, 1866, no. 190).

Isambert (*Gazette Médicale de Paris*, 1867, no. 7).

Hutchinson (*American Journal of Medical Sciences*, July, 1868). A man aged twenty-eight.

Pye-Smith (*Medical Anatomy, or illustration of the Relative Position and Movements of the Internal Organs*).

Bailey (*Transactions of the Obstetrical Society*, 1869).

Powell (*British Medical Journal*, vol. i. p. 349).

Valerani (*Annali Universali di Medicina*, February, 1869).

Triplett (*Boston Medical and Surgical Journal*, August, 1870).

Burgess (*St. Louis Medical and Surgical Journal*, November, 1870).

Hickman (*Transactions of Pathological Society of London*, vol. xx., 1870). Two cases: one, a boy six weeks old; the other, a woman aged twenty-eight, with endocarditic deposits on the mitral and aortic valves.

Schrötter (*Oesterreich. Medicin. Jahrbücher*, vol. xx.). A young man aged nineteen, with narrowing of the orifice of the pulmonary artery.

Secchi (*Berliner Klinische Wochenschrift*, no. 20, 1873).

Steudener (*Deutsche Klinik*, no. 1, 1870).

Besides these I find the following, not mentioned by Grüber: Veling (*Gazette Médicale de Strassbourg*, no. 1, 1854); Von Siebold (F. M. Heiland, *On the Relation between the Right and Left Halves of the Human Body*, Nuremberg, 1807); and

Sampson (*Philosophical Transactions*, vol. ix.). Of all these cases, sixteen were diagnosed during life; most of them in the more recent period. Detailed descriptions, however, are scanty.

With regard to the development of this interesting malformation, the view of C. E. von Baer (*Ueber Entwicklungsgeschichte der Thiere*, 1828) prevailed for a long time. The exceptional turning of the embryo to the right side instead of, as usual, to the left, and the coincident position of the vitelline sac to the right side of the foetus, were supposed to be the conditions on which the transposition depended. From the third day of incubation (at least in the chick), the embryo, lying with its long axis parallel to the transverse axis of the egg, and with its right side directed towards the apex and its left towards the round end of the egg, completes this turning towards the left. Hence, in the normal condition, in the gradual separation of the vitelline sac, the latter comes to lie to the left of the embryo. Among several hundred embryo chicks, Von Baer found only one in which this condition was reversed, and in which the turning took place towards the right; and in this case the heart showed an inverted arrangement of all its relations. Von Baer has no doubt that in this case transposition of the viscera had commenced.

Remak (*Untersuchungen über die Entwicklung der Wirbelthiere*), B. Schultze (*Virchow's Archiv*, Band vii.), Förster (*Die Missbildungen der Menschen*, 1865), and others, agree with von Baer. And in fact his view is supported by the observations made on symmetrical double monsters, in which the viscera are usually transposed.*

The conjecture expressed by Virchow (*Archiv*, Band xxii.) regarding the influence of the spiral twisting of the umbilical cord to the right on the production of transposition of the viscera, is contradicted by the relative frequency of the occurrence. Neugebauer (*Nägele's Geburtshilfe*, 1863), in 100 cases found the umbilical cord twisted to the right in thirty-nine.

On the other hand, Rindfleisch, in his *Pathological Histology*, has long put forth a theory which has much that is attractive in it. Starting from the physical premiss, that a column of fluid flowing through an elastic tube under strong pressure assumes a spiral twist, he applies this to the column of blood, and says: 'This property is shared by the blood-vessels, and the primitive cardiac tube behaves like a twisted cylinder, in the normal condition, like one twisted from left to right. With this, the apex of the heart is directed towards the left; and on this is dependent the normal position of all the viscera. There are, however, cases in which the rotation takes place in the opposite direction. The cardiac tube is then curved like a cylinder, twisted from right to left; the apex of the heart is directed towards the right, and the consequence is a complete transposition of the asymmetrical viscera.' How far this assumption is correct, I will not attempt to decide. In any case, the question still remains, 'Wherein lies the explanation of this exceptional rotation of

the blood-column?' Here, perhaps, the recent observations of Dareste may give some information. In the *Comptes Rendus* for 1870, he reports that he had succeeded in artificially producing transposition of the viscera, through a difference in the temperature to which eggs were exposed. Should his experiment be confirmed, it would be an important fact gained for embryology.

There are two other points of not less interest:

1. The condition of the spinal column in these cases.

2. The relation of individuals with transposed viscera to the almost universal law of right-handedness in man.

Professor Baum, of Göttingen, has directed attention to the first of these points. In the histories of my cases, I have expressly stated that in the child the spinal column was perfectly straight, while in the adult it was slightly convex towards the left. In most of the earlier described cases, this point is entirely unnoticed. And yet, in 1791, in his *Mémoire sur la Situation des Gros Vaisseaux*, Sabatier entered fully into this subject. He referred the normal curve of the spinal column to the right to the position of the aorta, the course of which is on the left side from the third to the eighth or ninth dorsal vertebra. Bichat (*Anatomie Descriptive*, tome i. 1866) and Bérard (*Bulletin de la Faculté de Médecine*, tome iii.) contradict this assumption, and ascribe the lateral curve of the vertebral column to the muscles of the right upper limb and their predominant use. But Bouvier (*Leçons cliniques sur les Maladies chroniques de l'Appareil locomoteur*, 1858), Böhling (*Die seitliche Rückgratsverkrümmung*, Berlin, 1851), and W. Grüber (*loc. cit.*), support Sabatier's view, and have again brought it into repute. Their grounds are the following.

1. The deviation of the spinal column takes place only in the part where the aorta lies along the side. Below the diaphragm it is not observed, although origins of muscles are still found here.

2. The influence of the blood-vessels on the bones is shown in many other parts of the skeleton.

3. The influence of the aorta occurs also in animals, in which nothing can be said of a predominant use of one limb.

4. In most of the cases where the aorta runs its course along the right side of the spinal column instead of the left, a deviation to the opposite side is observed, even in individuals who are right-handed.

In medical literature, only thirteen cases of lateral curvature of the thoracic part of the spinal column have been noticed. Of these, in nine recorded by Scoutetten, Pétrequin, Géry, Grisolle, Grüber, B. Schultze, and Pye-Smith, the curve was to the left; while in four recorded by Bérard, Rostan, Ross, and Luys, it was to the right. In six of the nine cases, the individuals are stated to have been right-handed; and the same is recorded of Bérard's and Rostan's cases. In both my cases there is right-handedness; but in the boy the spinal column as yet shows no deviation, in entire agreement with Bouvier's assertion (*op. cit.*) that, the younger the individual, the straighter the spinal column is. In the cases of transposed viscera recorded by Baillie and A. Cooper, the individuals used the right arm most; in Bujalsky's case the left was used more; but in these cases the direction of the spinal column is not described. In one case, observed by Böhling in Romberg's clinic, there was a strongly marked curve of the

* There seems to have been an exception in the case of the Siamese twins. At least, Eichwald and Heppner (*Jahresbericht*, 1871) assert that the left twin, Chang, had transposition of the viscera. [Sir J. Y. Simpson, in his account of the Siamese twins in the *British Medical Journal*, February 13, 1869, expresses the opinion, based on a careful examination made by Dr. Aitken, that the position of the viscera was normal in both.—*Trans.*]

spinal column towards the left. The man was left-handed.

While the small number of carefully recorded cases cannot settle the dispute between Bichat and Sabatier, most of them are in favour of the latter; and it is the more astonishing that only Bichat's view is taught in manuals of anatomy.

With regard to the second point, the relation of transposition of the viscera to right or left handedness, the question is a relatively new one. Hyrtl (*Lehrbuch der Anatomie*), has applied the arrangement of the large vessels in the thorax to the explanation of the irregular occurrence of left-handedness. Professor Oehl, of Pavia, communicated to him two cases of left-handed individuals, in whom, after death, the right subclavian artery was found to arise from the aorta beyond the left carotid. Hyrtl saw four such cases in the museum at Prague and three in Vienna, and is disposed to bring this vascular anomaly into causal connection with left-handedness. Pye-Smith also (*Guy's Hospital Reports*) has given his attention to this condition. In 296 cases he found this arrangement in force; in one of these, however, Peacock was able to determine the existence of right-handedness during life. Cases, however, were seen by Pye-Smith and others, in which not only was the left upper extremity more powerfully developed than the right, but this condition extended to the whole left half of the body. Just so it is not only the right arm, but the whole right half of the body, that enjoys the disposition to be better developed. This circumstance indicates a cerebral influence. Broca, in weighing forty brains, found that the left frontal lobe was distinctly heavier than the right. This was also found in 800 brains by Boyd (*Philosoph. Transactions*, 1861). Further, Gratiolet asserts that the left cerebral hemisphere goes in advance of the right in development. A number of neuropathologists—indeed, nearly all of them—place the centre for speech in the left frontal lobe. *A priori*, then, there is much probability in Broca's conclusion, that the general right-handedness of man is dependent on the earlier and more rich development of the left cerebral hemisphere. This, again, has its explanation in the direct and more free supply of blood through the straighter course of the left carotid (Leyden and Pye-Smith). From these facts it must follow that individuals with transposition of the vessels, which generally occurs in transpositions of the viscera, must have a disposition to be left-handed; and it would be extremely interesting if such a law could be established. But the communications above-mentioned leave the question open. In most of the cases, nothing is said as to whether the right or the left hand was most used. Among the few cases in which special mention of this point is made, left-handedness is in an exceptional minority (Bujalsky and Bühring). Most (8) of the cases were right-handed; so were also my two cases. They thus in no way direct us to a final conclusion, but they appear to contradict Broca's view.

In conclusion, I will not delay to offer my most hearty thanks to Professor Baum of Göttingen for his truly extraordinary kindness in placing at my disposal the literature of this interesting subject from his own library and that of Göttingen, and copying with his own hand what he could not send.

MOLLIÈRE ON SOME POINTS IN THE DIAGNOSIS OF SCLEROSIS OF THE NERVOUS SYSTEM.

M. Mollière's object in publishing these short notes (in the *Lyon Médical*) is to draw attention to some points, hitherto very obscure and but little studied, relating to organic diseases of the nervous centres. A more perfect knowledge of these details may enable the practitioner to combat these formidable affections in time; for, as M. Charcot has very judiciously observed, when we first come to diagnose sclerosis, the disease is completely established, and all hope of removing such alterations as exist is almost entirely dissipated.

The proliferation of the cells of the connective tissue (neuroglia) can be checked only at its early period of growth; at a later period, when this embryonic tissue is completely transformed into fibrous tissue (sclerosis) compressing and destroying the nervous elements, we can no longer hope to restore it to its natural state. It is greatly to be desired, then, that the physician should be acquainted with a certain number of symptoms which would enable him to recognise this interstitial morbid process while there is yet time for its successful treatment.

M. Charcot has taken great interest in this question, and has established these two important points, to which M. Mollière calls attention: 1. The development of the symptoms and lesions of locomotor ataxy in individuals previously affected with double atrophy of the retina; and 2. The frequent development of extensive sclerosis of the nervous centres in patients who have presented, for many years, the phenomena of well-marked or abnormal hysteria. With regard to the first kind of facts, M. Mollière has no personal observations of his own to offer; but of the second or hysterical kind, he is able to bring forward a certain number of cases. It is necessary to watch these patients for a considerable time in order to see their fatal end.

One of two cases brought forward by M. Mollière was a young woman with strongly marked hysterical antecedents, and who was admitted into the hospital with all the symptoms of the most striking hysterical paraplegia. This diagnosis was confirmed by all those present. She remained two months in the hospital without any great improvement. One morning she was seized with general symptoms of a formidable character, in consequence of some vexation. She died the same evening. At the necropsy, several patches of sclerosis were found on the pons Varolii, affecting deeply the subjacent nervous tissue. The medulla and spinal cord were healthy.

About the same time there was in the hospital a poor girl equally hysterical. Every one agreed in the diagnosis of the case.

It was a typical case of hysterical hemiplegia. However, for several months she had complained of violent pain beneath her left breast, to which little attention was paid on account of the whimsical character of the patient. She could still manage to walk, and what is more, if her hand were grasped unawares, she could be made to run as far as the end of the ward. She was again examined, when it was found that, besides an affection of the retinae, there was muscular atrophy of a most marked character on the whole of the paralysed side. From this moment, M. Mollière watched this patient with great attention, and all these symptoms were found to go on

increasing. When he lost sight of her, she was in a home for incurables. In short, all those strange and abnormal forms of hysteria, while simulating real lesions, do not simulate them so much as has been supposed, but are in many even the very proofs of those lesions. Hence, while we adopt a general mode of treatment for what we may consider as hysteria or a nervous affection, it would be well to employ, also, according to circumstances, some of those powerful remedies which are adopted in cases of organic lesions, and which are often inefficient because they are employed too late.

But while in women we sometimes find most valuable information for diagnosis and prognosis in affections which are said to be hysterical, among men it is in the existence of obstinate and prolonged neuralgia that we gather this information; so that every obstinate form of neuralgia, the general or local etiology of which is unknown, should be watched with great attention, and awaken a suspicion as to the existence of central and profound lesions. The following facts will serve as examples.

A patient enters the hospital with a most painful sciatica, especially at the level of the gluteal region. After some time, the pain is subdued. The patient is made to walk, but he is found to be ataxic, although he states that he walked properly before the neuralgic attack.

Another patient suffered from chronic gastralgia with obstinate vomiting. Affections of vision led to a proper diagnosis. The patient tottered, and had also affections of sensibility. Sclerosis of the cerebellum was considered probable. Later on he became ataxic, and could not walk, but his intellect was unaffected. There was, also, well marked muscular atrophy. It is the same in general paralysis.

J. LOCKHART CLARKE, M.D.

BOWDITCH ON THE COURSE OF NERVE-FIBRES IN THE SPINAL CORD.

In the *Boston Medical and Surgical Journal* for July 16, Dr. H. P. Bowditch gives an account of the results of some experiments made by him on the above subject. Experimental inquiry into the channels by which sensitive and motor impressions traverse the spinal cord has been made by several continental physiologists, especially by Woroschiloff. After describing the method by which he opened up the spinal cord in rabbits, Dr. Bowditch says that a systematic study of the effects of the mutilation was made, first on the production of reflex actions, due to irritation, by pressure and electricity, of the feet and ears of the animal; secondly, on the position of the limbs, both at rest and in movement; and thirdly, in the production of movements in the hind limbs, due to irritation by induced currents of the cord just below the calamus scriptorius. The animals were killed about five hours after the operation, and the portion of the cord operated upon was placed in alcohol and then examined.

In the first experiment, the anterior and posterior columns and nearly the whole of the gray substance were divided. After this section, no disturbance of the transmission of motor or sensitive impressions through the cord could be detected. Pressure on any of the four extremities produces vigorous movements of all four limbs. The animal sits and moves in a perfectly normal manner. Irritation of the spinal cord causes at first springing movements, and afterwards

tetanic flexion of both legs. Section of the lateral columns involving the cornua on each side (the counterpart of the first experiment) entirely prevents the transmission of impressions through that region of the cord. Irritation of one hind leg causes reflex movements in the same leg, or, if the irritation be strong, of the opposite leg as well. Irritation of a fore leg causes movements in the anterior, but not in the posterior part of the body. Irritation of the cervical cord causes movements in all the muscles of the body, except those of the hind legs. Section of the posterior columns alone is absolutely without effect on the condition of the animal. All movements are executed in a perfectly normal manner. There is nowhere hyperæsthesia or anæsthesia.

If, together with the posterior columns, portions of the lateral columns (the posterior portion) be also divided, the effect is much the same, except that in springing the extension of the hind legs takes place with diminished force, while the flexion of the limbs is unaffected. A feeble irritation of the spinal cord causes a powerful tetanic flexion of all the joints of the hind legs.

Division of the anterior columns with the adjoining portions of the lateral columns produces no effect, except that in springing the animal extends the hind legs more powerfully than in the normal condition. The result of these five experiments, showing that the channels of motor and sensitive impressions lie in the lateral and not in the anterior and posterior columns of the cord, is in opposition to the conclusions of many other investigators, and to the generally received opinion of physiologists.

This contradiction Dr. Bowditch considers as explained by the facts that the same portion of the cord is not always selected for operation and comparison, and that in his experiments the neighbouring parts were not compressed and injured through his method of operating.

Further experiments were performed, furnishing additional evidence that the lateral columns were the channels of motor and sensitive impressions. The cord was divided except the left lateral column, when irritation of either hind foot caused movements of the anterior limbs, the strength of the irritation required to produce this being greater on the uninjured than on the injured side. That is, there is hyperæsthesia of the injured side. Similar effects follow the section of one of the lateral columns. More extensive mutilations were performed, and the whole cord was severed except the posterior portion of the right lateral column, when irritation of the right foot caused only reflex movements of the hind limbs, while irritation of the left foot caused movements of the fore limbs also. There is complete loss of voluntary movements in the left hind leg, and irritation of the cervical cord has no effect in that limb, while in the opposite side, the springing movements are well marked. After section of all the cord except the anterior and middle portion of the right lateral columns, the movements produced by irritation of the hind legs are the same as those described in the case immediately above. Irritation of the fore legs causes movements of the right, but not of the left hind leg. Irritation of the cervical cord causes strong flexion of the right and extension of the left hind leg. On section of all but the anterior portion of the left lateral column, irritation of the hind leg, on the side of the cord completely destroyed, caused movements in the anterior

part of the body, but without hyperæsthesia. Irritation of the fore-limbs caused no movements in the hind limbs; and irritation of the cervical cord produced no movements in the hind quarters, except in the knee joint of the leg on the side where a portion of the cord was preserved.

Although these experiments proved the possibility of dividing the whole cord, except a very small portion, without preventing the conduction of impressions through that portion, yet, in view of the possible interference with the circulation in the retained part, due to the division of so much of the substance of the cord, it seemed to Dr. Bowditch desirable to seek to localise the channels of nerve-force in the different parts of the lateral columns, by retaining portions of both instead of only one of the columns.

The result of such experiments is, that motor and sensitive nerve-fibres are found in all parts of the lateral columns.

Sensitive fibres from both hind legs are found in each lateral column, but the fibres, in each column, which come from the leg on the opposite side are capable of producing stronger reflex movements in the anterior part of the body than are called forth by excitation of the fibres which come from the leg on the same side (crossed hyperæsthesia).

The centripetal fibres, whose excitation produces these strong reflex movements, as well as those whose section on the opposite side gives occasion to them, lie in the middle third of the lateral columns; while the anterior and posterior thirds contain sensitive fibres which call forth movements of only moderate intensity in the anterior part of the body.

Motor fibres for both legs are found in each lateral column, but the motor fibres in different parts of these columns are called into activity in different ways. The reflex movements due to irritation of a fore leg can be excited in a hind limb only when the anterior half of the lateral column on the same side is preserved.

The co-ordinated movements of sitting and springing, and those produced by irritation of the cervical cord, are transmitted to each hind leg through the middle third of the lateral column on the same side.

Tetanus of both hind legs may be produced by irritation of the cord, even when the whole lateral column on one side has been destroyed; but if in addition to this the anterior two-thirds of the lateral column on the other side have been divided, tetanus occurs only on the side where a portion of the cord is intact.

The author gives reasons, too long for a place in this report, for regarding the crossed hyperæsthesia above alluded to as caused by the division of the inhibitory fibres having their origin at the periphery and going to the centre of reflex action in the medulla. According to this view, the excito-reflex fibres of a limb have their course mainly, but not exclusively, in the opposite side, while the inhibitory reflex fibres lie chiefly on the same side of the cord.

To effect still more perfect localisation, external portions of the lateral columns were divided, and the conclusions drawn therefrom are as follows.

Motor and sensitive nerves are found mixed together in all parts of the lateral columns.

The fibres which preside over co-ordinated movements of the hind limbs, as well as those whose section causes hyperæsthesia on the side of the injury, lie in those parts of the lateral columns which are nearest to the gray substance. The motor nerve-

fibres of the foot and lower leg seem to lie in the lateral columns externally to those of the thigh.

In all these experiments, it was found that considerable portions of the lateral columns could be removed without affecting motion or sensibility in the leg, although the motor and sensitive character of the divided portion could be demonstrated with certainty. This would seem to indicate that the same muscle, or the same cutaneous surface, is represented in the spinal cord by fibres having various positions in the lateral columns. This agrees with the observations of Eckhard and others, which show that two or three adjacent spinal roots send fibres to the same region of the body.

The main result of all these experiments, namely, that the lateral columns contain all the channels of motor and sensitive impressions, receives confirmation from the observations of Stilling on the areas of the cross-sections of the spinal nerves and of the columns of the spinal cord at different levels. A comparison of these areas shows that the lateral columns increase in size from below upwards, as if each successive spinal root contributed a certain proportion of its nerve-fibres to their formation.

(To be continued.)

BLYTH ON CONTAGIOUS PNEUMONIA.

In a very interesting report presented to the Okehampton Rural Sanitary Authority at their meeting, August 7, 1875, Mr. A. Wynter Blyth raises this question and discusses it at length. His statement and argument is as follows.

The disease that principally prevails in the Okehampton district—and that has prevailed with great fatality since Mr. Blyth has been connected with the union—is pneumonia. Now pneumonia is generally supposed to be a simple inflammation of the lungs brought on by cold or wet, sometimes affecting one, or occasionally both lungs, and very frequently extending to the pleura, and when it does so it is described as pleuro-pneumonia. In a previous annual report, he suggested that there were at least two kinds of pneumonia, one apparently brought on by cold, the other propagated by seed—and hence a contagious disease, the one influenced by weather and by seasons, the other obeying the same laws as such diseases as small-pox, scarlet fever, etc. He remarks that it is no new thing for a disease which is propagated by seed to seize and attack in preference one particular organ. Small-pox determines to the skin, typhoid fever to the bowels, hydrophobia to a portion of the spinal cord, and therefore the determination of a contagious disease to the lung is nothing very extraordinary. Besides this, there is a disease in cattle, an infectious pleuro-pneumonia, and as we have a small-pox and sheep have a small-pox, and as we have a scarlet fever and horses have a scarlet fever (strangles), and as we have a typhoid fever and as animals also have a typhoid fever, if it be established that man is affected with an infectious pleuro-pneumonia, it is only another link in the chain of evidence showing the intimate connection between the animal and human organism. Dr. Christian Budd has for many years held that the pneumonia he had observed was infectious, and when Mr. Blyth first came into the district Dr. C. Budd called his attention to it, and related many remarkable instances in support of such a view. In this opinion Dr. C. Budd stood alone, Mr. Blyth believes, until

recently, but towards the end of last year, and up to the present time, there has prevailed in the North of Devon a most intense epidemic of pneumonia. Its infectious character was so marked that several medical men of standing and experience, who must have seen hundreds of cases of pneumonia, were astonished and puzzled at this to them new phenomenon, and were even inclined to doubt whether it was not rather a new scourge than an old well-known disease. For example, the following is a letter which Mr. Blyth received upon the subject. 'The disease alluded to in your letter and annual report has puzzled me much—it is unquestionably a pleuro-pneumonia which creeps on insidiously, first through one day, then the other. At the commencement of the attack, rigors and severe pain in the head, back, and legs, with, in some of the cases, persistent diarrhoea and great cerebral disturbance, have been unfailing symptoms.' He then gives a list of cases, which, suppressing names, is as follows. A man became ill of pneumonia in April, and died after ten days' illness; his wife caught the same disease a few days after his death. A farmer's daughter, about a mile from the house of the former patients, became ill of the same disease about the same date, and a fourth case followed in the neighbouring village, and subsequently there occurred four other cases in the same parish. 'Since November,' continues the writer, 'I have had, I should think, twenty cases. A farmer in another parish became ill April 16; I was sent for April 18, and he died about midnight. The servant woman went home ill of the same disease about a week afterwards, and gave it to her married sister, with whom she was staying. The idea had already occurred to me as to whether the disease could be in any way allied to the pleuro-pneumonia of cattle.' As further testimony of a recent and valuable kind, Mr. Blyth has here a letter which he received from Dr. C. Budd: 'Northawton, July, 1875.—Dear Dr. Blyth, I believe it was soon after your appointment that I first called your attention to the existence of an epidemic of pneumonia, which had then for some time prevailed in this neighbourhood. Since that time the epidemic has rapidly extended, and, I believe, now prevails over a large extent of the country. As I had many years ago recognised it as a blood disorder, capable of being propagated by contagion, my attention was early directed to means calculated to prevent its spread. As the lung is the organ especially attacked, it was reasonable to suppose, from analogy to other similar disorders, that the emanations from the lung were the main source of the infectious principle. I have, therefore, for many years, in private practice, disinfected the sputa. But, as it is probable that all the products of expiration carry with them the specific poison, I have considered this expedient insufficient; and have, in some cases, tried the effect of inhalation of carbolic acid vapour. The distress of breathing, however, which accompanies the disorder, renders it difficult to carry this plan out. Whilst always disinfecting the sputa, I have of late mainly relied upon isolation (as far as practicable) and free ventilation. To ensure this last essential, I have in labourers' cottages generally kept the bedroom window open all the night through. If you should be able, as I hope you may, to devise any means still more efficacious, you will confer an immense benefit on humanity, and deserve the gratitude of the community. Whether this disorder differs in its essence from the sporadic cases of pneumonia

one has been accustomed to see all one's life, further and careful investigation are required to determine. This, however, I have observed, that in favourable cases, *i.e.*, in cases of recovery, the course and duration of the malady are, in both cases, about the same.—Yours very truly, CHRISTIAN BUDD.' Thus, Mr. Blyth argues, there is ample evidence of its peculiar and infectious character. The figures in the death returns are of not much value, as a guide to its prevalence, for two reasons (1), under the term of pneumonia, that at least two diseases are confused, just as under the old term of typhus, two fevers, *viz.*, typhus and typhoid, were only a little time ago confused together; and (2), because, although it is a very fatal disease, yet a large proportion recover. Mr. Blyth has thought it his duty to lay the facts before the local sanitary authority prominently, though from not being recognised as an infectious disease, from its laws of propagation being at present a matter of theory and supposition, little can be at present done by them as a sanitary authority to prevent its spread, except insisting on disinfectants being used and isolating the patients where possible; 11·2 per cent. of the deaths during the quarter have been returned under the head of pneumonia in this union.

[In the annual report of the Cork Street Fever Hospital in Dublin, Dr. Grimshaw calls attention to the occurrence of epidemic pneumonia, and expresses an opinion as to its pathology identical with that of Mr. Blyth.]

ANATOMY AND PHYSIOLOGY.

MICHEL ON THE DISTRIBUTION OF THE FIBRES OF THE OPTIC NERVE IN THE HUMAN RETINA.—A concise account of the observations of Professor Michel on this subject will be found in *Zehender's Klinische Monatsblätter*, April, 1875. According to these investigations, the nerve-fibres in the optic papilla on the nasal side are superimposed one over the other in large broad bundles, while on the temporal side the bundles are comparatively small and contain but few fibres, and, as they approach the macula lutea, there are distinct intervals between them; in this situation, too, the bundles are straight, while in all others they are more or less arched. In the immediate neighbourhood of the papilla the nerve-bundles lie one over the other, an arrangement which is not met with in any other situation with one exception. Between the papilla and the macula lutea the intervals between the nerve-bundles are narrow and slit-like, and the bundles anastomose with each other at a very acute angle. The fibres which pass directly to the macula appear to lose themselves in the ganglion-cell layer, while those further removed encircle the macula and anastomose very closely and completely with each other. In the region between but immediately above the macula and the papilla the nerve-bundles are also slightly superimposed, and cross over each other, forming the exceptional instance above referred to. The entire arrangement of the optic fibres is that of a plexus, the bundles becoming smaller and flatter as they radiate towards the peripheral portions of the plexus, and the intervening spaces, which are at first very narrow and slit-like, become ultimately wider and broader. At the ora serrata, the nerve-bundles terminate for the most part by free extremities.

Within the papilla the blood-vessels run parallel with the nerve-bundles, but it sometimes happens that the fibres which pass straight to the macula lie immediately over a large branch of the central artery. Elsewhere, as a general rule, the arteries appear to be partially embedded in the nerve-bundles, and are distributed in the same direction with them.

BOWATER J. VERNON.

CIACCIO ON THE MEMBRANE OF DESCMET AND ITS EPITHELIAL COVERING.—In the *Memorie dell' Accademia delle Scienze di Bologna*, series 3, vol. 5, Dr. G. V. Ciaccio gives the results of his observations on Descemet's membrane. He has studied this membrane in man and in other animals by various methods (cauterisation of the cornea with nitrate of silver immediately after death; treatment with a 0.5 per cent. solution of chloride of gold, with permanganate of potash, and with chloride of sodium). From a comparison of the results, he has arrived at the following conclusions. 1. Descemet's membrane is composed of very fine fibres, cemented together by a rather tenacious material, and it is provided with microscopic spaces by which the anterior chamber communicates with the small lamellæ and channels in the cornea, and through these with the lymphatic vessels of the conjunctiva. 2. The stomata which are scattered among the epithelial cells lining Descemet's membrane lead to the above-mentioned spaces in the anterior chamber. 3. After irritation or inflammation of the cornea and iris, it happens in some rare cases that there are seen, in the spaces of the membrane of Descemet, lymphatic corpuscles along with the aqueous humour. 4. The substances of the epithelial cells of the membrane of Descemet which surrounds the muscles is traversed by the fibres, which are interlaced like a network. 5. The contractile power of these cells resides in the nucleus and in the protoplasm within it, being, however, greater in the latter.

A. HENRY, M.D.

LEWIN ON THE ACTION OF ACONITIN ON THE HEART.—L. Lewin (*Centralblatt für die Medicin. Wochenschriften*, no. 25, 1875), working under Liebreich's direction, finds the following results.

1. The action of aconitin in doses of 0.025–0.015 gramme in frogs diminishes very pronouncedly the frequency of the heart's action, and this diminution is most rapid when the drug is injected into the veins; it occurs more slowly when given subcutaneously, and slowest of all when it is injected into the stomach. The mean duration of this time when it is injected into the veins is one hour, and in subcutaneous injection, two hours.

2. In some cases this slowness was followed by an increase of the frequency of the heart's action, lasting for a very short time, the heart's action soon becoming irregular, or it passed into stand-still, always in diastole.

3. At the end of almost all experiments, an arrhythmic action of the heart occurred, mostly caused by a more frequent pulsation of the auricles, sometimes the auricles alone contracting.

4. The peripheral nerves suffered with medium doses (0.005–0.008 gramme) a marked diminution in their excitability, with larger doses paralysis.

5. *Post mortem* electrical stimulation did not always cause the heart to contract.

In warm-blooded animals the phenomena are more marked, the most pronounced symptom being the strong dyspnœa. In opposition to Achscharunow, the author finds that rabbits, even after an abso-

lutely fatal dose, can be kept alive by artificial respiration. The author assigns a direct action on the respiratory centre in the medulla as the cause of the dyspnœa.

As constant as the dyspnœa is a quantitative and qualitative change in the heart's action, similar to the effects already observed by Böhm and Wartmann. The author tabulates his views thus.

1. The anomalies in the heart's action, occurring in poisoning with aconitin, are not caused by an affection of the medulla oblongata.

2. The observed and apparently contradictory results of the experiment can be united into two groups. Both comprise a lesion of the ganglionic centres in the heart, and are thus distinguished: the one coincides with the integrity of the vagi, the other with their paralysis.

3. The integrity or paralysis of the vagi depends upon whether the intracardial endings of the vagus are stimulated for some time, or are paralysed at once.

4. The difference in the action is quite an individual one, and does not belong to the poison.

The often observed arrhythmical pulse is explained by the non-simultaneous and unequal effect of the aconitin on the one or other cardiac centre, perhaps caused by its unequal distribution in the blood.

ROUGET ON THE MIGRATIONS AND METAMORPHOSES OF THE WHITE CORPUSCLES OF THE BLOOD.—Ch. Rouget's new investigations on the circulation of the larvæ of frogs have shown (*Archiv. de Physiologie Norm. et Pathol.*, 1874, 812, and *Centralblatt*, no. 21, 1875) that the red corpuscles in their diapedesis through the walls of the vessels remain perfectly passive. The intravascular pressure causes one corpuscle after another to pass through the cell-protoplasm and the structureless cuticula of which the walls of the young capillaries consist. In that the red corpuscles are incapable of self-movement, they cannot again regain their normal forms, which they have lost by being passed through the capillary walls. They therefore soon degenerate in their foreign surroundings outside the blood-vessels. The white blood-corpuscles arise from the fixed connective-tissue corpuscles, and are returned to the blood by the lymph. In virtue of their amœboid movements they are able, independently of the blood-pressure, to pass through the vascular wall. As soon as they meet a red blood-corpuscle outside the vessel, they surround it with their processes. In the interior of the white corpuscle the red one is dissolved, it falls into pigment-granules, and thereby transforms the colourless corpuscle into a pigment-cell. The latter, just like the original leucocytes, are capable of amœboid movements; they pass partly into the vessels, and their further fate is unknown; and partly they form pigmented tunica adventitiæ of the vessels and nerves, together with the chromatogene layer of the subcutaneous tissue. The star-like subepidermal pigment-cells arise originally from white blood-corpuscles. On the application of mechanical stimuli, the pigment-cells which arise from the white corpuscles collect around the scar and form neoplasms whose structure is similar to the fungous granulations of the wounds of mammalia.

JAKOWICKI ON THE PHYSIOLOGICAL ACTION OF TRANSFUSION OF BLOOD.—A. Jakowicki (*Gazeta Lekarska*, 1875, no. 1-11, and *Centralblatt*, no. 23, 1875) confirms the results of W. Müller as to defibrinated blood when injected into an animal not pro-

ducing blood extravasations, as stated by Magendie, and also the results of Landois (*vide* LONDON MEDICAL RECORD), that injection or direct transfusion of foreign blood or of defibrinated blood is followed by a change in the entire blood of the animal, as manifested in the excretion of hæmoglobin in the urine. If the quantity injected be not too large, the urine clears up again and resumes its normal condition. In these experiments the blood of the cat, horse, and calf, were transfused into dogs.

In injection of blood where the corpuscles had been dissolved, no matter what was the method employed to produce solution, or injection of a solution of hæmoglobin, the author, like other observers (Francke and Naunyn), found that coagula were formed—specially pulmonary infarcts—which caused death. In dogs hæmaturia was constant, and often convulsions were present.

According to Alex. Schmidt, the fibrin-ferment is formed after the blood escapes from the vessel. In injecting defibrinated blood, a considerable quantity of this ferment is introduced into the blood. The author prepared this ferment after the method of Alex. Schmidt, and injected large quantities of it, after having tested it with the plasma of dogs' and horses' blood. The author arrives at the following conclusions. (1) The fibrin-ferment is a normal constituent of the blood circulating in the organism (in opposition to Alex. Schmidt). (2) The organism can destroy the ferment injected into the vessels, so that the surplus disappears after a time, and the quantity of the ferment returns to the normal. (3) The organism presents conditions which are able to limit the action as well of the ferments introduced from without as of that circulating normally in the blood.

HITZIG ON THE SEAT OF THE CEREBRAL FLUID.—G. Hitzig (*Reichert und Du Bois-Reymond's Archiv* 1874, *Centralblatt*, no. 19, 1875) remarks that the majority of authors generally found no fluid in the sac of the dura mater cerebri on the vertex. The author, on the contrary, from operations upon dogs, has convinced himself of the existence of a not inconsiderable quantity of fluid in that sac. On passing a fine scalpel during life between the dura mater and pia mater a fluid either clear or mixed with blood, always flowed out, whilst several hours after the death of the animal the operation was without result, thus coinciding with what is found in the human subject. On the contrary, the lateral ventricles were always full of fluid. Immediately after the death of the (poisoned) animal water trickled out of small openings in the dura mater, when here there was no question of blood-pressure. During life, therefore, there must be a higher secretion-pressure than the blood-pressure and elasticity of the tissues which press the brain against the skull. After death the water will be pressed into the brain from the sac of the dura mater by the remaining elasticity of the compressed brain.

MORIGGIA ON SUGAR IN THE FETUS AND ADULT.—Moriggia (*Reale Accademia dei Lincei, Estr. d. Sess.*, Feb., 1873, *Centralblatt*, no. 10, 1875) investigated the quantity of sugar and partly also of glycogen in numerous organs and fluids in the fœtus and adult of many classes in the animal kingdom. His chief results are: That the blood of carnivora and herbivora at all times of life and in all stages with similar food contains sugar. The fresh

bile of adult animals generally contains sugar, the acid or sometimes faintly alkaline reaction which sometimes appears, arises from the transference of the sugar into lactic acid. Sugar is always found in the muscles, heart and lungs, sometimes in the spleen, but never in the kidneys, urine, brain, salivary glands, or the pancreas of the adult or newly born fœtus. Sugar was found in the amniotic fluid up to the end of intra-uterine life, but the quantity seems to diminish towards the end of pregnancy. In very young fœtuses, whose whole body was examined at once, only traces of sugar were to be found; whilst at all later periods of foetal life it was to be found plentifully in the urine, in the bile, and peritoneal fluid, so that the fœtus may be regarded as truly diabetic [as Cl. Bernard had already shown]. Sugar was found plentifully in the muscles, lungs and heart, in traces in the spleen, pancreas, parotid, both placentæ, and the skin from the earliest foetal period to maturity. The latter is also true of the kidneys, and Moriggia supposes that their sugar passes through the urachus with the amniotic fluid. Sugar was never found in the brain. Sugar and glycogen were found plentifully at all times in the liver, just as in the adult. In the white and the yellow of eggs, fresh, old and hatched, there is much sugar.

The author regards the maternal blood as the source of the sugar in the fœtus, at least in the earliest period of intra-uterine life.

The obvious constancy in the presence of sugar at all times of animal life shows the immense importance and necessity of a certain quantity of sugar for the development and sustenance of the organism.

SEEGAR ON THE REDUCING ACTION OF SUGAR AND URIC ACID IN THE COLD.—J. Seegar (*Centralblatt*, no. 21, 1875) observes that it is well-known that uric acid, like sugar, can reduce cupric oxide when heated. In order to ascertain the worth of the usually cited control-experiment, he tested the solution with Fehling's solution and allowed the mixture to stand in the cold from six to twenty-four hours. It is said that if sugar be present reduction follows in the cold, whilst uric acid alone in the cold has not this effect. The author, however, finds that when the sugar is in small amount it loses the property of reducing cupric oxide in the cold. A 0.1 per cent. watery solution of sugar produced a scarcely perceptible reduction in the cold, whilst a 0.5 per cent. solution had no reducing action at all in the cold. A 0.5 per cent. solution of uric acid acts powerfully as a reducing agent in the cold (such a quantity, of course, never occurs in the urine). The usually cited control-experiment is, therefore, valueless, when we have to deal with small quantities of sugar.

HARVEY ON THE INTERMEDIARY SUBSTANCE OF THE TESTICLE.—Dr. R. J. Harvey, in a preliminary communication to the *Centralblatt für die Medicinischen Wissenschaften*, no. 30, upon the above subject, does not agree with Von Ebner, Hofmeister, etc., that the cells therein found are to be regarded as connective tissue corpuscles. He concludes that they are nervous structures, provided with nucleated vasomotor nerve-fibres. The cells are large, massive, and have a sharp contour, and sometimes contain pigment. There is well marked nucleus with nucleolus. The processes are best investigated in the rat by a modification of the gold method. In this animal the cells seem to possess only a single thick process; many are tripolar or multipolar; the greater number, how-

ever, being bipolar. These cells bear a special relation to the blood-vessels, their arrangement and relations to the vessels, however, vary with the animal investigated.

WM. STIRLING, D.Sc., M.D.

PATHOLOGY.

BRODOWSKI ON GIANT-CELLS AND TUBERCLES. Professor Brodowski, of Warsaw, has an article on this subject in Virchow's *Archiv*, vol. lxiii. Of late, numerous investigations on giant-cells and their connection with tuberculosis have been published. A few authors have adopted Virchow's view, that they generally originate from the connective tissue cells, while others (Klebs, Köster) consider them only as cross sections of capillary lymph-vessels, whose lining epithelium had become hypertrophic. Schüppel devoted much time to the solution of this question. He found delicate round or oval-shaped masses of protoplasm very much resembling giant-cells in smaller blood-vessels, and considers them as the germs (protoplasts) of giant-cells. As soon as nuclei appear in these masses, they become real giant-cells, and the walls of the vessels in which they were formed decay. Other investigators admit that the giant-cells are closely related to the blood-vessels, while they differ in their opinion about the origin of the formations in question. Some think that they originate from cells of the walls of the vessel; others believe that they may form from any cells.

The author found that giant-cells are unquestionably connected with changes in the blood-vessels, but that they do not originate from completely formed vessels, but only from the blastema of such. He admits only that giant-cells sometimes may have a mechanical connection with blood-vessels.

Aside from giant-cells we find in tubercles, as well as in other pathological formations, little cells with radiate nuclei resembling giant-cells, but more delicate than these. Besides, numbers of cells can be observed in a transitory state between the two mentioned forms, especially in the so-called tubercles of the spleen, the red marrow and sometimes in phthisic lungs. These facts made it evident to the author, that the smaller cells are only juvenile forms of the giant-cells. Dr. Brodowski found, further, long bridges of protoplasm as a connection between capillary vessels and the smaller cells, and that they were identical with those prolongations of protoplasm, which of late are pronounced to be the beginnings of new blood-vessels. If this bridge be solid and free from nuclei, the little cells connected with it are also free from nuclei, or contain only a few. In case the bridge contains nuclei, they are of the same form, etc., as those of the more developed germs of new vessels. Sometimes that part of the bridge near the vessel contains vacuoles. The author was sometimes enabled to inject in the corpses of infants, from the blood-vessels, the roots of the protoplasmic bridges, as well as the different kinds of giant-cells. The formation of the latter is therefore considered by him as the product of abnormal activity of the blood-vessels, characterised by hypertrophy of some parts of protoplasmic blastema of these vessels, and by a formation of an unusually great number of nuclei in them. Of course, the misformed blastema is not further developed,

only sometimes phenomena may be observed in these formations, which manifest a further development of blood-vessels—vacuoles: division of the protoplasm similar to that which precedes the formation of epithelial cells in capillary vessels.

The author thinks that the giant-cells sometimes may undergo similar changes as the bridges between them and the capillaries, *i.e.*, that they do not hinder the further development of the vessels.

Dr. Brodowski then explains some peculiarities associated with tubercles. Giant-cells are often found (in tubercles) in a network of fibres, in which are entangled numerous lymphoid cells. The author thinks with Schüppel, that the network resembles the angioplastic (vessel-forming) prolongations; like these, it often contains oval-shaped nuclei, and also vacuoles; it may probably change to giant-cells. The empty spaces in giant-cells, Brodowski thinks, are vacuoles, which are found, as well in normal angioplastic prolongations, as in hypertrophic giant-cells, and which, according to Rouget, play a prominent part in the formation of the calibre of the vessels. The presence of blood-corpuscles and pigment in the giant-cells will be understood, if we consider that injections often find their way into giant-cells by means of the protoplasmic bridges. The author thinks that the capillary vessels may be not the only place of origin for giant-cells, but that they may form from any protoplasm containing nuclei, and that they also may be formed from lymph vessels.

Dr. Brodowski found enlarged epithelial cells with several nuclei (similar to those found by Friedländer in the vessels of the pregnant uterus after the eighth month) in small vessels situated near the so-called tubercles, or in recent syphilitic formations. Sometimes the vessels were completely filled by such cells. In a case of tuberculous meningitis, he found besides giant-cells, in so-called tubercles, protoplasmic bridges in the small vessels near them, resembling those in which the giant-cells are embedded. The author proposes the name angioblast for all such protoplasmic formations arising from germs of new vessels.

When the old dispute, whether tubercles are specific or whether they are only a peculiar form of inflammation, seemed to be ended in favour of the latter view, Langhans, Köster, and Schüppel, declared themselves for its specific character. They found that a tuberculous knot always contains one or several giant-cells, embedded in a protoplasmic network between which are entangled lymphoid-cells. But soon afterwards cases became known, which proved that giant-cells are also present in other formations. Klebs found them in elephantiasis arabum, the author in lupus. Then Friedländer communicated his views on the matter, taking all formations for tubercles which contain giant-cells. Some time afterwards the author found them in the bronchi and in the left ventricle, when in a state of syphilitic degeneration, in chronic ulcers of the leg, etc. Friedländer, who observed them in still more places, considered such cases as localised tuberculosis. At last Köster communicated a number of similar cases, subscribing partly to Friedländer's views, but he did not admit their formation in healthy tissue. Adopting the views of the latter investigators, we had to consider syphilis, lepra, and glanders, likewise as tuberculosis. To avoid such a confusion, the author proposes, for a formation caused by so different

pathological irritations, a name taken from its histological character. He considers as the principal elements of this structure, besides a network of giant-cells (giant-angioblasts), a number of small cells resembling white blood-corpuscles. The author is convinced that this tissue is only a modification of granulation tissue. The latter consists of a number of small cells, a reticular tissue and a great number of recent vessels, while we find in our pathological structure, in place of these, only misformed germs of vessels (angioblasts). Sometimes the author observed even a few vessels in so-called tubercles of recent origin. As he thinks that the granulation tissue forms the base of these structures, he calls them *granuloma-giganto-angioblasticum*, which signifies only their anatomical character. They may be caused by inflammatory irritation, by infection with specific poisons or with substances formed in the midst of the cheesy products of inflammation, etc. Their constitution varies not only among different persons, but even in the same individual, according to the character of the inflammation, anatomical conditions and other peculiarities.

VON LANGENBECK ON THE OCCURRENCE OF CARCINOMA AFTER LUPUS.—In a paper read before the Medical Society of Berlin and reported in the *Berliner Klinische Wochenschrift*, no. 24, 1875, Baron von Langenbeck asserts that he does not acknowledge the supposed identity of lupus and carcinoma, and that he has been led to regard them as two distinct diseases. In some rare instances carcinoma may be developed on portions of skin affected with lupus but never except where the lupous ulceration has gone on for many years and resulted in not quite complete healing, or has left cicatrices which are subjected to prolonged irritation and inflammation. The occurrence of carcinoma on lupous portions of skin has no more significance than its far more frequent occurrence in cicatrices left by extensive burns of the face when these cicatrices, as may be those of lupus, are the seat of much irritative mischief. The clinical aspect of lupus differs much from that of cancer of the skin, and especially in the respect that the former disease may be cured by giving internal remedies, Zittmann's decoction, for instance; whilst, as is well-known, cancer never yields to such treatment. Of very many cases of lupus which he has observed, Baron von Langenbeck can recall to mind but three only, in which epithelioma was subsequently developed. All these patients had suffered early in life from lupus of the face, which, after long-continued ulceration, destroying much of the skin of the cheek, and portions of the nose and ear, had resulted in the formation of a cicatrix. The first case was one of a woman aged forty years, who, during her period of puberty, had been affected with lupous ulceration of the skin of the cheeks, nose, and upper lip. This ulceration, after partial destruction of the nose, terminated in the formation of a cicatrix which remained sound for fifteen years, at the end of which interval a small warty growth made its appearance near the remaining portion of the nose. This growth increased in size, involved the whole portion of the nose and upper lip, and finally sprouted out into a large cauliflower-like tumour made up of soft granulations. The subject of the second case was a man aged fifty-nine years who, from childhood up to his thirtieth year, had suffered from lupus of the face. The ulceration had involved the right cheek and caused extensive

destruction of skin. In the year 1875, the previously sound cicatrix presented a tumour, which spread rapidly over a large portion of the right side of the face. The third case was one of a man aged sixty-nine years, who, in 1865, was first attacked with lupus, which commenced in the right cheek, and subsequently spread over the nose and upper lip, and terminated in indurated and tuberos thickening of the integument. Eight years after the first appearance of the lupus, the apex of the nose presented a small tumour which speedily ulcerated, and then rapidly increased in size and involved the whole nasal organ. Baron von Langenbeck does not agree in a statement recently made by Dr. Lewin, to the effect that cicatricial contractions are characteristic results of lupus. This disease may result in cicatricial contraction when it occurs in parts where the skin is freely movable; and ectropion of a lower eye-lid, eversion of a lip, and narrowing of the oral aperture, may occur after lupous ulceration, though not less readily than after a severe burn or any other cause of destruction of the integument of this region. But there are certain forms of integumentary cancer, which, with extension of the disease and infiltration and ulceration of the affected parts, give rise to dense cicatricial formations, and so cause severe distortion. In a case of slowly spreading cancer of the cheek, the corresponding angle of the mouth, and also of the nose, may be dragged outwards and upwards as far as the malar bone. In one variety of cancer of the skin there is more or less formation of large corneous masses of epidermis, and sometimes, though rarely, cornua humana, several centimètres in length, are found at or about the cancerous part.

W. JOHNSON SMITH.

KLEBS ON THE REGENERATION OF PAVEMENT-EPITHELIUM.—E. Klebs (*Archiv für Experiment. Pathologie*, iii. 125, and *Centralblatt*, no. 30, 1875) has subjected the question regarding the source of the newly formed epithelial cells on the surface of wounds to a new investigation. He experimented on the web of the frog's foot, and has arrived at the result, in opposition to Biesiadecki, that the wandering blood-corpuscles are not concerned in the formation of young epithelium, and that the epithelium is exclusively formed by the outgrowth of the deepest layer of the margin of the wound. The outgrowth occurs either in this way, that the individual cells of this layer become contractile, ultimately become loose, and represent wandering epithelial cells, which again form themselves into nets and become flattened one against the other; or this occurs simultaneously in all cells of the epithelial margin, whereby a uniform growth of the epithelium occurs, which is only apparently formed by the excretion of a homogeneous plasma (Arnold), and is produced rather by the development of special and equally contractile protoplasmic cylinders, which also grow out of the cells of the epithelial margin. These latter break up by division into polygonal nucleated plates, which lose their contractility and represent the newly formed fixed epithelial cells. The nuclei in the epithelial cells concerned in the regeneration break down (passively, by contraction of the protoplasm) in the usual way into granules, lose their nucleoli, becoming clear balls, whilst new nuclei arise in the contractile protoplasm, by the separation and radiate arrangement of the granules of the protoplasm around a clear ellipsoid centre. The nucleoli are formed outside this ellipsoid and pass into

it, changing at first their place, and then fix themselves in the two centres of the ellipsoid, or also in the middle between both (nuclei with one or two nucleoli). A hyperplastic pathological development of the nuclei occurs by the apposition of clear balls, which arise outside the nucleus, and then unite with the nucleus. These forms may also disappear with the formation of holes and divided nuclei. In the formation of definite fixed epithelial cells the nuclei change with the formation of a membrane into bladders containing mucin, which may still have a nutritive function, but which are without value for proliferation and regenerative processes. The formation of new nuclei in the contractile epithelial plasma begins before or during the division, or even in the pieces, separated by division, and begins here also with the formation of clear balls.

WM. STIRLING, D.Sc., M.D.

KLEIN ON THE PATHOLOGY OF SHEEP-POX.—An important paper, by Dr. Klein, of the Brown Institution, on 'The Pathology of Sheep-pox,' has been published in the reports of the medical officer of the Local Government Board, and reprinted in the current number of the *Quarterly Journal of Microscopical Science*. The author gives first an explanation of his method, and afterwards describes both the microscopical characters of the sheep-pox virus and the anatomical changes at the seat of the primary and secondary eruptions respectively.

Pure lymph and lymph diluted with a half per cent. solution of common salt were employed for inoculation, but without any difference in the result.

Two methods of infecting the animals used were adopted: (1) inoculation by subcutaneous injection, (2) direct injection of lymph into the external mammary vein. The object of the latter method was to induce a disease as nearly as possible resembling the natural sheep-pox, and to procure a secondary eruption.

A specimen of clear lymph, after having been kept in a capillary tube for several days, was observed to contain the following structures: masses of granules of variable character; transparent spheroids with distinct border lines, and occurring in chains; highly refractive micrococci variously grouped; collections of decolorised blood-corpuscles with micrococci in the interstices; bacteria free, and in colonies; micrococci twice the size of those mentioned above enclosed in greenish envelopes, and occurring in couples or in small groups; clusters of spheroids corresponding to Cohn's *microsphaera baccinæ*. After this specimen had been kept for a period of twenty-four hours at the temperature of incubation, the masses of granules were found to have undergone a change, having resolved themselves into a felt-work of delicate granular filaments uniting the granules with each other. At the end of forty-eight hours the filaments had become more distinct, and the granules had assumed the appearance of green spheroids and micrococci. Another sample of lymph, perfectly fresh, was observed to contain granular pus-corpuscles, coloured blood-corpuscles, and numerous small highly refractive granules, either isolated or in couples, which exhibited molecular motion; in addition to these, after having been kept at 32° Cent. for twenty-seven hours, there appeared spheroids, either free or contained in swollen pus-corpuscles, and differing from nuclei in their greenish colour and homogeneous texture; besides micrococci arranged in dumb-bells or in colonies of convoluted chains;

and long filaments, some smooth, others still presenting the necklace-like structure. A few hours later the colonies had increased in number and size, while some of the individual micrococci had become larger and assumed the appearance of rods with terminal swellings.

Dr. Klein concludes from his observations that 'the highly refractive spheroid is the only form that can be regarded as characteristic of lymph of sheep-pox in its active condition.'

The author goes on to consider the changes which occur at the seat of inoculation. The primary pock he describes as being developed by three stages: (1) 'A progressive thickening of the integument over a rapidly increasing but still defined area;' (2) 'the formation in the rete Malpighii of vesicular cavities containing clear liquid (the "cells" of older authors), in which sooner or later organic or vegetable forms are developed;' (3) 'the impletion of these cavities with pus-corpuscles.'

The process commences in enlargement and generative changes of the cells of the rete, and in an increase of size of the papillæ of the corium, with proliferation of the endothelial elements of its capillary blood-vessels. The lymphatic canaliculi of the corium next become dilated, and in the more vascular parts filled with migratory lymph-corpuscles. About the third day after inoculation, the larger lymph-tracts become distended and filled with spheroidal bodies and branched interlacing filaments like a mycelium, besides conidia free or in an active state of germination. Coincident with these changes, a 'horny transformation' of the middle layer of the epithelial elements of the rete takes place, and the cells nearest the corium undergo active proliferation, while of those immediately beneath the horny layer some begin to dilate into vesicles, and others become flattened so as to form the intervesicular septa. The vesicles next increase in size and number, and ultimately coalesce. They at first contain a clear liquid, but subsequently are found to inclose 'masses of vegetation, similar to those which have been already described in the lymphatic system of the corium; with this difference, that the filaments of which the masses are composed are of such extreme tenuity, and the conidia are so small and numerous, that the whole possesses the characters of zooglæa rather than of mycelium;' the aggregations are produced by the detachment of the conidia from the ends of the filaments. The next step is the infiltration of so much of the rete as lies beneath the horny layer with migratory lymph-corpuscles, which soon find their way to the cavities resulting from the coalescence of the vesicles, and convert them into collections of pus-corpuscles. That migration is the source of these collections, Dr. Klein thinks proved by the fact that a number of amœboid cells may be observed *in transitu*, and that 'the corium itself, before so crowded with these bodies, becomes, as pustulation advances, quite free from them.'

The anatomical characters of the secondary pocks are, the author says, substantially the same as those of the primary ones. The horny transformation is, however, very partial, affecting only a few cells of the middle layer of the rete; and the vesicular cavities are found much nearer the corium. The author notes that 'even in those pocks which exhibited a marked central depression, the most numerous and well-developed vesicles were found towards the centre;' a fact which he considers 'inconsistent with the supposition that the depression is

caused by the disappearance of previously existing vesicles.' BUSHELL ANNINGSO, Cambridge.

SCHÖNEBERG ON A CASE OF APPARENT HERMAPHRODISM.—Dr. Schöneberg of Berlin relates in the *Berliner Klinische Wochenschrift*, July 5, 1875, a case of extreme hypospadias.

The subject was first seen when sixteen years old, for a supposed rupture, consequent on a strain. On examination, a round movable body, of the size of a hazel-nut, somewhat tender, was felt in the right labium: it was recognised as a testicle, and the supposed labia as a divided scrotum. The clitoris (penis) was about five or six centimètres (2 to 2½ inches) long, with a well-formed glans, but no opening. Some distance down and below the penis, the urethral orifice was discovered; still farther back was a shallow depression, not dissimilar to the vaginal orifice, and about five centimètres deep. It was surrounded by a ring, and partly closed by a sort of hymen. No internal genital organs could be made out. The person had been regarded as a girl by the parents. In general conformation of figure, the individual resembled a man rather than a woman. The breasts were not developed; the pelvis was small; the voice was harsh, and the larynx prominent. The parents were incredulous when informed of the real state of things. Four years afterwards, the mother again brought the patient for examination, the male characteristics having become more developed; the beard was beginning to grow. After examination by another medical man, the civil state was finally decided upon.

The person afterwards stated that he had experienced sexual excitement, with a fluid discharge, when in contact with women. W. C. GRIGG, M.D.

MEDICINE.

SOLGER ON THE SIGNIFICANCE OF PROLONGED EXPIRATION, AND ON TENDERNESS ON PERCUSSION.—Dr. Solger, of Reichenhall, writes, in the *Münch Aertzliches Intelligenz-Blatt* for June 22 last (no. 25, Jahrgang 22), that he has noticed that tenderness on percussion in the supraclavicular region is often associated with prolonged expiration, and with enlarged lymphatic glands. He uses a moderate-sized hammer, weighing about one ounce, taking care not to press on the edge of the plessimeter, or to make actual pressure upon enlarged glands. He says percussion with the fingers does not elicit this pain. The enlarged lymphatic glands noticed by him are seldom on the sterno-cleido-mastoid, and those in that situation generally depend on a different cause. The glands in question are found on the anterior border of the trapezius and towards the back of the head, chiefly in the lower part of the neck, especially in the triangle between the trapezius and the sterno-cleido-mastoid, whose base is formed by the scalenus muscle. There the cervical plexus, the sympathetic and vagus nerves, all meet; and the deep lymphatics of the chest, especially those of the pleura, are in relation with the cervical glands. To these glands, and to inflammation in the peribronchial connective tissue, causing compression of the smaller bronchi, he attributes the prolonged expiration heard in the early stages of many lung-diseases. Other theories are discussed, but there is little of novelty to the Eng-

lish reader; and the reporter thinks Dr. Solger not quite accurate in limiting prolonged expiration to the earlier stages only of lung-diseases.

LORENZUTTI ON A CASE OF PULSATING EMPYEMA.—Dr. Lorenzo Lorenzutti relates, in the *Annali Universali di Medicina e Chirurgia* for June, a case of which the following is an abstract.

A man named Pietra Ceconi, aged twenty-seven, a blacksmith, was admitted into hospital on April 28, 1874, suffering from severe dyspnoea, fever, cough with rather copious puriform expectoration, and pain in the left side of the chest, which was increased by touch. He had much night-sweat. The illness had commenced about a month previously. He had led an irregular life, being addicted to drinking and other excesses. His general appearance indicated exhaustion, as if by constant suppuration.

On examining the chest, there was found to be tympanic resonance at the left apex, then absolute dullness down to the costal arch; there was also dullness in the axillary line; behind, there was obscure tympanic resonance in the supraspinous region, and absolute dullness over the remainder of the chest. By auscultation over the region of tympanic clearness, amphoric breathing was heard; over the remainder of the chest there was absence of all respiratory recurrence, with the exception of some moist rhonchus in the lower part posteriorly. The heart was displaced to the left, and its beat was felt in the second intercostal space; from this as far down as the region of liver-dullness was a space about two centimètres wide, which gave a perfectly dull sound in percussion; the heart-sounds were normal. Over this space, and to the left of the sternum, between it and the nipple line, there was noticed frequent pulsation, evidently distinct from the rhythmical beat of the heart. No vocal fremitus nor respiratory movements could be perceived. Measure gave only a difference of two or three centimètres between the two sides, probably in consequence of the oedema which was present. The right lung was healthy, and performed its functions normally. The other organs were healthy; the urine was normal; pulse, 120; respiration, 32. The temperature could not be increased.

On April 30 there was observed a general pulsation synchronous with the heart-beat, affecting the lower two-thirds of the left side of the chest from the sternum to near the vertebral column; but being stronger in the mammary region and along the axillary line. There was also increase of the oedema, and slight increase of the dullness posteriorly.

A consultation was held on May 1, when it was decided that the case was one of empyema; a suspicion, however, was expressed that an aneurism also existed, and it was decided not to operate unless the symptoms became very urgent. Two days later, at another consultation, the patient being worse, an exploratory puncture with Dieulafoy's apparatus was made by Dr. Menzel, when about twenty-one ounces of putrid fluid escaped with force, and the pulsatory movement ceased. More than 100 ounces escaped, and the respiratory movements again became perceptible in the lower intercostal spaces; the respiratory sounds, however, were absent. In the course of a few days the exudation returned, and with it the pulsation; there was also a threatening of perforation at the fifth intercostal space. A drainage-tube was introduced at this point by Dr. Menzel, and was brought out at the sixth space in the axillary line. The cavity of the chest was then washed out daily

for nine days, with a solution of permanganate of potash (1 in 100). The patient died in a state of collapse on May 12.

At the necropsy, the left thoracic cavity was found to contain nothing but the contracted lung, and the air which had entered from without. There were some points of adhesion between the parietal and costal pleura, by easily lacerable bands. The lung was in a state of complete atelectasis at the upper part; inferiorly, it contained a little air. In the right lung there was slight bronchial catarrh; on its surface, especially between the base and the diaphragmatic pleura, were large masses of false membrane. There was recent pericarditis, and the whole heart was covered with a fibrinous investment presenting very fine villi; there was scanty fluid effusion. The muscular substance of the heart was rather yellow, and lacerable. There was slight atheroma of the aortic valves and of the ascending aorta.

The pulsation in this case can be attributed to no other cause than the propagation of the movements of the heart through the fluid. Cases of this kind are not frequent; three are recorded by Niemeyer, Jaccoud, and Roncati. Traube of Berlin says, in the *Berliner Klinische Wochenschrift* for February 12, 1872: 'In the course of last year I have met with two cases, which in some points presented an exception to the ordinary characters of empyema. In both, it could be determined with certainty that the heart was displaced. Nevertheless, there was distinctly perceived on the left side, precisely at the region ordinarily occupied by the heart, a succession of pulsations, synchronous with the systole of that organ.' To explain this, he has recourse to the movement of the heart from right to left, and the relative displacement of the fluid in the same direction. But why does this phenomenon not occur in every case of left pleuritic exudation? Traube asks whether the putridity of the fluid in his two cases may offer an explanation; since this has also been observed by others in the same conditions. He adds that in cases of empyema we see that the costal pleural is destroyed in several places; and without doubt these lesions permit a greater displacement of the fluid. But this does not seem to him to be a sufficient explanation, for the phenomenon under consideration ought to occur more frequently; and he believes that an explanation of the pulsation may be found in the simultaneous presence of a pericardial exudation, which existed in his cases.

In the same periodical, Dr. E. Müller speaks of similar cases, and adds some remarks in the diagnosis. He remarks that aneurisms differ from other pulsating tumours in having perceptible pulsation in a lateral as well as in a vertical direction, while other tumours pulsate only vertically. Empyema, however, may pulsate in all directions; and Müller cites in regard to this the differential diagnostic signs which McDonnell, of Dublin, described in 1844, viz., the dulness over the whole side of the chest, the presence of pulsation only over an external swelling, the absence of murmurs and bruits, and the distinct fluctuation. Müller, however, remarks that, as far as he has been able to observe, the pulsations may extend over the whole chest; that, in cases of aneurism, there may be no murmur or bruit; and he concludes that the diagnostic signs mentioned by McDonnell are unimportant when taken separately, and that their simultaneous pre-

sence may give a greater probability to the diagnosis of pulsating empyema. He adds that in empyema the swelling lies more usually to the left, while aneurism tends to the right; and that empyema produces a pulsating swelling or perforation generally below the fourth rib, a situation where aneurism is rarely met with. He further observes that there is not an absolutely certain diagnostic sign of pulsating empyema. With regard to the cause, he cites the opinion of Kussmaul, who maintains that it is not sufficient for the cardiac pulsations to be transmitted to the external swelling, but they must reach its walls without having lost any of their intensity.

A. HENRY, M.D.

BESNIER ON SUDDEN DEATH DURING THORACENTESIS.—At the meeting of the Société Médicale des Hôpitaux, on June 25, M. Besnier reported the history of a case of sudden death during the operation of thoracentesis. A middle aged lady had suffered during about a fortnight from the signs of a severe pleurisy on the right side, with extensive effusion. There was no cardiac complication; but the general condition of the patient was indifferent, and the fever ran high. It was noticed that the intercostal spaces were unusually tender on the affected side. On puncture with the aspirator, a sanious and extremely offensive liquid was evacuated. Scarcely half-a-pint had been slowly withdrawn when the patient suddenly became extremely pale, her features became fixed, and it was found that the heart had ceased to beat and the opposite lung to breathe. All efforts to restore animation failed. Death had been almost instantaneous. There was no *post mortem* examination.

M. Besnier suggests that the mere pain of the puncture may possibly have reflexly arrested the heart. In enfeebled and very depressed subjects very slight causes may suffice to induce fatal syncope, even if the muscle of the heart be healthy. Bernard, Chossat, Bernstein, and others have shown that in animals even a slight amount of pain may suffice to stop the heart in contraction, particularly if the animal happen to be much enfeebled.

This case, far from furnishing a contra-indication to puncture in thoracentesis, is rather a proof of the danger of delay. The patient was operated upon too late. Her strength had rapidly given way, just as occurs in other forms of gangrenous inflammation.

A. B. DUFFIN, M.D.

JOUSSET ON CHRONIC AORTITIS.—M. Jousset, in a memoir on this disease presented to the Académie des Sciences, divides it into two forms; one painful, known by the name of angina pectoris; and the other very little painful or not at all so, respecting which he lays down the following proposition. 'Chronic aortitis is a common affection; it is habitually mistaken for and confounded with an affection of the heart, or with interstitial nephritis. Chronic aortitis sometimes succeeds acute aortitis. In this case all the causes of the latter affection operate; the use of alcohols, tobacco, coffee and tea are the etiological circumstances which favour the development of chronic aortitis. All the patients in whom I have observed it were gouty or suffered from hæmorrhoids, and were over thirty-five years of age. The principal symptoms are habitual dyspnœa, and from time to time severe attacks of suffocation. These acute attacks have the characteristics of cardiac dyspnœa. The pulse becomes quicker and smaller at the same time, and ends by disappearing.

A lypothimic state is present, with cold perspirations and sometimes complete syncope. During the attacks, expiration is convulsive and prolonged. Insomnia, loss of strength, and anæmia, are the remaining symptoms of aortitis; they lead to cachexia characterised by œdema, albuminous urine, and subdelirium. Death supervenes by asphyxia, syncope, or uræmic accidents. The physical signs are divers modifications in the aortic sounds, the constant formation of a plateau in the sphygmographic traces, and, at an advanced stage, the increase of aortic dulness.'

NOËL GUENEAU DE MUSSY ON WHOOPING-COUGH.—Dr. Noël Gueneau de Mussy (*L'Union Médicale*, July 10), attributes those chronic forms of whooping-cough which persist sometimes for several years, and thus form a remarkable exception to the laws which govern other contagious maladies, to a morbid condition of the bronchial glands. He further considers that in whooping-cough generally the affection of the bronchial glands forms the intermediate link between the congestion of the respiratory mucous membrane which characterises the catarrhal period, and the irritation of the pneumogastric which is the special feature of the spasmodic stage of the disease. In the first stage of whooping-cough the congestion of the mucous membrane is visible in the fauces and throat. The uvula is red and injected, and two bands of rosy red colour are seen running along the inner side of the anterior pillars of the fauces, until they unite at the base of the uvula. The isthmus and pharynx are similarly injected, and the glands of the latter are prominent, giving to the mucous membrane a granular aspect.

This congestion of the throat and fauces presents special features of form, seat, development, and course, which not only distinguish it from the laryngopharyngeal congestions of catarrh and influenza, but characterise it as an exanthem of the mucous membrane, analogous to the exanthemata of cutaneous surfaces. M. Gueneau de Mussy believes that he has fully proved the exanthematous character of certain other disorders, such, for example, as hay fever, the gastric and intestinal disturbance which often accompanies urticaria, and probably the pulmonary and gastric symptoms in measles. Whooping-cough would seem to have its special exanthem also, and to be further characterised by a special tendency to congestion of the bronchial glands, this latter condition being the immediate cause of the spasmodic phenomena.

The existence of the enlarged glands may be detected, as M. Gueneau de Mussy has previously shown, by careful comparative percussion along each side of the upper sternum, with the finger laid parallel to the axis of that bone, and similarly along the spinal groove from the seventh cervical to the fourth or fifth dorsal vertebra. This gives a difference in the percussion note, and in the feeling of elasticity and resistance; while auscultation reveals more feeble but rougher breathing than natural on the side of the affected glands. In well marked cases the respiration may be even of a blowing character. Deficient expansion resulting from the compression of the main bronchus, or one of its chief branches, by the enlarged glands, may be detected by grasping the base of the thorax at each side, while the patient makes a slight effort of coughing.

W. B. CHADLE, M.D.

HART ON BLOODY SWEAT.—In the *Richmond and Louisville Medical Journal* for January, 1875, is an account of a case of bloody sweat, by Dr. W. P. Hart, of Washington, Arkansas. A young unmarried man, twenty-four years of age, of good constitution and character, had been under Dr. M. C. Boyse for some days, feeling stupid, listless and drowsy, with rigors and other feverish symptoms. After five days he was as follows.

On November 5, at 7 A.M., he was stupid, listless and sleepy; pulse 100, respiration $4\frac{1}{2}$ per minute. He complained of soreness and tenderness when pressed over the stomach and bowels; was nauseated and vomited occasionally. He was ordered five drops of turpentine in half an ounce of saturated solution of chlorate of potash every three hours. At 1:30 P.M., the ejections from the stomach, the actions from the bowels, the urine, and the sputa, were all bloody, and the blood was oozing from the pores of the skin all over the body. The points of discharge were thickest over the body, but there were also some over the extremities and the face; his night-clothes were spotted with blood, and the blood not only ran through his night-clothes, but on to the bed-clothes, some of the stains being as large as a quarter of a dollar, and one or two of them as large as a Mexican dollar. He complained of a distressing itching over the body; there was no discoloration of the skin when the blood was removed, but it was rather unnaturally white and clear over the body and extremities. His face was flushed, and the vessels of the face and neck were filled and turgid. The prescription of the morning was continued, and it was ordered that the whole body be anointed with equal portions of turpentine and lard, the counter-irritation over the spine repeated, and cold to the head and warmth to the feet.

On Friday morning, November 6, at 3 A.M., Dr. Hart was called by Dr. Boyse to see the case with him. The patient was stupid and drowsy, but was conscious and rational when fully roused. He complained of nothing except a little oppression about the chest. Pulse 100, and respiration $5\frac{1}{2}$ per minute, deep and full. There was not much heat of skin, no perspiration, no rigors nor chilliness, nor any evidences of periodicity; there was no discoloration of the skin, other than from the bleeding; tongue not much coated, but too large and flabby, and livid, but little cough. Auscultation showed considerable effusion about the right lung. The sputa and vomit, as well as the fæces and urine, were bloody. The hæmorrhage from the surface had decreased since the application of the turpentine. There were considerable twitching and subsultus. The application of turpentine and lard to the surface was continued, and the turpentine emulsion with the saturated solution of the chlorate of potassa internally; he was also ordered twenty drops of tincture of chloride of iron every two hours, and twenty grains of bromide of potassium as often as necessity might require, to quiet nervousness. He had no appetite, but little thirst. At 5 P.M. his pulse was 100; respiration 5 per minute; temperature 100° Fahr.; skin pleasant and soft; the stupor was rather increasing; it was hard to keep him awake long enough to examine him; sensibility was partially destroyed, and he was not conscious of his condition; he had no complaint, except the annoying itching of the skin, which kept him scratching constantly when awake. There was some soreness about the middle lobe of the right

lung, and the sputa were of a mahogany or brick-dust colour. He had vomited twice since 1 P.M., and thrown up what he had eaten, together with some bilious matter, but no blood. The action of the heart was laboured and tumultuous, the first sound being quite loud; the radial pulse was weak but regular. The external and internal remedies were continued.

On November 7, at 8 A.M., the pulse was 96; respiration $4\frac{1}{2}$ per minute; temperature $98\frac{1}{2}^{\circ}$ Fahr. There was a very marked and peculiar churning sound about the heart's action; the mouth and teeth were dry, and sordes was beginning to form; stupor was deepening, and the nervous symptoms were increasing; the kidneys had not acted for eighteen hours. He got up and passed about three half pints of urine, which was turbid and milky; tested by nitric acid and heat, it showed a great quantity of albumen. There was no discharge of blood from any organ, except a few points on the mucous surface of the lower lip. The former treatment was stopped, and first were substituted three grains of sulphate of quinia and one-fiftieth of a grain of strychnia every three hours, alternated with two drachms of brandy in a little lemonade. At 10 A.M. the fingers and toes were cool, the pulse more feeble, and stupor deepening. The pulse was faster when he was sleeping by eight beats per minute than when he was awake, and the respiration slower by one per minute when sleeping than when aroused. Reaction came on by one o'clock, and at 5 P.M. there was considerable excitement. Pulse 110, firm and full; respiration 6 per minute; temperature 101° Fahr. He passed about one pint of turbid urine; there was no action from the bowels. He lay in a semi-comatose state; when aroused he was listless and incoherent. He was ordered, in addition to the former prescription, half an ounce of saturated solution of chlorate of potassa every three hours.

November 8, 8 A.M.—The nervous twitching and subsultus were not so great: stupor about the same; the face was flushed, and the vessels of the face and neck were full and distended. There were a number of pimples or elevations on the forehead resembling mosquito-bites. The blood was oozing from the mucous surface of the lower lip at several points; the teeth, gums, and tongue were dry, but the tongue was not so large and livid. Pulse 100, soft, regular, and of good volume; respiration 7 per minute; the air entered the lungs well; temperature 100° Fahr.; skin soft and pleasant. He had not vomited during the night; the bowels had acted three times, thin and watery, and coloured with the iron; he passed three or four pints of turbid-looking urine of a strong ammoniacal odour. He complained of nothing. The treatment was continued. The body was ordered to be anointed morning and evening with the turpentine and lard, with a few drops of carbolic acid added. He called for the application to allay the itching of the skin. At 5 P.M. there was a slight increase of fever. Pulse 105; respiration 6 per minute; temperature 101° Fahr.

November 9, 8 A.M.—Pulse 90, soft and regular; respiration 5 per minute; temperature 100° Fahr. There was not so much stupor; the nervousness was not so great. The bowels and kidneys were acting well; the urine was returning to its natural colour. He bled half a pint from the arm, which had relieved the turgid vessels and flushed face. No muttering or delirium. At 5 P.M. the patient appeared to be better; the stupor was passing off; the twitching and

subsultus were almost entirely relieved. Pulse 96, soft and regular, and of good volume; respiration 8 per minute; temperature 100° Fahr. The kidneys were acting sufficiently, and the urine was almost natural in colour.

November 10, 8 A.M.—The patient's condition was less encouraging than last evening. Pulse 94, small, and feeble; respiration 7 per minute; temperature 100° Fahr. The stupor was about the same; he had vomited three times, and thrown up a dark grumous matter resembling decomposed blood; there was no secretion about the mouth, and he had considerable thirst. He had had two bloody actions from the bowels, but they were not swollen or tender under pressure; the kidneys had acted twice freely and the urine was of good colour; the urine contained but little albumen. All treatment was stopped, and the bowels ordered to be moved with castor-oil to rid them of decomposed blood or other substances that might act as poisons or irritants. At 5 P.M. the pulse was more feeble, the respiration and temperature not changed. The bowels were moved three times, the last action being much better than the first two; then he refused nourishment; he had great thirst, and there was a cadaveric appearance about the face and extremities. The iron, quinine, and strychnine were resumed at one o'clock, with as much brandy as he would take.

November 11, 8 A.M.—The patient was not so stupid. Pulse 96, volume small and weak; respiration 7 per minute, not so deep and sighing; temperature 99° Fahr. The face, gums, and lips were blanched and anæmic. He had had two small grumous ejections from the stomach; and three large bloody actions from the bowels. The kidneys were performing their function very well. There were no fulness, hardness, or soreness about the bowels. He had considerable nervousness and subsultus. He was anxious and concerned about his condition, and refused all nourishment, and had much thirst. The treatment was continued, with twenty-five drops of Thayer's fluid extract of ergot every three hours.

November 12, 8 A.M.—Pulse 84, small and feeble; respiration 7 per minute; temperature 98° Fahr. The stupor was not so great; he was more easily aroused; the extremities were cool. He complained of weakness and prostration. The blanched anæmic appearance was more marked. The stomach ejected everything, even water. He had two small bloody actions from the bowels; the kidneys were acting pretty well. All treatment was stopped, and one-eighth of a grain of sulphate of morphia was ordered to try to allay the irritation of the stomach, also a mustard plaster over the epigastric region. At 5 P.M. the patient had rested, and expressed himself as feeling better. He had not vomited since he took the first potion of morphia, which had not increased the stupor, but he was more wakeful. He had taken more nourishment than during any day of his sickness, and had retained it. Pulse 96, respiration 8 per minute, temperature 100° Fahr. He was taking milk-punch, which he relished. No medicine was given during the night.

November 13, 8 A.M.—The patient was quiet, with very little nervousness or stupor, rational; pulse 99, respiration 7 per minute, temperature 99° Fahr. He vomited four times, the ejections being tinged with bile; the bowels acted twice freely, mostly of decomposed blood; the kidneys were acting freely. The urine was of good colour. The

anæmic and œdemic appearance was more marked and he was growing weaker. He refused nourishment. The mouth was very dry and the teeth coated with sordes. He had great thirst, but he could not retain water, brandy, or anything else without its nauseating him. A fly-blisters, measuring four by six inches, was ordered and applied over the stomach.

On November 14 he was steadily declining under the drain from the stomach and bowels. He looked as though his body were completely drained of blood, and presented the appearance more of statuary than a living being. The kidneys had ceased to secrete; he vomited almost instantly everything taken into the stomach. His restlessness and suffering were intense until 4 A.M. of the 16th, at which time he expired.

The privilege of making a *post mortem* examination was positively refused by the friends of the deceased.

TYSON ON BRIGHT'S DISEASE.—In the *Philadelphia Medical Times* for July 10, Dr. Tyson takes up the subject of Bright's diseases of the kidneys and discusses at much length their treatment. He prefaces his remarks by giving a brief review of the chief forms of the disease so as to give definiteness to his remarks on treatment. Acute nephritis he regards as being tubal in its nature; and the chronic forms he gives, as the large white kidney with its tendency to dropsy; the gouty or cirrhotic form, with its absence of albuminuria; and thirdly, the amyloid, or rather albuminoid kidney, associated with exhausting drains. In the acute form he advocates external warmth, with cups, dry or wet, over the loins if suppression of urine be present. The supplementary action of the skin can be utilised, and to excite cutaneous action he prefers the union of nitrous ether and ipecacuanha, with the warm or cold pack, preferring the latter. Purgatives he employs chiefly to expedite the action of other measures. In uræmic coma, two drops of croton oil upon the tongue often do good service. Diuretics he criticises, taking up the position that increased secretion is generally associated with increased flow of blood to the kidneys. He thinks the great matter is the selection of the diuretic, and prefers digitalis, from its effects in increasing the blood-pressure, salines, and diluent drinks. He uses digitalis freely in these cases, combining it with the citrate and acetate of potash. The washing out of the tubules by these measures restores the kidneys. The external use of digitalis in severe cases is insisted upon.

In the treatment of chronic Bright's disease the chief indications are, (1) to improve the quality of the blood, which is anæmic and laden with urea and allied impurities; and (2) to combat the different complications which threaten life. For the first end, iron with quinine and strychnine is to be used freely, the best forms being Basham's mixture, or the tincture of the chloride with nitrous ether. As to food, an excess of nitrogen is to be avoided, as tasking the kidneys too much, and vegetables and milk should form the staple diet. The necessity for woollen garments next the skin is insisted upon, and the general avoidance of cold is advocated. There is no doubt that residence in a warm and equable climate is often of signal service in cases of chronic Bright's disease; and cases are reported where the albumen has disappeared, and recovery apparently taken place in a warm climate, where the pre-

vious duration was such as to make the recovery highly improbable. By attention to these matters, he thinks, in the form of contracted kidney, life may only be limited by its natural termination; but a brief carelessness may quickly lead to a fatal result. When there is any dropsy in any of the forms, but especially in the large white kidney, action upon the skin and purgatives are called for. The depressing effect of the hot baths during the bath may be obviated by tying a wet handkerchief round the head. As to purgatives, they relieve the dropsy, but are exhausting if continued. Elaterium is the cathartic preferred. When the dropsy cannot be subdued by these measures, punctures are indicated. The use of calomel is objected to. 'It requires to be mentioned only to be deprecated.' Contrary to what is ordinarily held, the use of opium in full doses, after the example of Dr. Loomis, of New York, is advocated; not, however, without reservation, and with mention of chloral and the bromides.

WEIR MITCHELL ON REST IN NERVOUS DISEASE.—Under this heading, Dr. S. Weir Mitchell contributes an article that forms the fourth number of Dr. Seguin's 'Series of American Clinical Lectures.' In order to get the full benefit of this particular treatment of the disease, it is often necessary to put the patient to bed, and prevent, as far as possible, all voluntary effort. The effect is much the same as when a fractured limb is placed in splints. The muscles become flabby, the vessels lose their tone, the skin suffers in its nutrition, the joints become stiff, and for a time the function of the part is lost until the effects of the rest are counteracted by stimulated activity. But when the whole body is permitted thus to remain inactive, the effects are more general and serious. The appetite is lessened, the digestion may suffer, the bowels become constipated, the circulation enfeebled. The temperature falls and the pulse becomes 'a third slower.' Another consequence to which allusion is made as a serious consideration is that this inactivity, at first enforced, may in the end become a permanent condition. This is especially true of women, who are very apt to become bedridden under these circumstances.

The first class of cases mentioned, for which the treatment by mechanical rest is advised, consists of those in which pain is the most prominent symptom—the neuralgias. The fact is pointed out that when a nervous centre is in a morbidly irritable state, the impressions produced by normal functional activity become converted into sensations of pain.

The author mentions a rare form of writer's cramp, which is attended with pain, and which may always be relieved by rest. Next, a variety of affections of the central nervous system is mentioned, in which this treatment is regarded as exceedingly important. A disorder peculiar to women is described, which is characterised by a condition of defective nutrition, in which a painful sense of fatigue is the most prominent symptom. Besides, the patient has a low temperature, the pulse is usually accelerated, more or less anæmia is present, with an increased proportion of white blood corpuscles. Every attempt at exertion, whether mental or physical, immediately occasions an extreme feeling of weariness, so that ultimately the power of exertion is almost entirely lost. The treatment consisted in keeping the patient in bed, and prohibition of the slightest exertion. At first the patient was not even allowed to turn herself

in bed, and was fed chiefly by the rectum. To counteract the effect of the loss of normal muscular exercise upon the circulation, etc., recourse was had to massage and faradism of the muscles.

Allusion is also made to the use of rest in the early stages of spinal congestion, meningitis and chronic myelitis, but especially in locomotor ataxia. Mitchell was first led to adopt this treatment in the latter disease, in consequence of seeing several perfect recoveries in the painful stage of the affection, following fracture of a limb, compelling the patient to a season of quiet in bed.

J. MILNER FOTHERGILL, M.D.

REISLAND ON THE TREATMENT OF LEAD COLIC BY LARGE ENEMATA OF LUKEWARM WATER.—Dr. Reisland, of Wurzen in Saxony, writes to the *Berliner Klinische Wochenschrift* of May 24, 1875, strongly recommending the use of large clysters of lukewarm water in lead colic and constipation. He used an irrigator, and introduced four and a half litres (nearly a gallon) of water on one occasion, and about two-thirds of this quantity two or three times after, in the same patient, a plumber, aged fifty. The results were relief from pain, and the passage of a large quantity of fæces. [As, however, opium had previously been given, and castor-oil was administered afterwards, the case can hardly be quoted as a pure example of the success of the method recommended. The reporter believes that the use of enemata in acute plumbism is in vogue in most of the metropolitan hospitals. The case, however, deserves note, as showing that very large quantities of fluid can often be introduced into the bowel without injury, and sometimes with great relief symptoms.—*Rep.*] W. B. WOODMAN, M.D.

BUSENLECHNER ON [?] IDIOPATHIC CRAMP OF THE MUSCLES OF THE UPPER EXTREMITIES TREATED WITH QUININE.—The Vienna *Medicinisch-Chirurgisches Centralblatt* of April 30, 1875 (no. 18, Jahrg. 10) opens with a paper on the following case. A married woman, aged twenty-four years, of delicate build, and pale skin, suckling an infant eight months old, had suffered for some days from slight bronchial catarrh, and severe headache; intensified, as common in such cases, by attacks of coughing. Vertigo, tired sensations in the legs, and tremblings in the arms, were also felt by her. For all these she used domestic remedies, but on being attacked with violent cramp in the arms she consulted Dr. Busenlechner, of Hernals, near Vienna. He found her flushed in the face, sweating profusely all over, and all the muscles of both upper extremities strongly contracted and hard as a board. The pain was described as unbearable. Warmth and friction, with stimulating liniments had failed. Satisfied from careful examination that there were no symptoms of any very grave lesion of the brain or spinal cord, he prescribed a full dose of chloral-hydrate. This relieved, and for some days she was free from cramps. Then they returned, and the chloral failed—so did morphia—both giving only very temporary relief. Castoreum was quite useless. Subcutaneous injections were also of only temporary benefit. Cross-questioning elicited the fact that the cramps were slight in the mornings, unbearable in the afternoons. He gave her five grains of quinine, and for eight days she was quite free from pain. Then tremors began in the fingers—the way the cramps always came on—and he gave her another dose of quinine.

There was no relapse at the end of six weeks. Dr. Busenlechner dismisses the idea of intermittent fever, as the spleen was not enlarged. Was it due, he asks, to inflammation of the neurilemma of the nerves of the muscles themselves? or to causes, little understood, like those inducing migraine, in which also quinine proves prophylactic? Or was it a psychical affection, partly from lactation or from the bronchial-catarrh causing irritation of the nerve-centres in a reflex manner? In any case, both physician and patient were well satisfied with the effects of quinine.

STRAUSS ON CONTRACTIONS.—In a thesis (*Archives Générales de Médecine*, July, 1875), M. Strauss speaks of tonic persistent and involuntary contractions of one or several muscles of the animal system.

Different chapters are devoted to the study (1) of contractions connected with the diseases of the cerebro-spinal axis; (2) of hysterical contractions; (3) of the contractions connected with the diseases of the muscles or nerves, partial contractions; (4) of the reflex contractions; (5) of contractions in diseases of poisoning; (6) of tetanus. In diseases of the encephalon, precocious contractions are connected with a deep lesion attacking the excitable parts (mesocephale), or with a superficial lesion of the brain, or meninges.

The rotation of the head and conjugate deviation of the eyes are an accident of contraction. Tardy contractions succeed the lesions which attack the internal capsule and bring on secondary degeneration of the medulla.

The spinal affections which are accompanied by contractions are those which give rise to a change in the lateral funiculi, either primary or secondary; amyotrophic lateral sclerosis (Charcot); transverse primitive or consecutive myelitis; sclerosis *en plaques*, etc.

Hysterical contractions, whether general or local, have no known lesion; in one case, however, M. Charcot found a symmetrical sclerosis of the lateral funiculi, which would approximate to the hysterical contraction of the special forms. M. Lasègue has shown, especially in the localised forms, that pain may be the occasional cause of an hysterical contraction, which may thus be approximated to the reflex contractions. Contractions from myositis are rare, and so are ischæmic contractions in the human subject. Amongst partial contractions, the most important to be aware of are those of the diaphragm, spasm of the glottis, and contraction of the muscles of the face. Reflex contractions are more particularly observed after articular affections, functional spasms (Duchenne), nodular rheumatism, conjunctivitis, fissures, etc. Contractions in diseases of poisoning supervene in ergotism, acrodynia, and scurvy. Tetanus is referred by M. Strauss to a transitory disturbance of the medullary circulation.

RENDU ON SPONTANEOUS ANÆSTHESIAE.—Those anæsthesiæ which are not artificially induced, and which are due in the first instance to a spontaneous modification of the general health, may be classed under the name of spontaneous anæsthesiæ. Anæsthesiæ may have reference to a change in the receptor system or sensorium of the medulla, of the conductor nerves or the peripheric extremities; but the origin of these last anæsthesiæ are entirely unknown. With reference to a certain number of affections

it is difficult to say whether the anæsthesia relates to a change in the peripheric nerves or the nerve-axis (saturine anæsthesia, etc.). Disturbances of the circulation would have a great influence on the production of anæsthesia. The anæsthesia, according to an analysis of M. Rendu's work, published in the *Archives Générales de Médecine* for July, 1875, are studied in it successively in cerebral diseases, mental affections, special maladies, lesions of the nerves, neuroses, chronic poisonings, acute and chronic diseases, and skin-diseases. The progress of anæsthesia and their different nodalities are studied by M. Rendu in a very complete manner in these different classes of diseases. But, throughout these expositions, the writer is guided by one leading idea, which is, to establish the relative importance of the different sources of cerebral, medullary, and peripheric anæsthesia, and to show to which of these causes each of the anæsthesia passed in review belongs. In peripheric anæsthesia a nerve is diseased; the path of transmission of peripheric impressions towards the encephalon is interrupted, the whole region to which the nerve is distributed is struck with insensibility, which is circumscribed and distributed without any symmetry on the surface of the skin. In diseases of the medulla, general sensibility is found to be totally abolished in acute myelitis progressing rapidly upwards; partially affected in circumscribed myelitis; and scarcely changed at all in certain forms of diffused myelitis. Whenever the spinal lesion implicates the posterior portions of the grey axis, the sensory disturbances become predominant, while the changes limited to the anterior portions of the nervous centre leave the peripheric insensibility intact or nearly so. In diseases of the encephalon, the analysis of facts has allowed the circumscription of one spot of which the lesion brings on hemi-anæsthesia, which is the posterior portion of the foot of the radiating corona of Reil. However in a great many cerebral affections, affections arising from diffuse lesions, and mental affections, it is impossible to explain the production of anæsthesia; it would be easy to explain them if the existence of sensitive centres at the surface of the encephalon could be discovered.

DUJARDIN-BEAUMETZ ON THE EXPECTANT METHOD OF TREATMENT OF ACUTE ARTICULAR RHEUMATISM.—At the meeting of the Paris Academy of Sciences, on June 14, M. Dujardin-Beaumetz referred to the continuous increase of the partisans of the expectant method in the treatment of acute articular rheumatism. For a long time, as M. Fonsagrives points out, 'Doctor Six-weeks' has been esteemed as the best doctor for rheumatism, although M. Fonsagrives himself warmly contests the doctrine of expectation in rheumatism. Gouzé and Dewalsche, who were the first to maintain, in 1853, that the expectant treatment was the best for this disease, never imagined that their doctrine would obtain such a success.

M. Dujardin-Beaumetz (*Bulletin Général de Thérapeutique*, June 30, 1875) reviews the principal arguments brought forward by the advocates of expectation, arguments which may be classed under three principal heads: 1. Ignorance of the nature of rheumatism, which is antagonistic to the formulation of a rational plan of therapeutics: 2. The connexion which has been established between gout and rheumatism, and the consequences which have thence been deduced, that it is dangerous to cure attacks

of rheumatism, and that drugs may be the cause of serious complications: 3. That finally, medicines have no influence on the duration of acute articular rheumatism. M. Dujardin-Beaumetz examines and discusses each of these arguments. To the first, he answers that rheumatism is not the only disease in this predicament; we do not know the nature of intermission, still we combat it by sulphate of quinine. Still farther, thanks to the progress of experimental therapeutics, we can address ourselves more specially to certain groups of symptoms which appear to predominate in rheumatism; and all the drugs which have a markedly depressing action on the pulse and the temperature seem to exercise a favourable action in this disease. It is thus that veratrine, colchicum, quinine, trimethylamine, the cyanides, and even cold baths seem to exercise an action on rheumatism. Therapeutics have therefore made more rational progress in the last few years. To the second argument, it is easy to answer that no recorded fact has as yet shown that a reasonable amount of medication has ever been prejudicial, either by increasing the attacks or by producing serious complications. As to the third argument, it is much more difficult to give any certain proof of the action of medicines on the duration of rheumatism. Legroux regretted, in 1850, the absence of reliable statistics on this point; and M. Dujardin-Beaumetz expresses similar regret at the present moment.

With regard to the duration of rheumatism, M. Dujardin-Beaumetz divides acute rheumatic cases into three groups; in the first, he classes the 'rheumatic attacks which only last a week; in the second, those which, on the contrary, resisting all medication, last between one and two months; finally, in the third group, he places the average rheumatism, or that which lasts from three to four weeks. If, from the commencement of the rheumatic attack, there were positive signs which allowed a certain prognosis, the question would be most easily determined; but unfortunately it is not so, and, notwithstanding an assemblage of symptoms based on the intensity of the fever, the mobility of the pains, and the seat of the rheumatism, nothing positive respecting its duration can be affirmed. However, when the patient has been under careful observation for some days, when, the rheumatism having lasted a week, the fever is still very high and the pains acute, it may be concluded that it is a case either of persistent rheumatism or rheumatism of average duration; and if active medication be then resorted to, such as the administration of quinine, veratrine, colchicum, trimethylamine, the cyanides or other remedies, the rheumatism will, in a great number of cases, be arrested in its progress, stop short, and be cured in a relatively short space of time. But duration is not the only element in rheumatism; pain is a no less important one, and also demands active therapeutic measures.

Notwithstanding all these reasons, however, M. Dujardin-Beaumetz establishes that the medicinal means for the treatment of acute articular rheumatism accumulate continuously, and that each, vaunted in its turn, is afterwards pitilessly rejected. These infatuations and dislikes alike arise from too much being required from these proposed medicines, they being required to cure all cases. Never being applied to the primary cause of the disease which escapes us, the appropriate medicines can only reach one group of more or less predominant symptoms. Here lies the cause of the successes and failures;

thence the fact that there is no specific for acute articular rheumatism. In conclusion, M. Dujardin-Beaumez shows that the partisans of the expectant system do not bring forward any veritably scientific reason in support of their doctrine, whilst, on the contrary, their adversaries can produce a large number of facts in which rational medication has abridged the duration and lessened the gravity of the rheumatic attack. *

DISEASES OF CHILDREN.

VILLENEUVE ON A CASE OF PUNCTURE OF THE PERICARDIUM.—M. Villeneuve gives the following details of a case of this kind in the *Marseille Medical*.

On May 17, 1873, I was called by a colleague to see a child five years and a half old suffering from pericarditis. I found the little patient in a very serious state; his face was swollen and mottled, his eyelids swollen, his lips blue and cold, the pulse too weak to be counted. The lower extremities were cold and cedematous up to the thighs; the scrotum was infiltrated. A very marked arching, of the size of the hand, was remarked at the precordial region. This arching was distinctly fluctuating, and presented an undulating movement corresponding with the respiration. This was short and strongly whistling. Auscultation of the anterior portion of the chest gave no results. Neither respiratory murmur nor heart-sound could be heard. Nothing could be heard at the posterior part of the thorax, but the resonance of the whistling respiration and some sibilant râles. According to the account given by the parents of the child, this state was the consequence of a fall on the chest which had occurred two months previously, and after which he had begun to suffer from dyspnoea and swelling of the legs. The treatment adopted was diuretic drinks, and the application of seven leeches to the precordial region, followed by seven blisters placed one after another on the same place. No improvement, however, resulted from this treatment, and I was called in consultation. I believed the little patient to be dying, and only likely to last a few hours. Not knowing what plan of medical treatment to adopt, I resolved to try what surgery could do. With the consent of the parents, to whom I explained that this expedient was but a forlorn hope, I applied M. Dreulafoy's aspirator at the most projecting point of the tumour, and where it was most fluctuating, and thus removed, by the help of a preliminary vacuum, two syringe-fulls of a perfectly transparent lemon-coloured fluid. When I had removed the cannula, the small wound remained open, and a somewhat powerful jet of liquid spurted out of the opening. This arose in consequence of the internal wall of the cavity having been very much thinned by the repeated applications of blisters. Very much annoyed by this accident, I quickly put my finger on the opening, and had some difficulty in closing it with cross-pieces of diachylon plaster, because the child, who began to recover from the asphyxial stupor, cried, threw himself about, and caused a small amount of serous matter to exude from the puncture at every movement. I completed the dressing by a compress, held in its place by a pledget of lint, and a small body-bandage. I could then, by applying the ear to the chest, hear the pulsations of the heart, which were still confused

and tumultuous. The pulse allowed me to count 160 pulsations in the minute; the symptoms of asphyxia also gradually improved; and I left my little patient in a very satisfactory state. From that time forward the improvement continued; the cedema gradually decreased, the appetite returned, and the pulse became regular. But it is a remarkable fact that the puncture made by the trocar did not close, and that the pericardial serosity continued to flow copiously and even in jets, at every dressing, which was done twice in the twenty-four hours. After some days the serosity became less transparent, thicker, and, finally, quite purulent; it continued to flow copiously during five months. The patient, however, left his bed, walked, and recovered his appetite. About that time an abscess formed at the level of the wound, and was opened. Only healthy pus escaped from it. This abscess healed up, and gradually the pericardial fistula only yielded a smaller and smaller quantity of pus until the sixth month after the operation, when it closed up definitively. From that time the child regained health, and he is now, as far as can be ascertained, perfectly well.

I should like to draw the attention of my colleagues to the rarity of facts of this kind, and especially to the persistent continuance of the fistula, nearly six months after the operation. Finally, I beg my colleagues to be very careful to ascertain the exact condition of the heart, which appeared to me to be perfectly healthy, and gave no indications from auscultation.

MEYER ON THE USE OF TEPID BATHS IN THE FEBRILE DISORDERS OF INFANTS.—Dr. Meyer, in the *Deutsches Archiv für Klinische Medizin*, March 8, 1875, gives the results of some experience in the application of this treatment to infants under a year old. In two cases of decided pneumonia in children of seven and eight months old, he gave baths at 84° and 80° Fahr. In febrile affections with digestive disturbances he gave to infants under two months old baths varying from 93° to 79° Fahr.

A case related by Dr. Lutz, concerning an infant twenty-eight days old who was attacked by ambulatory erysipelas, deserves careful consideration, for it is certain that in this instance the cure was due to cold baths. The author adds that he has seen a child of three weeks old submitted to the same treatment recover from a very serious attack of ambulatory erysipelas. On the second day the day temperature was 104.36°, the night 105.6°; a bath of 89.6° was given. After the bath the temperature gradually diminished, and the child recovered after the appearance of a subcutaneous phlegmonous abscess.

Erysipelas erraticum belongs to those morbid forms which are successfully treated by baths. The temperature of the bath should be low in proportion to the infancy of the patient.

This treatment is also of the greatest utility in the gastro-intestinal febrile catarrh, which often appertains to infectious diseases, and, in Dr. Meyer's opinion, arises in infants from typhic virus or some analogous poison. Thus he saw an infant three months old, whose brother, fourteen months old, had been successfully treated for acute typhoid fever by cold baths and quinine, and while there was another case of the same disease in the same house, suddenly attacked in the night with gastro-enteritis, and the next day show a central temperature of 107.6°. Dr.

Meyer was only called in a short time before death, and could do nothing for the child, whose case he quotes only to show the relationship between typhus and what is supposed to be idiopathic gastro-enteritis.

As collapse is rapid in children, and the cooling of the extremities very quick, no notice is taken of the elevation of the temperature when the thermometer is not used. These very rapid gastro-enteritis are essentially different from those which are connected with digestive disturbances, and to which a good hygienic treatment suffices to render the prognosis favourable. Rilliet and Barthez have demonstrated that the intestinal lesions of infantile dothineritis are much less marked than they are in the adult. On the other hand, vomitings in infantile typhoid fever are very frequent, and thus much of infantile gastro-intestinal catarrh may depend on typhic infection, in the same way as Liebermann and Hagenbach admit to be the case in the febrile catarrh of adults. However, Dr. Meyer reproaches himself with not having, up to the present time, endeavoured to ascertain if in these circumstances the spleen was enlarged. He quotes a case in which treatment by cold baths was employed. Collapse, imminent death, vomitings, and diarrhoea, were present. The rectal temperature was $104^{\circ}9'$. A bath, with an initial temperature of 95° , gradually lowered to 86° , was given for eight minutes. The child was quieter after the first bath. Directions were given to take the rectal temperature every three hours, and to give a fresh bath so soon as it exceeded $103^{\circ}1'$. It only reached that height once after the second day. After the first bath the moanings ceased, and the child, who until that time had refused all food, began to take it, and finally recovered. In a similar case there were convulsions, after which the rectal temperature rose to $104^{\circ}5'$. The bath was cooled from $93^{\circ}2'$ to $80^{\circ}6'$, and then repeated; the first day the temperature keeping itself above $103^{\circ}1'$. The next day the temperature was normal, and recovery ensued. These cases encourage Dr. Meyer to employ baths so soon as the temperature exceeds $103^{\circ}1'$, in dothineritis, pneumonia, scarlatina, erysipelas, in fact, in all diseases showing a high temperature. The number of cases will certainly increase if, whilst combating the gastro-intestinal symptoms, means can be taken to lower the fever. How young soever the children may be, the cold baths may be used; but, unless there be precise indication to the contrary, the temperature of the bath should not fall below 84° .

JACOBI ON THE TREATMENT OF ACUTE RHEUMATISM IN INFANCY AND CHILDHOOD.—In one of a series of clinical lectures, Dr. A. Jacobi treats of the occurrence of rheumatism among children, which has been regarded by many as unfrequent. He, however, believes the affection to be quite common, but often overlooked. After a full discussion of the diagnosis and pathology of the disease, he devotes several pages to the various modes of treatment adapted to the various symptoms. Rest for the joints in a semi-flexed position, the application of ice in the acute stage, and hot poultices when the temperature has been reduced, in order to hasten the absorption of the effusion, are some of the remedies to be first applied. Later, when it may be supposed that no further absorption of effusion will take place, gentle compression by collodion, flannel bandages, cotton with linen bandages, elastic bandages, and plaster

of Paris, will be found serviceable. Puncture of the joint and the use of the aspirator cannot be objected to when the contents are purulent, and may sometimes be used in copious serous effusion. The mild galvanic current also hastens absorption. The usual anodynes are to be used locally for the relief of pain. Internally, to relieve vascular pressure, aconite, digitalis, veratrum, colchicum, or quinia is administered. The latter, Dr. Jacobi thinks of great value. The bisulphate of muriate may be given in a dose of five grains once, twice, or three times daily to a child of one or two years. Where the stomach rebels against the remedy, the rectum may take its place. The lecture concludes with a few remarks on the choreic manifestations of rheumatism, in which ergot in large doses is recommended.

BUDIN ON PULMONARY APOPLEXY IN AN INFANT.—M. Budin, in the *Annales de Gynéc.*, August, 1875, records the case of a single woman delivered naturally of a healthy living foetus, when on the third day œdema of the lower extremities, with blueness and coldness of the feet, were observed, together with rapidity of respiration. No abnormal symptom was discovered on auscultation and percussion of the chest. The child died the next day. At the *post mortem* examination, both lungs were found to be the subject of multiple hæmorrhagic infiltrations. No other lesions were detected. No cause for the condition could be assigned.

[The question of attempted suffocation seems to be not improbable.—*Rep.*]

ARTHUR W. EDIS, M.D.

SURGERY.

MUSCROFT ON A CASE OF SIMULATED TETANUS. In the *Cincinnati Clinic* of June 12, Dr. C. S. Muscroft relates the following case of simulated tetanus.

David Frick, aged fifteen, American, of German descent, was employed in a furniture factory. He had always been healthy and strong, with no tendency to nervous diseases. His father died suddenly six years ago of tetanus, with no injury or any other cause to account for the disease than a simple cold. His mother is still living and quite healthy. The patient was brought into hospital at five o'clock P.M., April 6th; he was quite conscious and rational at the time, so that he was able to give his own history. He reported that about an hour previously, while oiling a frizzling machine at the factory, his right arm was caught by the revolving bit of the machine, carrying his body around with its rotations and inflicting several severe wounds to his arm and chest. The body was whirled round four or five times before it was released, and was thrown off about twenty feet against a wall. The patient was unconscious for a few moments, but soon came too. Hæmorrhage from the wounds was very profuse, so that the attending physician, Dr. Cassat, was obliged to tie the radial and anterior interosseous arteries and several smaller muscular branches. The edges of the wounds were also brought together, as best possible in their condition. Stimulants were given to the patient in large quantities.

He was a moderately well nourished and muscular boy, of rather dark complexion, brown hair and eyes. Pulse 102. Skin moist and warm. He complained of great thirst.

When admitted, the patient was very noisy and obstreperous, refusing to stay in hospital, and demanding continuously to go home and see his mother. He acted very much like one partially under the influence of alcohol.

On examination, there was found on the right arm an irregular lacerated wound, extending from two inches below the elbow to the base of the thumb and into the palm of the hand about one and a-half inches. It presented the appearance of having been gouged out by a sharp instrument, leaving a considerable loss of substance. The wound was quite deep, reaching in some places down to the bones. On the right side of the chest there was found another deep and irregular lacerated wound, running in a curved line from one inch anterior to the axillary line downwards and backwards about six inches, and corresponding in position to that of the fifth and sixth ribs. The ribs were not exposed or injured, nor were there any symptoms present pointing to injury of the pleura or lungs. Besides the wounds mentioned, there were excoriations over the abdomen and upper portion of the right arm. Hæmorrhage from the wounds had not quite ceased, but was readily controlled by cold applications.

Dr. Muscroft ordered the arm to be placed on a firm support, and cold water to be applied to it and the wound on the chest. The patient very soon became quiet, and fell asleep; and seemed to rest well until eight P.M., when he began to be very restless and noisy. At nine o'clock he vomited a large quantity of whisky, after which he again remained quiet until ten o'clock. He now began to toss and strike about in bed, crying out loudly at times. Shortly afterwards he was seized with convulsions, which, as the nurse reported, were so severe that it required several men to retain him in bed. These convulsions recurred at intervals of about twenty minutes, becoming, however, gradually less violent and more tonic.

The patient by this time was totally unconscious and insensible of what was going on. This state of affairs continued until twelve o'clock at night, when the resident physician found the boy in the following condition. Respiration rapid, irregular, and quite stertorous; all muscles in a rigid state of contraction; opisthotonos and trismus well marked; pupils widely dilated and fixed; some divergent strabismus of the eyes; great pallor of the face; pulse rapid, full and strong, slightly irregular at times; body warm and covered with profuse perspiration. The tongue was protruded between the teeth. This attack lasted about five minutes, after which the muscles were somewhat, but not entirely, relaxed. At intervals of from ten to twenty minutes, the same train of symptoms recurred during the remainder of the night with more or less severity. Urine was passed in bed involuntarily.

At 8 A.M. on April 7, as attacks were occurring with more frequency, Dr. Muscroft ordered inhalations of chloroform during the paroxysms, and the hypodermic injection of one-eighth of a grain of morphia every two or three hours, as symptoms demanded. The effect of the inhalation of chloroform was most immediate and marked. The pulse became stronger and less frequent, the muscles relaxed, breathing became quiet and regular. The pupils were observed to contract almost instantaneously after the first few whiffs, and reacted promptly to stimulus of light in a very few minutes. These inhalations were repeated as often as spasms occurred, and were continued with the injections of morphia

during the day and following night, after which morphia was given alone. The effect of the chloroform was to check the convulsions, though the fingers remained clutched, and the lower limbs were rigid. The vomiting continued.

On the 8th the respirations were laboured and irregular; in the evening the muscles were much less rigid, and the morphia was continued. The improvement steadily persisted, and the last observation was made on—

April 11.—Pulse 84, temperature 97½°. He was resting very quietly; the wounds were suppurating and healing well. From this day the patient improved rapidly, no untoward symptoms having occurred.

Dr. Muscroft regards the very violent symptoms in this case as having been produced by the effect of the severe injury, causing, in the first place, great shock and insensibility, and, in the second place, the great prostration, with excitement to the nervous system, which was mainly due to fright. The symptoms were also very much aggravated by his having taken large quantities of whisky immediately after the injury, the amount being about twelve ounces. The plan of treatment adopted was for the purpose of quieting the brain and nervous system until healthy nutrition was restored and the great mental impression of fear relieved. There is no doubt, if the patient had not been kept constantly under the sedative influence of chloroform and morphia until the tetanic convulsions ceased, that he would have died. This patient was discharged from the hospital in the end of May, but the arm was not quite well.

O'MEAGHER ON PISTOL-SHOT WOUND OF THE ABDOMEN.—In the *New York Medical Record* of July 17 is given the following account of a penetrating pistol-shot wound of abdomen, by Dr. William O'Meagher, where the bullet passed *per rectum*, the patient making a perfect recovery.

About 4 P.M. on April 25, 1875, an able-bodied labourer, while standing at the bar of a liquor store drinking with some acquaintances, received a pistol-shot from the hand of one of them. He was carried to his home near by, where I saw him shortly afterwards lying on his back in bed, somewhat sobered, complaining of pain, faintness and chill, and restlessly moving from side to side.

A brief thorough examination disclosed the usual appearance of a bullet-wound of small size, from which there had been only a few drops of blood externally; how much internally was for future determination. It was also evident that the bullet had penetrated and lodged in the abdominal cavity, having entered at the right upper angle of the umbilical region, the situation of the wound corresponding, as nearly as can be ascertained, with a portion of the transverse colon, the commencement of the duodenum, possibly the greater curvature of the stomach, distended by a hearty meal and fermented liquor. Although the pistol was fired within a few inches of the body, the bullet failed to pass through, owing to the obstacles presented by a coarse cotton blouse, a thick-padded vest, four folds of a heavy blue flannel shirt, and a cotton wool undershirt. Without any unnecessary delay in vain efforts to find the bullet, the wound was cleansed, and closed by a compress of old linen, wet with cold water, covered with oiled silk, and kept in place by a broad bandage, tightly applied. During the exa-

mination and dressing he vomited freely about a quart of partly digested food and beer, in which, after careful examination, neither blood nor bullet could be detected. An opiate, combined with an alkaline diaphoretic, was freely administered, and ice, with carbonated water, allowed in small quantities, to allay thirst. Directions were given to examine the excretions closely; and absolute rest on the back, with the knees in the flexed position, was enjoined.

That night he was tolerably comfortable, vomiting a little, at intervals, somewhat feverish, and unable to sleep. Next day symptoms of peritonitis set in, with a chill, followed by increased pain and tenderness of the abdomen, and a little later by tympanitis, so that I was obliged to loosen the bandage and apply a bag of pounded ice to the wound. Five grains of Dover's powder, with a grain of calomel, were then administered every three hours. Under this treatment he was more comfortable that night, sleeping a little at intervals, and feeling better next day, the fever having abated somewhat, and the gastric disturbance having subsided into a kind of abortive hiccough. The iced bag was replaced by a wet napkin, covered with oiled skin.

On the third day, feeling much better, he expressed a desire to evacuate the bowels, observing that he thought he would be helped by the operation. After some hesitation I resolved to give him an oleo-terebinthinate enema, which acted promptly in two free evacuations, followed by speedy relief of all the symptoms—pain, tympanitis, gastric irritation, etc. A careful examination of the passages discovered nothing unusual to prolonged constipation, and I began to hope the intestines had escaped injury. On the fourth day he was much better, but still expressed a desire to go to stool, notwithstanding the free use of opiates, taken as at first prescribed, with very little drink, and no nourishment. After some deliberation I prescribed a castor-oil draught, which operated in the usual way, producing three passages, in the last of which the bullet was found imbedded in a small mass of fæces, requiring considerable washing to remove. After this, his progress to complete recovery was uninterrupted by any untoward symptom, care being taken only to confine him to light nourishment. In nine days the wound was entirely healed, a little circumscribed induration alone remaining around the scar. He was kept in bed for two weeks altogether, as a precaution. The bullet was part of a patent cartridge, and weighed only forty grains, apothecaries' weight.

I have seen him occasionally since, and, although unable to labour at hard work, he says he feels well and strong, suffering no inconvenience except from an occasional twinge in the site of the wound, and from the bandage which he still wears.

The favourable termination of the case, I think, was owing to the smallness of the missile; to the early closure of the wound; to the entire absence of attempts to find the bullet by probing, a species of surgery not only meddlesome, but dangerous; to abstinence from food and drink except in small quantities; to absolute rest and a good constitution.

J. MILNER FOTHERGILL, M.D.

JACOBSON ON CENTRAL CICATRISATION IN CARCINOMATOUS ULCERS.—Dr. Jacobson, of St. Petersburg, reports in the *Berliner Klinische Wochenschrift*, No. 27, 1875, a case of carcinoma of the face, on which he bases his views that the presence

or absence of central cicatrization cannot be regarded as of any value in the differential diagnosis of lupous and carcinomatous ulcers. A man, aged forty-three years, was admitted into Professor Bogdanowsky's clinique for the treatment of a circular ulcer of two years' duration, over the left masseter muscle. The base of this ulcer was soft, and presented over most of its surface healthy granulations, and here and there patches of exposed and eroded muscle. The margins were slightly thickened and indurated, though not surrounded by a zone of infiltration, and at some parts were undermined. The discharge was not profuse, and was free from bad smell. Three weeks after the patient's admission, the ulcer commenced to heal at its posterior and inferior margins, and two weeks later, a small cicatricial islet appeared near the anterior margin, and afterwards increased slowly in size. Small portions of this removed from time to time and submitted to microscopical examination, presented all the histological characters of carcinoma, and of that rare variety described by Waldeyer under the name of carcinoma granulosum. In vertical sections of small portions taken from the centre of cicatrization and the parts beneath, Dr. Jacobson found a superficial layer of stratified epithelium, from which papilliform protrusions passed into the subjacent tissue. This superficial layer and its extensions were made up externally of hardened epithelial cells, and internally of young cylindrical cells, some of which were dentated (*Stachel-Zellen*). Below the epithelium was found a layer of granulation-tissue, made up above of soft round cells and a homogeneous intervening substance, and below of closely applied spindle-cells, which, as they were traced downwards, acquired more and more the characters of fibrous connective tissue. In sections taken from the more central parts of the cicatrised islet were found irregular groups of closely applied young cells, resembling, both in shape and in arrangement, those of epithelium, and containing disproportionately large nuclei. In the midst of each of these groups were found masses of cells concentrically arranged around glistening corneo-epidermoid centres, and around the groups was an infiltration of round distinctly nucleated cells, larger than white blood corpuscles. Before removal and microscopical examination of portions of the cicatrised centre, the ulcer was regarded as a simple chronic sore, as it presented no microscopical indication of a carcinomatous character; there was not any infiltration either of its base or of its margins; the surface of the ulcer was soft, and did not present any tubercles or warty prominences; the granulations presented a very healthy appearance; the margins of the ulcer presented no irregular thickening, and the surrounding portions of integument were not indurated; the neighbouring lymph-glands were not enlarged, and the discharge from the surface of the ulcer had not a bad smell. The absence of the superficial signs of carcinoma in this case were due to the fact, that the epithelial masses were covered by a layer of ordinary granulation-tissue capable of undergoing cicatrization.

The author endeavours to explain how cicatrization could be started in an ulcer like this, in which the cutis, the normal epithelial structures, and the fascia over the masseter muscle, had been destroyed. He holds that the cancerous deposit, as it had reached the surface, must be regarded as the starting point of this cicatrization, and that either the cancer-cells had penetrated the granulations, and instead of having

undergone the usual degeneration on the surface had, under some unknown conditions, taken an epidermoid arrangement, and induced through further development scarring of the ulcer; or on the other hand that the process had been commenced at one circumscribed spot on the surface, and had caused through the influence of contact the conversion of the granulation cells into epidermis. The microscopical preparation clearly proved, the author states, that cicatrization had started from the cancerous masses.

The view that a malignant ulcer presenting the so-called cicatricial centres must be regarded as one of a lupous, and never as one of a cancerous nature, is opposed by the author, who points out that, according to modern pathologists, epithelium in the developed organism can arise only from epithelium. He states that in the extensive hospital practice of Professor Bogdanowsky, he has, in the course of three years, observed but three cases of lupus with central persistent scar-like islets which, though regarded by many authorities as patches of cicatricial tissue, failed under the microscope to present the slightest trace of epithelium. On these grounds, the author holds that the occurrence of central cicatrices with epidermic coverings at spots where the skin with epithelial structures has already been destroyed, points with fair certainty to the diagnosis of the disease as an ulcerating epithelial new growth. Lupus is, and remains to the last, a granuloma, and cannot develop on its ulcerated surface a true cicatrix.

W. JOHNSON SMITH.

DELERY ON A FOREIGN BODY IN THE AIR PASSAGES.—In the *New Orleans Medical and Surgical Journal* for July, a remarkable case of recovery when a foreign body had been in a bronchus four months is related by Dr. C. Delery. He was called, October 20, 1873, to visit E. Toulmé, aged sixteen, who had swallowed a berry covered with sharp points or thorns. He found the patient much troubled with a kind of croupal cough, and experiencing a feeling of uneasiness which was apparently felt at the upper extremity of the œsophagus. He directed him to swallow five or six pieces of stale bread one after the other. It seemed as if the foreign body were being moved, for at each deglutition the feeling of uneasiness was felt lower down, till it disappeared entirely at the sixth deglutition; the last unpleasant feeling having been experienced as if quite near the cardia. Dr. Delery was satisfied that the berry had dropped into the stomach, and left the patient. The next day the patient began coughing as badly as ever, without experiencing, however, the feeling of uneasiness above described. An abundant foamy expectoration soon appeared. The next day an emetic provoked the expulsion of three or four small thorns. The patient experienced momentary relief; he soon, however, relapsed. He then went on alternately better and worse until early in April. About the 15th fever set in, with a spell of coughing which could only be checked by strong doses of morphia. The next day broncho-pneumonia was evident by auscultation, and by the sputa. The trouble had now reached its paroxysm; skin hot; pulse 120, and even 130 at times; constant croupal coughing; the patient was very restless, with almost complete loss of sleep. Active treatment was directed against the condition of broncho-pneumonia; the agitation and insomnia subsided after injecting subcutaneously a sixth of a grain of acetate of morphia.

On April 25, 1874, Dr. Delery was hastily summoned. An extraordinary feeling of uneasiness had suddenly come on; the patient had called his parents to his bedside, being under the impression that he was about to die. His face was much altered, contracted, and blue; feeling as if he were about to suffocate, he made signs that a basin be brought to him; he suddenly sat up in bed, and vomited a mixture of bile and mucus, in which the whole berry was found. Since then his health improved daily, and he is stouter now than he has ever been.

KOCHER ON THE ANALOGIES OF DISLOCATION OF THE SHOULDER AND HIP-JOINTS, AND THE METHODS OF REDUCING THEM.—Dr. Kocher contributes, in Volkmann's *Sammlung Klinischer Vorträge*, an article in which he bases the methods of reduction of dislocation of the shoulder and hip on the anatomical structure of the joints. He remarks that these joints possess several points of analogy, especially in their ligamentous apparatus. The Y-ligament of the hip-joint, which proceeds from the anterior inferior spine to the linea intertrochanterica, and is connected with the zona orbicularis, has its analogue in the coraco-humeral ligament, which, arising from the coracoid process, divides into two branches, one of which is inserted into the greater tuberosity, the other into the lesser tuberosity of the humerus. From both these branches fibres proceed to the capsule, and perform the same functions as the orbicular ligament. These anatomical analogies indicate a similar mode of reduction. The dislocations of the shoulder and hip are essentially either forwards or backwards.

1. In dislocations upwards and forwards (subcoracoid and ilio-pubic), the special movement for reduction is flexion, which in the case of the shoulder must be preceded by strong rotation outwards, while in the case of the hip this has already been done. After flexion, rotation inwards and extension follow. In the hip, extension follows immediately on flexion.
2. Dislocations downwards and forwards (axillary and obturator) require rotation outwards, which must be preceded by flexion and traction.
3. Dislocation downwards and backwards (infraspinous and sciatic) require rotation inwards, flexion, traction, and finally rotation outwards.
4. Dislocations upwards and backwards (subacromial and iliac) require flexion or the utilisation of that already existing, traction and rotation inwards.

The methods under consideration are essentially those of elevation and rotation. Elevation serves either for relaxation of the stretched portions of the capsule (the ilio-femoral ligament by flexion, the coraco-humeral ligament by flexion and abduction) or for stretching them so as to form a firm point for leverage.

Irregular and old dislocations require somewhat modified procedures.

The use of chloroform in the reduction of dislocations should be limited, according to Kocher, as muscular contraction may often be useful.

PARONA ON A CASE OF AVULSION OF THE TUBEROSITY OF THE TIBIA.—This case is reported by Dr. F. Parona in his *Rendiconto Biennale di Clinica Chirurgica* (extract in *Annali Universali*, June, 1875). There are recorded in medical literature (according to Dr. Sellier) about thirty cases of

the patello-tibial ligament. In two only, recorded by Richet and by Sistach, the rupture was accompanied with the avulsion of a lamina of bone from the tuberosity of the tibia; and in one case, seen by Nélaton, and recorded by Binet, there had been fracture of the patella three years previously.

Dr. Parona's case was as follows. A robust man, a carter, came into the hospital at Novara in 1870, with a transverse fracture of the right patella. An immovable apparatus was applied, and in ten weeks he was able to walk about with the aid of a stick and a knee-cap. Six months later, in consequence of an energetic contraction of the triceps, the fibrous band of union gave way, and the patient was admitted into the hospital at Pavia. According to his account, the treatment consisted in the application of two India-rubber rings, one above and the other below the knee, which were drawn together by straps. At the end of two months, fibrous union had taken place to a sufficient extent to enable the patient to walk many miles with the sole aid of a stick.

On May 13, 1872, during an effort to maintain his equilibrium, the right leg being completely extended, he felt a severe pain in the knee, and found himself unable to stand. On the same day he was admitted into hospital, under the care of Dr. Parona, who found the knee very painful and rather swollen. The patella was displaced upwards, inwards, and forwards; the fibrous callus marking the fracture was felt to be firm, and about a centimètre or more in length. The patello-tibial ligament was detached from its point of insertion; crepitus was felt, indicating separation of a portion of the tuberosity of the tibia. The leg was placed in the extended position, on a slightly inclined plane; and when the local swelling had disappeared an immovable apparatus was applied. At the end of twenty days he returned home; and some months afterwards was able to walk long distances with the sole aid of a knee-cap.

RÄTZEL ON A CASE OF HERNIA OF THE BLADDER.—In an inaugural dissertation (Berlin, 1874), Rätzell relates a case of total prolapse of the bladder in the sac of an inguinal hernia. The case, which occurred in Langenbeck's clinic, was that of a man, aged forty, who was admitted with strangulated inguinal hernia of the left side. After the intestine had been reduced, a second sac was perceived, which was fortunately recognised as a bladder before being laid open. It was immediately reduced. The patient died of suffocation in consequence of some of the contents of the stomach passing into the trachea during violent vomiting. On *post mortem* examination, the bladder was found to have returned to its former position.

A. HENRY, M.D.

TAYLOR ON SOME OF THE ELEMENTS OF DIAGNOSIS IN THE DIFFERENT STAGES OF DISEASE OF THE HIP-JOINT.—In this paper (*New York Medical Record*, May 8, 1875) Dr. C. F. Taylor concludes that 'the symptoms generally relied on as diagnostic of disease of the hip-joint are worthless for all practical purposes of either anticipating the graver stages of the disease, or of affording indications for treatment. They pertain, for the most part, to the fully developed disease, and are therefore observed too late for purposes of diagnosis; and next, the symptoms of impending danger to this joint exist, in the majority of cases, long before the time of actual danger has arrived, and it is

possible—I might almost say always possible—to anticipate by prompt and effective treatment, and to prevent, by cutting short the disease, the development of those symptoms which, at a later and less curable stage, are often relied on for evidence of the disease itself.'

Our space only allows a very brief notice of a paper which extends over seventeen columns of print, and we must say that the value of the paper is much diminished to our minds by the author having omitted to state what he precisely means by 'the symptoms generally relied on as diagnostic.' Every one, we should have thought, agrees that the stiffness of the joint as testified by the movement of the pelvis along with the femur in passive motion, from involuntary contraction of the muscles, is one of the most valuable signs of early hip-disease, and this is Dr. Taylor's conclusion also. He speaks lightly of the value of pain as a symptom of hip-disease, and he explains the absence of pain, which is doubtless occasionally noticed (though in most cases pain is really present at one time or other, as Dr. Taylor's own cases show) by the very fact of muscular contraction preventing movements of the joint. But, however that may be, the muscular rigidity has long been insisted on by most authors as the best sign of the disease in its earliest stage. Dr. Taylor makes a most just distinction between the active muscular contraction set up by inflammation, and the passive contraction of the muscles following on deformity and displacement of their attachments which American authors call 'contracture.' Dr. Taylor relies chiefly on sufficient extension (with rest) in order to relax completely the muscular contraction, carrying this extension to a much greater degree than is usual in this country. He speaks of a case (at the age of thirteen) in which, beside an instrument exercising a force estimated at 100 pounds, he also put a weight of fifty pounds on the foot. This amount of extension was used for six weeks; and, at the end of that time, he was, as the author phrases it, 'set up,' then wore the extending splint for two months more, and was then well.

The paper will repay perusal, especially as showing the importance of attention to the early stages of hip-disease, and the great advantage which may be obtained by early and persevering treatment. Many cases are, no doubt, perfectly curable if taken in time, which are overlooked till the disease has reached a stage at which no complete recovery is possible.

T. HOLMES.

STOKES ON SUPRACONDYLOID AMPUTATION OF THE THIGH.—Mr. William Stokes, professor of surgery in the College of Surgeons, Ireland (*Dublin Medical Journal*, August, 1875) considers the supracondyloid method superior to those of Velpeau, Syme, Gritti and Carden, or to excision of the knee joint. The latter he considers a very dangerous and disappointing operation. He gives two cases as illustrations of the supracondyloid operation, both undertaken for disorganisation of the knee joint, following disease of the bones of the leg. Both cases are perfect successes, as may be seen by the woodcuts copied from photographs, which accompany the paper. Stokes briefly reviews the history of amputation at the knee as practised by Velpeau, Syme, Carden and Gritti, discussing the method of the last named and modifications of it at some length. He insists on the importance of being very exact as to the point at which section of the femur is

made in supracondyloid amputation (*i.e.*, from half to three-quarters of an inch above the antero-superior margin of the cartilage of incrustation), in order to avoid tilting of the patella or opening of the medullary cavity. Even when this point is carefully attended to the patella will tilt in some cases, so he recommends sewing its freshly cut surface to the surface of the femur by carbolised catgut sutures. He summarises the advantages of the operations at the knee over those in the lower third of thigh; and then tables the special advantages which he considers the supracondyloid method to give as follows.

1. The posterior surface of the anterior flap being bound by natural synovial membrane, suppuration, and risk of purulent absorption, are lessened.

2. The risk of the patella shifting its place is prevented by the high section and the use of catgut sutures to unite it to the femur.

3. The osseous curtain formed by the split patella to the end of the femur lessens the chance of pyæmia, and is not so liable to slough away as Langenbeck's periosteal curtain.

4. The vessels are divided at right angles to their continuity instead of obliquely, as in other flap operations.

5. The posterior flap diminishes chance of any wide gaping posteriorly, while the oval shape of the anterior one tends to form a rounded cone stump.

6. The normal attachments of the extensors are preserved.

[This operation is doubtless a very good one in some cases, but we should question some of the advantages claimed, and think those which are real are more securely attained by the modified Carden operation of Professor Lister, fully described by him in his article 'Amputation,' in Holmes's *System of Surgery*, vol. v. 2nd ed. We have seen numerous excellent, nay, perfect results by Mr. Lister's method.—*Rep.*]

J. KNOWSLEY THORNTON.

MOUTARD-MARTIN AND FÉRÉOL ON THE INDICATIONS FOR TRANSFUSION OF BLOOD.—M. Moutard-Martin, in the course of a discussion at the Société des Hôpitaux, reported in the *Bulletin Général de Thérapeutique*, for June 30, remarks that most generally anæmia from hæmorrhage terminates by recovery except in rare exceptions, and that, in consequence, too great importance should not be ascribed to the success obtained in these cases by transfusion, since very probably the patients would have recovered just the same without the operation. M. Féréol regretted the persistence with which M. Moutard-Martin throws doubt on the utility and efficaciousness of transfusion in certain cases, particularly in cases analogous to those reported by him. Not only is this operation formally indicated in cases of hæmorrhagic anæmia, but it is also important not to wait too long before performing it, and not to allow the patients to become exhausted under the influence of these hæmorrhages, which end by becoming continuous and incessant. For instance, M. Féréol questions if a patient, whom he saw in conjunction with M. Moutard-Martin, and who succumbed notwithstanding transfusion, would not have been saved if the operation had been performed a week earlier. The same holds good in a case reported by M. Lorain, and in which the patient was only operated on in the last extremity. As to three cases reported by M. Raynaud, which have also been represented as failures, one of them is not accepted as a failure by M. Féréol; it is that of a patient who

came completely to himself after the operation, spoke, and even declared himself as being very disgusted at being brought back from the other world, where he described himself as being very comfortable. This patient succumbed to a rupture of the carotid, which came on again after the operation; but the transfusion had none the less completely revived him. It results from these facts, according to M. Féréol, that, in cases of anæmia from hæmorrhage, operation may be performed at the last extremity with some chances of success, but in the case of anæmia resulting from chronic affections, we must not wait, but must operate before the patient is completely exhausted. For his own part, he is persuaded that if he had waited longer before operating on his patient, she would infallibly have succumbed to a fresh hæmorrhage. Although seven weeks had elapsed since transfusion was performed, the menses had not again made their appearance. M. Moutard-Martin said that it was necessary in the first instance to clearly lay down the indications for transfusion. The first of these indications is, according to him, complete exhaustion followed by hæmorrhages, whether these hæmorrhages be sudden or come on in succession. But he none the less persists in the opinion that the majority of cases which have been set down as successful cases of transfusion would, perhaps, have spontaneously terminated in recovery. M. Moutard-Martin is very reticent on the question as to whether transfusion should be tried in other cases than in hæmorrhagic anæmia; for instance, in certain morbid constitutional cases. He believes that it should not be attempted in cases of organic change. M. Bucquoy believes, like his colleagues, that the indications for transfusion should first be clearly formulated. They are in harmony on these two points: 1. That anæmic hæmorrhage is the first of the indications; 2. That the existence of an organic lesion which has brought on constitutional anæmia is a formal contra-indication. But between these two conditions there are intermediary states which merit examination from the transfusion point of view. For instance, M. Bucquoy has sometimes had occasion to observe young women, who after a more or less difficult confinement, lose blood during several months and fall into a profound state of anæmia, from which they cannot be raised by any of the plans of treatment usually employed; who, besides, can neither take medicine nor food, and, attacked by diarrhœa, finally succumb without displaying any organic lesion. M. Bucquoy questions whether, in these cases, it may not be an indication to have recourse from time to time, at longer or shorter intervals, to small transfusions frequently repeated. M. Dujardin-Beaumetz pointed out, that in cases of essential anæmia, transfusion, as a rule, only affords momentary results, as proved by a case of transfusion performed some years since in M. Béhier's wards at the La Pitié Hospital, which was a failure. M. Féréol reminded the speaker that in this case, which occurred many years ago, it had been acknowledged that, in consequence of a mistake, too large a quantity of blood was injected, which, perhaps, was not entirely without influence on the fatal result by which the operation was almost immediately followed.

RIGAUD ON THE TREATMENT OF STRANGULATED HERNIA.—M. Rigaud (of Nancy) read a note at the meeting of the Société de Chirurgie on June 9, on some points of the manipulative part of

the operation for strangulated hernia. It is impossible, he said, to lay down invariable rules for this operation. Those which anatomists have established—to divide the integuments layer by layer—are defective; for the latter have undergone such modifications that it is impossible to recognise them. The only indication which it is necessary to formulate, is to come down on the bowel without perforating it; it is only in its vicinity that prudence is necessary. M. Rigaud has therefore for some time adopted the following plan. When he has incised a certain number of layers, and he thinks he is in the neighbourhood of the intestine, he abandons the bistoury, and tries to make a slight fold on the surface of the tumour by seizing it between the thumb and first finger, previously dried and covered with starch powder. If he feel a globular swelling below this fold, he is not on the intestine, and again has recourse to the bistoury. He afterwards again tries the above plan; and if, below the new fold he has made, he find a cavity instead of a globular tumour, he concludes that he is down on the intestine. Another way of assuring himself that he sees the intestine, is to touch it lightly with the bistoury; the muscular layer being provided with a large number of vessels, a somewhat large quantity of blood escapes from it. This wound is entirely without danger. These precautions greatly simplify the operation for strangulated hernia, and M. Rigaud lays great stress on them. This surgeon never employs chloroform, for the involuntary movements which the patient makes under the influence of this anæsthetic may cause perforation of the intestine. It is only the first stage of the operation which is painful; and that is so brief, that the majority of patients, sustained by the hope of speedy relief, support it well.

DUPOLOY ON IGNIPUNCTURE IN THE TREATMENT OF HORDEIFORM CYSTS (GANGLION) OF THE WRIST. Dr. Duploup, Professor at the Naval School at Rochefort, in an article on this subject, in the *Bulletin Général de Thérapeutique* for June 30, refers to two cases under his care, which have been reported *in extenso* by one of his pupils, Dr. Guiland, in a thesis *De l'ignipuncture* (Paris: 1875.)

A female, aged twenty-one, had suffered from a large palmar ganglion of the wrist for six years. It extended above the wrist and down into the palm. It was punctured and painted without benefit. Subsequently M. Dolbeau, of Paris, incised it in its upper part, and evacuated a large number of hordeiform bodies; but this was followed by a return of the swelling. Dr. Duploup next punctured it above and below, scarified the lining membrane, and let out more of the loose bodies. This was followed by acute inflammation, but not by obliteration of the sac. Lastly, he resorted to ignipuncture, making twenty punctures on the first day and twelve on the fourth day. This proceeding was not followed by the least suppurative inflammation; nevertheless the tumour gradually subsided, and in a month had shrivelled up. The fingers, however, were almost immovable; but recovered motion under the use of gymnastic exercise.

In the case of an agriculturist, who presented a ganglion without any hordeiform bodies in it, he applied forty-one points of ignipuncture. These were only followed by areolar inflammations at each point. Three weeks later a small swelling appeared at the upper and inner part of the tumour; this was

treated by four more punctures, which sufficed to cause the ultimate disappearance of the cyst.

He thinks it must be admitted, from the experiments of M. Julliard, that the heated needles only irritate the walls they traverse to a very slight extent, and determine adhesions between them proportioned to the number of punctures. The exudations are soon transformed into cicatricial tissue, which contracts like other scar tissues, and thus is formed what he calls the caustic suture.

In cases presenting hordeiform bodies, he would recommend the evacuation of those bodies as a preliminary operation; and after the employment of ignipuncture, he would advise early resort to passive movements of the fingers and faradisation, to prevent the contraction of the fingers.

MATERIA MEDICA AND THERAPEUTICS.

MAURY ON THE PHENATE AND SALICYLATE OF QUINIA.—Considerations of a purely theoretical order led M. Maury (*Lyon Médical*, July 18 and 25, 1875) to think that a compound of phenol (carbolic acid) with quinia might be found to exhibit the specific virtues of the alkaloid in conjunction with the antiseptic properties of the acid. A phenate of quinia had already been prepared by Ramel in 1871, by acting on sulphate of quinia with potassium phenate. For this double decomposition, Maury substitutes direct combination. He adds pure phenol to an alcoholic solution of freshly precipitated quinia; the phenate crystallises out in twenty-four hours. The salt thus prepared is in needle-shaped crystals, soluble in alcohol, insoluble in water, but nevertheless very deliquescent. Its taste is bitter and somewhat caustic, and its unstable character unfits it for internal use. Maury found himself constrained to admit that the result of his exertions was not likely to prove of much practical value. It next occurred to him that the supposed advantages of the phenate of quinia, without any of its obvious disadvantages, might be obtained by substituting salicylic acid for phenol. Salicylic acid is known to possess all the antiseptic properties of the latter substance; but it is free from disagreeable odour and has no corrosive action. It may be made to combine with quinia either directly, or by double decomposition; sulphate of quinia and salicylate of soda yielding salicylate of quinia and sulphate of soda. The salt crystallises in prismatic needles, and is not deliquescent. It contains 70.1 per cent. of the alkaloid, and 29.9 of the acid. It is soluble in alcohol, both hot and cold, but insoluble in water. Acids decompose it, throwing down a precipitate of salicylic acid. It is bitter to the taste, but not at all caustic; three grains, taken internally, caused no disagreeable symptoms; the urine had the characteristic odour of meadow-sweet, and gave a violet colour with ferric salts; the presence of the alkaloid could not be detected in it. Experiments with yeast showed that the salicylate had a marked power of checking and arresting fermentation; but it is not easy to determine how much of this property belongs to the acid and how much to the base. It still remains to be seen whether the new compound possesses any clinical superiority over the salts of quinia usually employed in medicine.

BOILLE AND GUBLER ON THE HYDROBROMATES OF QUINIA AND ESERIA.—The hydrobromate of quinia was originally prepared (by M. Latour) by acting on bromide of potassium with the acid sulphate of quinia. The product of this double decomposition, though sufficiently pure for medical purposes, is never free from a considerable admixture of sulphate of potash. M. Boille (*France Médicale*, August 5, 1875) has contrived a modification of the above method, by which a perfectly pure compound may be procured. Bromide of barium (free from chloride) is substituted for bromide of potassium; the insolubility of the barium sulphate rendering it easily separable from the hydrobromate of quinia. Two salts may thus be obtained, corresponding to the two sulphates of the alkaloid. The neutral hydrobromate contains 75 per cent., the acid hydrobromate about 60 per cent. of quinia. Both salts crystallise readily in long prisms of a pearly-white or yellowish tint. They are far more soluble than the corresponding sulphates; and it is in this that their superiority consists. For, whereas one part of sulphate of quinia requires 30 parts of boiling water, 788 of cold water, 60 of absolute alcohol, and 36 of glycerine to dissolve it, the corresponding hydrobromate requires only 5 parts of boiling water, 60 of cold water, its own bulk of absolute alcohol, and 10 parts of glycerine.

M. Gubler has experimented clinically with the hydrobromate for about twelve months. The physiological effects produced were essentially those of quinism (headache, tinnitus aurium, deafness); occasionally, however, some degree of muscular lassitude and drowsiness were noticed, and attributed to bromism. The full effects of the drug, whether physiological or remedial, may be obtained by giving 40 centigrammes (about 6 grs.) in two doses. It is well borne by the stomach. Its chief practical merit appears to be its solubility; it is well adapted for hypodermic injection. M. Gubler finds that a ten per cent. solution in water, with a little alcohol, answers all requirements, without causing any inflammatory accidents at the point of injection.

The unstable character of the salts of eseria (the active principle of Calabar bean) has been a great obstacle to their employment; the sulphate, hydrochlorate, and oxalate being amorphous, hygroscopic, and readily altered by the action of the air. M. Duquesnel has succeeded in obtaining a hydrobromate of eseria in stellate tufts of crystals. This compound is freely soluble in water, and does not undergo change when kept in a dry place. Its solutions are perfectly neutral, and exhibit the characteristic myotic properties of the base.

COLOMER ON THE GLYCEROPHOSPHATE AS A SUBSTITUTE FOR THE PHOSPHATE OF LIME.—A series of experiments performed by Dr. Lestage led him to the conclusion that neither the phosphate nor the biphosphate of lime appears in the urine when given internally—that they pass through the alimentary canal without being absorbed. The lactophosphate and glycerophosphate of lime, on the other hand, effect an entrance into the blood, and are eliminated, in appreciable quantity, by the kidneys. The former of these salts is not suited for medicinal use; its administration to guinea-pigs was followed by the rapid emaciation and death of these animals. No such untoward consequences were noticed to follow the administration of the glycerophosphate. Colomer accordingly suggests

(*Gazette des Hôpitaux*, April 3, 1875) that the latter salt should be prescribed instead of the ordinary phosphate. The compound is a definite one, and may be obtained, though with some trouble, in micaceous crystals, soluble in cold water. It has an agreeable, sweetish taste, and gives rise to no unpleasant effects. It may be given in doses of from 7 to 15 grains before meals.

The preparation of the glycerophosphate is very tedious, and its cost relatively high. Some economy may be effected by omitting the final process of crystallisation, which is the less necessary as the salt is best administered in solution. It is possible that the phosphovinate of lime, a cheaper compound, may hereafter be found to possess the same advantages as the glycerophosphate. On this point, however, the author declines to express an opinion.

THOMPSON ON THE ACTION OF RED OR AMORPHOUS PHOSPHORUS.—Mr. Ashburton Thompson who has done much to rehabilitate free phosphorus in medical opinion, describes a series of experiments with the amorphous variety of the metalloid (*Pharmaceutical Journal*, July 17, 1875). Previous inquirers had established its inert character, by giving it in considerable doses to the lower animals. Mr. Thompson administered it to twelve persons, three of whom were healthy, five suffering from general debility alone, while the remaining four were cases of 'hepatic obstruction,' hysteria, menorrhagia followed by pelvic cellulitis, and acne of the face. The material employed had been carefully freed from all traces of free phosphorus, with which the allotropic variety is often contaminated. The quantity given reached half-a-drachm, taken three times a day for forty days. This amount was taken in powder, and followed, without any interval, upon a course of a scruple, taken three times daily, for thirty days. In other cases, smaller doses were administered. The general result of the trials was negative, corroborating fully the usual statements concerning the absolutely inert character of this form of phosphorus. No symptoms of any kind were noticed, and no remedial effect was produced in the few patients who were suffering from definite maladies. This does not, of course, as Mr. Thompson is careful to observe, exclude the possibility that amorphous phosphorus may exert a specific influence over some particular disease; but it renders any such prospect unlikely.

E. BUCHANAN BAXTER, M.D.

BRUEN ON QUININE IN PERTUSSIS.—In the *Philadelphia Medical Times* for July 17, Dr. Bruen gives the results of the administration of quinine in pertussis as follows.

In many cases, if the drug be used continuously, it either signally fails to relieve or else it affords but slight benefit. The proper method is to administer it by rapidly increased doses for a period not longer than five days, after which it should be stopped, and after an interval, if necessary, recommenced.

If at any time during the twenty-four hours the paroxysm be especially violent, it is a good plan to administer the quinine at such intervals that a full dose shall be given one hour or two before the spell is expected. I have known of cases which have been most benefited when the quinine has been given in large amount in two doses. This, I have been told, has been the best means when the spells were very violent during the night. I have never used the drug in this way myself. The amount of

quinine given in pertussis seems often limited by the fears of the medical attendant. I have found that to accomplish good the medicine must be pushed to a quantity equal to a full antiperiodic adult dose. To a child under three years old at least ten grains should be given in twenty-four hours; to one of twelve years, from sixteen to twenty grains in the same time. It is only by using these full doses that good can be accomplished or cures made.

In many instances I have seen it cut down immediately the number of the paroxysms from forty or fifty daily to only eight or ten; the case afterwards rapidly recovering similarly to those which have run their full course. In more rare cases it is positively curative, but the great relief afforded is amply sufficient to make us employ it when other means are so constantly ineffectual.

In my hands it did not usually moderate the violence of the paroxysms: this effect is generally seen to occur gradually after the spells have been reduced. I have seen only a few cases where unfavourable symptoms appeared during the treatment by quinine; one child of fourteen months, who had taken ten grains of quinine for two days, manifested symptoms of congestion of the brain, which yielded promptly to treatment, the disease being also cured. In one or two other cases a little drowsiness and headache were the only unfavourable symptoms, but these effects came on gradually, and I believe there is no danger in using quinine freely as I have recommended, provided we watch our patients with ordinary care.

DUNCAN ON APOMORPHIA.—In the *New York Medical Record* for August 7, Dr. Duncan gives an account of the hypodermic use of apomorphia as an emetic in children. He writes: A great deal has been written about the hydrochlorate of apomorphia, since its discovery in 1868. I obtained a specimen of this drug several months ago, and have ever since been using it whenever occasion has demanded an emetic, and now believe that, in this capacity, its value cannot be too highly estimated. It acts more rapidly and certainly, and as efficiently as the best of the older emetics, considering them to be turbit's mineral, tartar emetic, and ipecacuanha.

The qualities which recommend it particularly are:

1. The rapidity of its action; 2. the absence of danger from an over-dose; 3. the lightness of its secondary effects; 4. the shortness of the period of nausea; 5. the easy manner of its introduction.

The average time at which emesis has occurred, after its introduction under the skin, is 2.9 minutes, which is very much less than the shortest time noticed when using the yellow sulphate of mercury.

The longest time for emesis to appear was 4.15 minutes in a case of alcoholism, while the shortest was 1.75 minutes in a case of capillary bronchitis.

That this feature is one to be appreciated, there is no gainsaying by anyone who has ever witnessed the relief produced by vomiting, in children with croup or capillary bronchitis. In cases of poisoning from the introduction of any of the corrosive poisons into the stomach, this gain of several minutes would be incalculably valuable.

In speaking of the absence of danger from an over-dose of apomorphia, reference is made to the use of the English preparation of the drug which is entirely pure, and not to the German, which, according to reputation, contains an impurity of morphia.

But having given gr. $\frac{1}{15}$ to a child of six years,

without detecting any symptoms of the effect of opium, I feel free to express the belief that danger from this source is not to be apprehended.

Again, since any pronounced action is limited to the production of vomiting, as no symptoms of gastro-duodenitis, nor disturbance of the cerebral functions, nor any of those of the depression frequently witnessed after the exhibition of other powerful emetics, are noticed, one feels safe in its administration. The entire visible effect of the drug disappears after the lapse of an hour or an hour and a half, and the child's system does not seem to have been disturbed by it.

That there are other effects than emesis is recognised, such as a tendency to sleep, a slight weakness of the legs, yawning, etc., but they are very slight and soon disappear after vomiting ceases.

In the introduction of apomorphia, the shortening of the period of nausea and retching is a great boon to children, who are spared several minutes of agony; for in three cases out of five, no change in the child's face, indicating nausea, can be seen until with one great effort the entire contents of the stomach are ejected.

The hypodermic method of using this drug makes it applicable to many cases in which an emetic could not otherwise be exhibited, for children at times absolutely refuse to swallow any medicine, and can be compelled to take it only after a long, exhausting struggle, which usually results in the loss of much of their strength.

Again, its superiority in this respect would be very marked in cases of poisoning, where the substance in the stomach might cause a chemical change of the drug introduced into that organ.

The dose of apomorphia, hypodermically used, for an adult, ranges from gr. $\frac{1}{10}$ to gr. $\frac{1}{20}$, but in children it is quite large in proportion.

For a child of 18 months	.	.	gr. $\frac{1}{50}$.
" " 2 years	.	.	gr. $\frac{1}{40}$.
" " 3 "	.	.	gr. $\frac{1}{35}$.
" " 3½ "	.	.	gr. $\frac{1}{35}$.
" " 5 "	.	.	gr. $\frac{1}{30}$.
" " 8 "	.	.	gr. $\frac{1}{25}$.

Glycerine seems to preserve the strength of the drug, and alcohol will dissolve it more readily than water, so that I recommend it to be prepared after the following formula: B. Apomorphiæ, gr. vii.; Spiritus rectificati, ℥xx.; Glycerin, ℥x.; Aquæ, ℥l. M. In a child of two years, $\frac{1}{35}$ of a grain may be used.

J. MILNER FOTHERGILL, M.D.

HUTCHINS ON APOCYNUM CANNABINUM AND ITS USE IN DROPSICAL AFFECTIONS.—At a meeting of the Medical Society of County of Kings, New York, on May 18, Dr. Hutchins stated that, in a case of general anasarca, complicated with pleuritic effusion and hydropericardium, where the patient, a man aged sixty, was suffering from extreme dyspnoea, the result of the enormous distension, after the failure of all the expedients used to excite the kidneys, he had made a trial of the apocynum cannabinum, based on the experiment of Dr. Jewett, of Canandaigua. The drug was obtained from a well-known house and prepared *pro forma*, and was administered without effect. Specimens were obtained from other drug-houses, and several fluid extracts were used, and still without effect. Dr. Jewett was appealed to for advice, and some of the drug, of his own collecting, was forwarded, prepared according to directions, and administered to the patient. In forty-eight hours

the man, who had been frightfully distended, was reduced to a skeleton. Though he died about a year afterwards, the water never again accumulated, any disposition thereto being immediately relieved by the infusion of this drug.

With additional supplies, obtained from Dr. Jewett, Dr. Hutchins had promptly relieved two cases of dropsy following scarlatina, and one case of phlegmasia alba dolens.

Dr. Jewett, under date of February 16, 1875, writes: 'The woody fibre of the root has little value. You will find the bark intensely bitter, and that it has to be used with some caution, or it will provoke vomiting and diarrhoea. Its great value consists in its diuretic action, which will be impaired by any hydragogue cathartic. Sometimes its effects are direct and positive, at others, and especially in case of vicarious action of bowels, it is more tardy. I have the report of a case from Buffalo of hydrothorax, with general dropsy, where the amount of urine in the first twenty-four hours was incredible, after all the ordinary remedies had been exhausted, and the man "given up." The milk-weed was given empirically by the nurse, and the patient is fast recovering. If your patient will bear stimulants, I would give the medicine in gin, and combine with it an ounce or two of juniper berries, breaking the skin of the berry, but not the seed. Put half an ounce in a pint of gin, add an infusion of two ounces of juniper berries in a pint of water. If the stomach and bowels be irritable, give a teaspoonful every four hours. Give two, three, or four teaspoonfuls at a time, if the stomach will tolerate it, until the effect is obtained. An experience of thirty years in its use has given me unbounded confidence, if properly used. I could astonish you with the cases that have come under my observation since the publication of the article in the *Transactions*.'

Under date of June 14, 1875, Dr. Jewett writes: 'A case came to my notice yesterday where a medical man, who was sceptical as to its efficacy, was induced to try it at my request, as every other remedy had been exhausted. The preliminary arrangements were made for the funeral. The patient took the milk-weed, and is well to-day.'

Dr. Hutchins argued that Dr. Jewett's experience with the apocynum cannabinum of his own collecting, and the prompt action of the drug furnished by Dr. Jewett in the cases above related, combined with the fact of the utter failure to produce any appreciable diuretic effect from the various specimens or fluid extracts, as kept by prominent drug-houses, lead to the conclusion that the apocynum, capable of producing diuresis, is not usually, at least, to be obtained in the shops. The *Dispensatory* asserts that the root is the official part. Dr. Jewett alleges, and the facts support his assertion, that the bark of the root is alone active.

Four specimens were shown to the society, one from Dr. Jewett, which was the bark of the root, and three others obtained from three leading drug-houses in New York, one being the woody fibre without the bark, one being the whole root, and one being the leaves and stems.

Dr. Hutchins was cognisant of a case of an elderly gentleman, subject to occasional attacks of dyspnoea from hydropicardium, which were speedily relieved by a very minute dose of the fluid extract frequently repeated.

Dr. Armor said that he had similar experience in the use of the apocynum. In a case of general

anasarca under his observation, a few years since, at the suggestion of a consultant physician, he was induced to try this, to him, at that time, a new remedy. The dropsical accumulation was immense, and all the usual remedies had been tried in vain. The apocynum was administered in the mode suggested by Dr. Hutchins, and within seventy-two hours the patient was drained almost to the condition of a skeleton. The effects were the most marvellous that he had ever witnessed. The patient was somewhat exhausted, but readily rallied under the use of general tonics and stimulants. He was kept on the use of quinine and tincture of iron for months afterwards, during which time there was little or no return of the dropsy. Encouraged by the prompt and powerful action of the new remedy, he determined to give it further trial in the wards of the Long Island College Hospital, but his experience there somewhat disappointed his hopes. In one case of general anasarca the effects of the remedy were almost as prompt and powerful as in the case just cited—the fluid rapidly disappeared, and the patient, under general supporting and tonic treatment, made a good recovery. In other cases, however, apparently similar in every respect to the ones reported, the remedy—although the same preparation of it was used—had little or no effect. The cases were apparently similar, and the remedy and mode of administration were the same. In the cases in which he failed to remove the fluid by the apocynum, he subsequently tried the usual remedies, such as digitalis, squills, calomel, iodide of potassium, etc., with similar results. On the whole, he was favourably impressed with the remedy, and would give it further trial. He had little confidence, however, in cathartics, diuretics, apocynum, or any other medicinal substance, in removing fluid effusion in closed cavities when it results from acute or subacute inflammation of serous tissues. A very marked distinction should be made between an effusion in a closed cavity, the result of an exudation, and that which results from a transudation. In the one instance it is an inflammatory product, and requires time or surgical interference for its removal; in the other it is a mere transudation, the result of a general dropsy, and is readily removed by appropriate medication. It is only in the latter form of effusions into closed serous sacs that he would have confidence in apocynum, or watery cathartics, or diuretics; in other words, the value of these agents is in proportion to the general character of the dropsy.

Dr. Burge referred to cases lately treated by him with the fluid extract of apocynum cannabinum. 1. A lady, three weeks after confinement, consulted him on account of ascites and general anasarca. The urine was highly albuminous. Ten drops of the fluid extract every three hours caused profuse and persistent diuresis. The anasarca was promptly and permanently relieved. At the end of three weeks the peritoneal cavity was emptied by means of the aspirator. The patient continued the remedy in five-drop doses three times a day, and at the end of one month the disposition to effusion seems to be overcome. 2. He was called to see a child aged six months, and found him with hot dry skin, staring expression of countenance, the fontanelle prominent, and with a feeling of fluctuation. The mother said he was extremely restless, and she thought his urine scanty. Half a drop of the fluid extract of apocynum cannabinum was given every three hours, in some pleasant vehicle. After several doses, he vomited once. The medicine was then given three times a

day, and after the second day the fontanelle was perfectly natural, and the child seemed as well as ever. At the end of three weeks he had a similar attack, which was treated in the same manner and with the same result. He is now well. Dr. Burge took exception to the view which was strongly expressed by members of the Society, viz., that medicines had no power to reduce an accumulation of serum in the pleural and peritoneal cavities. These effusions often subsided spontaneously, and why might they not be hastened by appropriate medication? In cases of acute pleurisy and rapid effusion, the fluid was often as rapidly absorbed, and Dr. Burge had always ascribed some efficacy to the means which he had employed.

WINTERNITZ AND TAUSZKY ON THE USE OF WATER IN FEVERS.—At a meeting of the New York Medical Library and Journal Association (*New York Medical Record*, June 4) Dr. R. Tauszky read a paper on the views of Dr. Winternitz, of Vienna, on the uses of water in fevers. The following is a brief abstract.

The mortality from fevers has lessened considerably since the application of water in their treatment has been practised by skilful hands. Febrile diseases become more dangerous to life the greater the production of heat within, and the less active the removal of the heat from the body. It is the principal duty of the physician in the management of fevers to lessen the fever heat by all the means at his command. If our interference with disease is not precise, we can never expect measurable results. We must know how to do if we wish to do right, and a strict method is necessary in physical therapeutics. We are at present far from possessing precise methods, but the little we do have of precision is of great value.

The following, according to Winternitz, are the methods in which water is to be used: Simple ablation, friction baths, half baths, full baths, shower baths, wet pack, continuous local and continuous general baths.

The indication for simple ablation, or the sponge-bath, is where the temperature is not over 101° or 102° Fahr. When used in higher fever, it is principally for its effect as a nervous stimulant; it also prepares the skin for more potent measures. This means must be repeated every half-hour, accomplishes the desired result only in a very unsatisfactory manner, and will produce elevation rather than lowering of temperature if not followed by a more potent measure.

The friction-bath is more useful than the simple ablation, and is accomplished by wrapping the patient in a sheet wet in water at a temperature of 62° to 53° Fahr. Before applying it, cool the head for the purpose of preventing congestion of the brain, which would otherwise follow. This bath has the advantage of being purely a nervous stimulant. It causes dilatation of the blood-vessels of the periphery of the body, and must have, as a matter of course, a great influence upon the action of the heart. Rubbing the skin gently also increases the amount of evaporation more than fifty per cent.

In children, especially in the eruptive fevers, when this bath is used the exanthema will appear in full view, thus rendering diagnosis certain in many cases where it was before uncertain. It is especially serviceable also in acute articular rheumatism, first wrapping up the inflamed parts and rubbing the

cooler parts of the body until these become warm. The half-bath must be continued from twenty to thirty minutes, and the temperature should not be lower than from 65° to 54° Fahr. It may be assisted by pouring water over the neck, chest, and back. If the patient be very sensitive, it is well also to first place a cloth over the head and pour water upon that, particularly if dealing with patients who are unconscious. The half-bath is preferable to the full-bath. In the full bath, the weight of the water prevents proper reaction. The disadvantages of too cold a bath are that the colder the water used the quicker the reaction, and the sooner the return of the fever-heat; and it is also too powerful a nerve-stimulant, and will sooner exhaust a patient. A patient should never feel chilly while in a bath, and as soon as the skin begins to assume a bluish colour he should be at once removed.

The patient is more likely to feel chilly in the full bath than when the half bath is used. It may be set down as a rule, that the water used for lowering the temperature when fever is present must be of a lower degree than for cooling the healthy body. Elevation of temperature will soon take place when the wet pack is used, but there is no means of reducing the pulse as quickly as it can be done by this method. The principal rule to be observed in the use of water is to methodically repeat whatever method of application is used, and neither during the day nor during the night to permit the continuance of a high temperature for much length of time.

OBSTETRICS AND GYNÆCOLOGY.

MATTISON ON AN EASILY EFFECTUAL METHOD OF ARTIFICIAL RESPIRATION.—Dr. J. B. Mattison writes, in the *New York Medical Record* of June 12: Among the different means of restoring asphyxiated infants, artificial respiration, after the manner of Hall or Sylvester, has long held a foremost place, and been successfully resorted to after the failure of other measures. More recently another plan, that of Schultze, has come into notice; and as it may be unfamiliar to many practitioners, and is undoubtedly of value, the following description will, perhaps, be acceptable.

‘The operator seizes the child under the arms, the index finger of each hand in the armpit, the thumbs over the anterior portion of the trunk, the remaining fingers placed along the back, which is turned to the operator, while the head is steadied between the palms of the hands. As the operator stands, the child, so held, is allowed to swing between the outspread knees. The tractions thus made in both directions upon the ribs, by the pectoral muscles above and the abdominal muscles below, produce the widest separation of the ribs, while the weight of the liver causes descent of the diaphragm, and thus inspiration is produced. Next, with extended arms, the operator swings the child upward until the breech and legs fall forward toward the abdomen. When the body is thus doubled up the ribs close together, the diaphragm is pushed upward, and forcible expiration takes place, driving out through the mouth and nostrils great quantities of mucus and fluids—when respiratory movements have taken place prior to birth—from the air-passages. Still keeping the arms extended, the child should be allowed, after a few moments (?) to swing back between the legs. In

this way expiration and inspiration are to be maintained until spontaneous respiration occurs. As the temperature is apt to fall during the swinging movements, warm water should be kept handy in which to occasionally plunge the child.

We desire to call attention to another method, the value of which we have, on more than one occasion, demonstrated to our intense satisfaction, and which has, we think, advantages over that just detailed, in being more simple, seemingly not so rough, and we judge, equally efficacious.

We disclaim originality. Credit in that direction is due to Professor Harvey L. Byrd, of Baltimore, who, in an article entitled 'A "Speedy Method" in Asphyxia,' published in the *Baltimore Medical Journal*, November, 1870, and reprinted in the half-yearly *Compendium of Medical Science*, January, 1871, described its *modus operandi*, and cited cases confirming its value.

The method we present has, however, some modifications of Dr. Byrd's, and is as follows.

The infant being upon its back, firmly grasp the outer thigh, the index finger and thumb encircling, and the inner limb resting on the forearm, while the little finger is extended as far as possible up the back to form a fulcrum with the corresponding finger of the opposite hand. In the hollow formed by the thumb and forefinger of the right hand allow the neck of the infant to rest, with the palm under the shoulders and the little finger extending down the back to meet its fellow of the other hand. Now, gently and regularly depress the vertex and inferior extremities as much as practicable below the horizontal, say forty-five degrees, thus facilitating inspiration, and, after a proper interval, elevate them to the same extent, forming a concavity of the chest and thereby forming expiration. Continue these movements without interruption, taking care to permit no impediment to the exit and entrance of air during the upward and downward movements of the head and chest, and also exercising caution against too much lateral motion of the head during their continuance. The conjoined use of Desormeaux's douche, or a little cold water dashed occasionally on the epigastrium, will tend to enhance the efficacy of this method; indeed, its employment does not at all preclude the use of whatever auxiliary measures may be deemed advisable.

In Dr. Byrd's plan, the ulnar edges of the hands are placed in contact to form the fulcrum beneath the infant's back, the thumbs extended and the radial borders being alternately elevated and depressed. Simulate the normal respiratory act. Modified as above, its advantages are: a much firmer hold of the body is obtained, thereby diminishing the chances of slipping; it is less fatiguing to the operator, and it obviates a necessity for an attendant to prevent any considerable departure of the head from its antero-posterior axis with the vertebral column.

We speak whereof we know regarding the efficacy of this method, having had ample evidence in that direction. Among other cases, notes of a remarkable instance of infantile asphyxia, in which it was, we confidently believe, the life-saving instrumentality, not only in establishing respiration after a notably protracted absence, but in maintaining existence through a perilously prolonged narcosis, go far in substantiating the statement of its originator, that 'it is, *par excellence*, the remedy in the asphyxia of newly born infants.'

SLOCUM ON HIRSUTIES GESTATIONIS.—In the *New York Medical Record* of July 10, the following case of hirsuties gestationis is related by Dr. Charles E. Slocum.

Mrs. R. has borne three children at full term, and suffered one abortion at six or eight weeks. A peculiarity that has attended each gestation, is the growth of beard on the sides of the face and under the chin. This hairy growth has uniformly started at the commencement of pregnancy, or become perceptible soon after the cessation of the menses, and continued until childbirth, and the uterus has assumed its antefecundated status.

Her attention is first called to the parts soon to be covered with hair by a sense of heat and itching, which is allayed but a short time by rubbing, and which continues about three months, with more or less annoyance, and then subsides to return again after accouchement and remain until the falling of the hair.

The hair is thick-set, fine and soft in texture, straight, and lighter in colour than the hair of the head. Its length at childbirth is one to one and a half inches, when its growth apparently stops, and after a period of time varying from four to six months (first child six months, second and third children four to five months), or about the time when the uterine system resumes its catamenial function, it falls, and the face assumes its normal smoothness.

This hirsute condition during gestation is the only peculiarity in this lady's history. She has uniformly enjoyed health. The menstrual flux was established when she was between thirteen and fourteen years of age, appeared regularly, and was attended with no peculiarity. From the age of fifteen to the time of her marriage, two years later, she suffered slightly from dysmenorrhœa, but not since marriage.

July 27, 1871, she gave birth to her first child, it being about one year after marriage; November 11, 1872, after one year, three and a half months, to the second; January 12, 1874, she suffered an abortion at one and a half or two months, experiencing but little trouble therewith; and November 13, 1874, ten months thereafter, her third child was born, apparently at full term, as it certainly was in full vigour.

At the time of her abortion the growth of hair on the face was very noticeable, and she became so soon again pregnant that the growth continued until the second conception was completed.

There has been nothing peculiar in the appearance of her children.

Mrs. R. is of medium height and size, with dark-brown hair, hazel eyes, and a fair skin, which becomes of a darker hue when she is in the pregnant state. There was but little nausea following conception, and she was vigorous and able to attend to her household duties at all times. No change or peculiarity other than that already noticed occurs.

J. MILNER FOTHERGILL, M.D.

GOODELL ON THE MANAGEMENT OF HEAD-LAST LABOURS.—In a paper read before the Philadelphia County Medical Society (*Philadelphia Medical Times*, March 20, 1875), Dr. Goodell remarks that mortality in these cases is, by some authors, such as Churchill, placed at one-third; by Hodge at 33 per cent.; and by Capuron and Cazeaux at 75 per cent., in difficult cases. He believes that the causes are—first, their irregularity of the presenting part,

and the escape of all the liquor amnii as soon as the membranes rupture; next, the delay in the expulsive stage; and then, when the breech is born, compression of the cord and placenta, the partial detachment of the latter, the embarrassment to the uteroplacental circulation from the lessened size of the womb, and, finally, what is not uncommon, the long pauses between the pains. There is yet another cause, which the author thinks is not so generally known, but which is the most frequent cause of death before delivery, or of feeble vitality, or of death after delivery; namely, arrest of the placental circulation inducing a craving for oxygen on the part of the child, which sets up prematurely respiratory movements; the air not gaining access to the nostrils, the bloody mucous discharges in the maternal passages are sucked up into the lungs, plugging up the bronchi, tending to produce immediate asphyxia or death within a few days from lobular pneumonia—*atelectasis pulmonum*. He strongly recommends the following mode of treatment. Firstly, shorten the first stage of labour by ten or fifteen-grain doses of chloral hydrate, given every half hour, which promptly relaxes the rigid cervix; prevent, if possible, the early rupture of the membranes, retaining them, if possible, until the os is fully dilated; then break up the wedge which is formed by the placement of the foetal parts, by bringing down one leg, as advised by Dr. Barnes, especially one nearest the pubic arch, but use no traction, unless absolutely necessary, and then only during a pain, lest the arms should become distended. This operation should not be delayed after the foetal heart-beats become feeble. Should the breech have descended into the pelvis, then, instead of applying the blunt hook to the groin, use the forceps, supplementing it by suprapubic pressure; deliver the head as rapidly as possible. If the arm cause an obstruction, do not hesitate to use force, even to the breaking of a bone, to bring it down, as the life of the child is imperilled and every moment is of consequence. Traction should then be used, and the amount of force which can safely be used is very great. Dr. Matthews Duncan, in an article in the *British Medical Journal* for December 19, 1874, showed that the neck of a small dead child can resist a force of 100 to 110 lbs. without dislocating the vertebrae, and a force of about thirty to forty pounds more before producing decapitation. In the living child, Dr. Goodell considers that a still greater force can be safely applied; in fact, he believes that, in the stooping position of the accoucheur, it would be difficult to use greater force than the neck of the child can bear. The great object is to exert the minimum traction-force in such a way as to produce the greatest possible mechanical advantage. The mechanism of the delivery of the foetal head in breech-cases he describes as follows. The head is made up of the frustums of two cones meeting on a common base, the one anterior to the biparietal diameter, the other posterior—the ‘fore cone,’ and the ‘hind cone.’ Looking from below upwards the head is sure to be wedge-shaped; this is designated the ‘wedge.’ When the foetus is pulled through the brim, except in rare cases of contracted pelvis, the bitemporal diameter or fore cone engages the conjugate diameter of the pelvis; the biparietal and broader hind cone passes to one or other side of the osseous points (promontory of sacrum and symphysis pubis). The shorter the conjugate diameter the more inflexible is this law. The head descends unflexed, the transverse diameter of the pelvis being usually large enough to admit the passage

of the occipito-frontal diameter of the foetus. The chin can scarcely ever catch against the edges of the brim. This adjustment of the head is due to the round hard surface of the occiput, which glides off the sloping promontory. The broader surface of the occiput against the brim of the pelvis causes the head to flex and rotate. If the theory of the mechanism is the sound one, the occipital protuberance is the more likely to hook over the edge of the brim and cause a flexion of the head, which is exceedingly undesirable during the passage of the head through the conjugate diameter. The rule, therefore, to pull the face downwards is pernicious in its effects, and entails loss of traction-power. Dr. Goodell adopts two methods to extract, according as the pelvis is contracted in its conjugate diameter or not. In the one case, he applies the traction-force in the direction of the outlet, in order to get the sacral side of the head as low down as possible; this descent of the head is further increased by the assistant pressing over the pubes backwards and downwards; without for a moment retarding, but rather increasing, the original traction force, its direction is reversed and the body of the child swept behind the coccyx. The sacral side of the child's head is deeply pressed in, and the pubic glides round the pubes. Should the neck be short or the pelvis deep, pass a muslin sling over the neck so as to meet in front of the chest, and pull. Should this not succeed, when the size of the head rather than narrowness of the brim is at fault, he uses a pump-handle movement with a range of oscillation for the axis of the outlet anteriorly to as far behind as the coccyx, posteriorly; when the promontory of the sacrum is sharp, the head will not descend until either the sacral parietal bone is broken in or deeply depressed. To facilitate this mode of action, he advises the patient to be placed on her back, as an assistant can use more abdominal pressure; the nates are brought to the edge of the bed. As soon as the head escapes through the brim, which it does with a jerk usually, the body of the child should be brought round in front of the woman's abdomen; if traction fail to deliver, then apply forceps, even at the risk of rupturing the perinaeum, as the life of the child is in imminent danger, and is of more consequence than the soft maternal parts, which can be readily stitched up. Since the writer has adopted this method, his mortality in breech-cases has greatly diminished.

W. C. GRIGG, M.D.

BOISSARY ON THE CEPHALOTRIBE AND ITS USES.—In a communication presented to the French Société de Chirurgie (*Bulletin Général de Thérapeutique*, June 30, 1875), M. Boissary points out the abuses made of cephalotripsy in certain cases where the forceps, properly applied, would be sufficient to terminate the delivery. He recalls a certain number of cases in which he succeeded in extracting the foetus with the forceps, whilst colleagues who had preceded him could not finish the delivery without using the cephalotribe. Similar errors cannot be avoided in the future, except by giving a more complete education in the art of delivery to young practitioners, and by teaching them the practical application of the forceps.

MOUSSOUS ON A CASE OF TRIPLE BIRTH.—Dr. Moussous (*Archives de Tocologie*, August, 1875) gives the history of a case where three living children were born prematurely at the eighth month, owing to the excessive distension of the abdomen.

The pains were very feeble, and gradually ceased; the first child, which presented by the head, being delivered by the aid of forceps; the second presented by the breech, and the third by the head. The placenta was a single mass, weighing over two-and-a-half pounds. The cords were inserted in three different ways; one being central, another on the margin, and the third upon the membrane, about three finger-breadths from the placental edge. The vessels from each cord anastomosed with the other vessels.

There were three amniotic bags, but it was difficult to ascertain the exact condition of the chorion.

The development of the children accorded with the insertions of their umbilical cord into the placenta, that attached to the centre being the most vigorous. The children were living a month after birth. The mother did well.

LEBLOND ON SPONTANEOUS ABORTION.—Dr. A. Leblond (in *Annales de Gynécologie*, August, 1875) contributes an article founded on clinical experience, eleven of the cases being recorded in relation to the medico-legal value of the integrity of the membranes in abortion in the early months of pregnancy. He summarises his conclusions as follows.

1. When abortion occurs '*en bloc*,'—that is to say, the embryo being contained in the sound membranes exempt from solution of continuity, it is very probable that the abortion is spontaneous; at least, that the abortion has not been provoked by agents which determine the expulsion of the ovum without implicating the membranes.

2. When the membranes are ruptured, but healthy, we ought to conclude that in all probability abortion has been provoked.

3. When the membranes present pathological alteration, the medico-jurist can conclude nothing from an examination of the expelled product. He should remember, nevertheless, that the abortion results probably, then, from disease of the ovum, and that it is due to spontaneous production.

NEPVEU ON THE RUPTURE OF OVARIAN CYSTS.—Dr. G. Nepveu (*Annales de Gynécologie*, February, 1875), has collected from various sources the results ensuing from this accident; references being given to 155 separate cases, 128 of which ruptured into the peritoneal cavity, eleven into the large intestine, the others perforating the abdominal wall, bladder, vagina, and uterus. Of 127 of these cases, sixty-three proved fatal. The various modes of dealing with this complication are briefly noticed, the author contenting himself with indicating the different methods resorted to.

PINARD ON A CASE OF CÆSAREAN SECTION POST MORTEM.—Dr. Pinard (in *Gazette Obstétricale*, August 5) gives an instance of a primipara, aged twenty-two, who died from a cerebral tumour of hæmorrhagic origin, after a severe attack of epileptiform convulsions.

Cæsarean section was performed five minutes after death, the child being resuscitated with some little difficulty, and dying three hours afterwards.

GUENEAU DE MUSSY ON METRORRHAGIA ARRESTED BY THE APPLICATION OF HEAT TO THE LUMBAR REGION.—Dr. Noel Gueneau de Mussy (*Annales de Gynécologie*, July, 1875) gives the history of two cases where hæmorrhage was arrested by this

method, after various other remedies had been tried in vain. The author regards the cases as interesting, and the method worthy of further investigation.

PORTAL ON THE EMPLOYMENT OF CHLORAL IN PUERPERAL CONVULSIONS (ECLAMPSIA).—Dr. Portal (in *Bulletin Général de Thérapeutique*, August 15, 1875), mentions three cases in which chloral was employed with success. They were all the subject of albuminuria; the first was attacked six hours after parturition, the two others during labour. One was delivered naturally during the attacks of a still-born fœtus; the other was delivered of a living fœtus by the aid of the forceps, on account of the pains having disappeared when the attacks had ceased.

The first had had twenty-four attacks, coming on regularly every quarter of an hour; the second eight attacks and the third seven. Ninety grains (six grammes) of chloral were administered in each case. In the two latter, twenty-five milligrammes of morphia were also injected.

All the patients recovered. In six previous cases treated by leeches and inhalation of chloroform, the author 'had six deaths to deplore.'

LEWALD ON THE ABSORPTION OF MEDICAMENTS BY INFANTS FROM THE MOTHER'S MILK. Dr. Lewald (*Lyon Médical*, June 20, 1875) records some interesting experiments of this nature upon animals. He concludes that we can administer a greater quantity of iron to the infant by means of the mother's milk than by any other method. Bismuth, oxide of zinc, lead, arsenic, antimony, iodine, and its compounds were all detected in the milk, in various quantities, and at varying intervals after its administration to the mother. Quinine and mercury also pass readily into this secretion. The author thinks it is not demonstrated that alcohol and the narcotics can be eliminated by the milk. [He can scarcely have observed the children in large towns, or noted the instances of narcotism in the infants by the administration of opiates to the mother.—*Rep.*]

PUECH ON COMPLETE ATRESIA OF THE FEMALE GENITAL ORGANS, OR UNILATERAL HÆMATOMETRA.—Dr. Albert Puech (*Annales de Gynécologie*, August, 1875) concludes an interesting series of four articles on this subject in the present number.

He tabulates twenty-eight cases collected from various sources, where operation had been resorted to, and, excluding one where the result is not given, shows that no fewer than eight of these died, most of them from peritonitis.

He gives in detail the history of twelve cases which are of much clinical interest. After discussing the various modes of operating, he contends that the success is less intimately dependent upon the mode of operation than upon the condition of the patient at the time of operation. His conclusions are thus briefly summarised.

Complex atresia is spoken of when, the genital canal being double, one of the halves is imperforate in some part of its extent.

The obstruction was found eleven times at one of the uterine orifices, and twenty-three times in the vagina.

In twenty instances it was on the right, and eight times only on the left side.

In two cases the uterus was bilocular or partitioned; the others were instances of bicorned uterus in different degrees.

The catamenial secretion from the side of the

uterus where the aperture was patent was more or less regular, sometimes even suspended for many months, but with some few exceptions moderate in quantity.

The phenomena of retention caused by the imperforation began sometimes before the first menstruation, sometimes coincidentally, sometimes later. They consisted in pains at the menstrual period, generally coincident with the hæmorrhage, in the loins and sacral region, internal pressure directed towards the vulva, and above all in the appearance of a tumour occupying one or other side of the hypogastrium and a great part of the pelvic cavity, interfering with locomotion, and producing dysuria and even retention of urine.

The tumour was elastic, more or less voluminous, painful on pressure, moderately resistant, sometimes even plainly fluctuating, limited above, inclining to the side, and losing itself below in the pelvis proper. A tumour at the vulvar outlet, or in the genital tract, was also discovered, depending upon the seat of obstruction.

When the obstruction was at the vaginal outlet, the vulva was half opened by a cervical tumour, violet coloured, evidently fluctuating; the cervix being pushed up, and often beyond the reach of the finger.

When the obstruction was in the middle or upper part of the vagina, the vulva was normal, as also the vagina below the seat of obstruction.

Where the obstacle existed at one of the uterine orifices the open os was flanked laterally by a spherical tumour, pushing the cervix to the opposite side.

Whatever was the seat of the obstruction, pressure upon the hypogastric tumour was transmitted to the finger *per vaginam*, and *vice versâ*. In proof of these different data, exploration by means of the sound inserted in the horn remaining patulous confirmed the diagnosis of a complex atresia, and prevented its being confounded with congestive dysmenorrhœa, ovarian cysts, periuterine hæmatocèle, etc. In cases of doubt, an exploratory puncture clears up the diagnosis.

The modes of termination are identical with those of simple atresia; spontaneous rupture of the obstacle; perforation of the intermediate partition between the two horns; passage of blood from the horn into the Fallopian tube, and thence into the peritoneal cavity; peritonitis, provoked by the repetition of the crisis.

Treatment allows two indications; 1. The evacuation of the retained blood; 2. The maintenance of the opening created.

On account of the considerable mortality (eight deaths in twenty-six cases), the operation requires great precautions. It should be effected seven or eight days after the cessation of menstruation, as soon as possible from the commencement of the accident.

Considering the tendency to recur, the obstacle should be opened largely, and not punctured. Contrary to the practice of many, we ought to abstain from all pressure upon the tumour, and from prolonged examinations, which predispose to peritonitis.

ARTHUR W. EDIS, M.D.

GUÉNIOT AND BLOT ON THE USE OF MECHANICAL FORCE IN DELIVERY.—M. Guéniot read at a late meeting of the Paris Société de Chirurgie (*Bulletin Général de Thérapeutique*, June 30) a

paper on this question, to the study of which he had been led by the numerous presentations of obstetric apparatus which have lately been made. The machines used in surgery, from ancient times, were disused in the eighteenth century in consequence of a declaration of the Royal Academy of Surgery to the effect that they were dangerous. At the present day they are again in favour, and all surgeons, when they wish to use considerable and continuous power, have recourse to them. No one can contest the services they render when it is required to overcome muscular resistance, to rupture ligaments, or break bones. But may it thence be concluded that mechanical means are useful in obstetrics? Here, as a matter of fact, there is no muscular resistance to surmount, no bones to break, no ligaments to rupture; besides which, the wounding of the organs beyond the pelvis is far more dangerous than that of the muscles and bones. These considerations alone would almost be sufficient to exclude machines from surgical practice. However, prolonged and vigorous tractions are, in certain cases of dystocia, really useful both to the mother and child. Generally speaking, the unaided strength of the operator is enough, but, if efforts be prolonged for a certain time, fatigue supervenes, and the tractions are no longer equal; it even sometimes becomes impossible to continue them. In these cases a well-regulated machine, the intensity of which would vary according to the desire of the operator, would unquestionably be of service. The use of machines in obstetric practice is, therefore, in principle, logical and legitimate. The difficulty is to know in what cases recourse should be had to them. M. Guéniot believes that they are indicated when the pelvis is malformed, or when the head of the fœtus is of uncommon size, but never when the obstacle is constituted by the soft parts. He likewise proposes at a subsequent meeting to study the particular cases in which the accoucheur is authorised to have recourse to traction apparatus, and all the characters which they should present.

M. Blot, on the same occasion, expressed himself as completely opposed to the use of mechanical means in obstetrics; the power produced by them being blind and capable of giving rise to the most serious accidents. This power is only necessary in cases where there is an enormous disproportion between the capacity of the pelvis and the fœtus which must pass through it; generally the hand of an expert accoucheur can terminate the delivery, with the help of a good forceps. The most important thing is to establish the diagnosis and to recognise exactly the position of the fœtus; handiness will afterwards suffice to perform the necessary versions. When, in some quite exceptional cases, the extraction of the fœtus cannot be accomplished, there is no further cause for hesitation; nine times out of ten the fœtus is dead. The only thing to be done is to save the mother, and for that the cephalotribe is sufficient. M. Guéniot, however, persisted in his belief that, in violent and prolonged manipulation, the strength becomes exhausted and loses all regularity; he maintains that with a well-regulated machine, provided with a dynamometer, effects can be produced which could not possibly be obtained by the hand alone.

It is, in fact, impossible to determine the precise amount of power to be employed in an obstetrical operation, for it depends on the individual constitution; but it is certain that, with tractions of from

forty to sixty kilogrammes, the parturient woman is not exposed to any danger. Besides, when prolonged efforts of traction are necessary, the hand ceases to give the sensation of the strength employed.

HODGE ON COMPRESSION OF THE FŒTAL HEAD BY THE FORCEPS AND CEPHALOTRIBE.—Dr. H. L. Hodge (*American Journal of Obstetrics*, May, 1875) gives his personal observations upon the use of the forceps, as a compressing power. He believes that the impropriety of compression sanctioned by some of the best obstetric authorities is fundamentally erroneous, and greatly restricts the practical use of obstetrical instruments. The following propositions serve to indicate the nature of his views. 1. The vault of the foetal cranium is so constructed as to render it capable of compression. 2. Compression does actually occur in labour. 3. Compression of a foetal head can be effected to a great extent with safety to the child. 4. The death of the foetus during labour from pressure results from two cases—(a) the diminution or suspension of the functions of placenta and funis, and (b) from the cessation of the circulation generally. 5. Compression upon the head of the foetus can often be made by the forceps, not only with safety, but with great advantage during labour. 6. Delivery in moderately contracted pelves can be effected with greater safety by the forceps than by podalic version. 7. The obstetric forceps, when well constructed, is the best extractor in cases of dead children, and also in cases of craniotomy. 8. On the principles thus inculcated, the introduction of cephalotripsy into obstetric practice by M. Baudelocque, junr., should be regarded as the greatest improvement in operative midwifery since the seventeenth century.

HICKS ON REPOSITION OF THE PROLAPSED UMBILICAL CORD.—Dr. J. Braxton Hicks (*London Obstetrical Journal*, 1875), recommends the following as an easy and efficient plan for replacing a prolapsed funis. The patient being on the left side, in the usual obstetric position, one hand is placed over the lower abdomen, and the other is introduced into the vagina. The funis is then to be passed within the os, and the head being lifted up, it is to be passed by its side, and then above it. The external hand should have already, during the act, made out the position of the head, and now should press it downward toward the os. That it really does so, the internal hand will readily tell. While the head is pressed down from without, the internal hand is withdrawn slowly, taking care that the funis does not follow. The external hand continues its pressure over the period of two or three pains. When the uterus has fairly settled around the head the patient may be left, for the funis is effectually prevented from again being prolapsed.

ROBERTSON ON TWO FŒTUSES SUPPORTED BY ONE PLACENTA AND ONE SET OF MEMBRANES.—Dr. J. C. Robertson (*Medical and Surgical Reporter*, May 29, 1875), reported an obstetrical case having the following points of interest. 1. There was one placenta, one chorion, and one amnion—yet two foetuses. 2. Both foetuses were contained in the same amniotic cavity, in no way united, and presenting no evidence of an intervening membrane. 3. The placenta presented a healthy appearance, nicely developed, very similar to an ordinary placenta at a single birth. The woman was the mother of four healthy children, and supposed herself five months pregnant. She made a good recovery.

PSYCHOLOGY.

VAN ANDEL ON HYPODERMIC INJECTION OF ERGOTINE IN CERTAIN CASES OF ACUTE MANIA.—In the *Allgemeine Zeitschrift für Psychiatrie*, Band xxxii. Heft 2, Dr. A. H. van Anandel reports the results of cases of mania in which he has injected ergotine, together with his reasons for pursuing this method of treatment. This paper is especially interesting when considered side by side with that by Dr. Mann, an account of which was given last month in the LONDON MEDICAL RECORD. The author first gives a short description of the class of cases to which he considers this plan most applicable; they are those in which a previously healthy patient, after a week or two's restlessness, suddenly breaks out into a state of violent mania, with raised temperature and symptoms of congestion in the head, such as flushed face, injected conjunctivæ, throbbing carotids, contracted pupils. In these cases of acute delirious mania opium is contraindicated; tartar emetic in large doses quiets the patient, but injures the digestion, and fails to cure the insanity; prolonged baths or the wet sheet are of doubtful benefit. Ergotine had previously attracted attention by its use in the treatment of migraine, and Crichton Browne had given it in some cases of epileptic insanity and chronic mania without much result. Brown-Séquard saw the vessels of the meninges contract after the injection of ergotine, and this was confirmed by Hermanides. Van Anandel first used this treatment in the autumn of 1873. His patient was a female epileptic in the 'status epilepticus'; she had had a similar attack two years before, which had lasted a long time, and was not perceptibly benefited by the usual methods of treatment, viz., ice to the head, leeches, bromide of potassium, morphia subcutaneously, etc. Both in this case and in another similar one, in which death from exhaustion was feared, great good seems to have resulted from the new treatment; in the former case the attack did not last one third so long as the previous one had done. Each injection consisted of one decigramme (about one and a half grains) of ergotine in half a gramme each of glycerine and rectified spirit.

Another case is related pretty fully by the author. It is that of a robust sailor, aged forty, who, in one fortnight, had three distinct attacks of furious mania, each lasting several days. The latter two of these outbursts were treated by injections of ergotine, and the application of ice, with good results. The patient has since remained quite well. In all, fifteen injections were made in the fortnight, the same dose as above being given twice daily when required. The symptoms of cerebral congestion disappeared with each remission of the symptoms. This was the only case in which the injections were followed by small local abscesses, but these gave little trouble; in some other cases small tender swellings formed at the seat of injection. No disagreeable local results have been caused in cases where ergotine has been administered in this way for *post partum hæmorrhage*.

The author has now employed this method of treatment in many cases to counteract hyperæmia of the nervous centres. He reports the usual effects to be lessening of excitement, the gradual cessation of raving, crying and storming, the patient, although confused, becoming more manageable, and that sometimes the injection was followed by a refreshing

sleep. As cases of acute delirium are often of short duration and frequently are never sent to an asylum, it is desirable that any method of treatment which is followed by markedly beneficial results, should be known to the profession at large; but, as the author rightly remarks, further observation is needed, aided, if possible, by thermometer and sphygmograph.

NASSE ON THE TREATMENT OF PSYCHOSES BY OPIUM.—An abridged report of a paper by Nasse, in which he relates his experiences of the above treatment, is given in the *Allgemeine Zeitschrift für Psychiatrie*, Band xxxii., Hefte 3 and 4.

After reviewing the history of the methodical opium-cure in insanity, the author remarks that the discredit into which it has fallen of late is chiefly owing to the practice which prevailed some years ago in Germany of giving opium indiscriminately in all recent psychoses having undoubtedly yielded bad results, and partly also to the want of special indications for the employment of the drug. Nasse dissents from the ordinarily received opinion that opium in large doses only yields favourable results in melancholia and never in mania; it is in order to combat this view that he reports his experiences in the large institutions at Sachsenberg and Siegburg.

During twenty years he has treated 160 cases (forty-eight males and 112 females) by this method with the following results. Out of seventy melancholics (twenty males and fifty females) only six were cured (these were all females); whereas of seventy-six cases of mania (twenty-five males and fifty-one females) twenty-two were cured (seven males and fifteen females). Fourteen cases of delusional insanity (*Wahnsinn*) were also subjected to the treatment without any favourable result.

Of the melancholics the cases chosen were, as has been usually recommended, as recent as possible; the standing of the disease varied from one to three or four months, without seeming to influence the final result; they were frequently cases which exhibited suicidal tendencies or delusions of eternal perdition, but were usually free from hallucinations or bodily complications other than anæmia.

In mania, the treatment was never applied in recent cases; the author is convinced of the unfavourable influence of opium during the first few months; for similar reasons he rarely employs, in these cases, subcutaneous injections of morphia or hydrate of chloral, and then only for a short time. But we are to look for benefit from opium in cases of chronic mania of from four to seven or more months' standing, when the maniacal symptoms with sleeplessness, great excitability, emaciation, and anæmia, persist and threaten exhaustion and dementia, but in which there is no organic disease or deep brain-mischief. In men, these cases commonly follow intemperance, and in women they occur after serious hæmorrhages.

The cases of delusional insanity which were treated were generally of long standing, and such as exhibited melancholic tendencies.

The only cases which were reckoned as recoveries were those in which the symptoms did not recur after the cessation of treatment; and the patients were not discharged until they had been under observation several months. In melancholia often, but in mania less frequently, temporary improvement was observed during the treatment, but it ceased with the administration of the opium.

The method generally pursued was to commence with two grains twice a day and to increase the dose rapidly. The usual quantity given in the twenty-four hours was from four to eight grains, but in one case as much as twenty-four grains was administered. As soon as favourable results are evident, the increase in the dose should cease. The treatment was continued for from two to eight weeks or more, once for thirteen weeks with good effect. In discontinuing the opium, where it has had a good effect, the doses should be gradually decreased, but more rapidly than they were increased at the first. If good results were achieved at all, they were generally produced by doses of from four to eight grains in the day.

The effects of the opium-treatment upon the system were as follows. Considerable nausea was frequent; vomiting was rare and only occurred in cases in which the drug was otherwise ill-borne; in one half of the cases which ultimately recovered no nausea or other disagreeable effect was observed. Constipation was only caused at the first; later on there was rather a tendency to diarrhœa; sometimes attacks of colic occurred. As a rule, the frequency of the pulse was diminished; in one case it sank to 40, but with the cessation of the treatment it returned to 124. Itching and burning of the skin, which ceased with the administration of the opium, were repeatedly noticed. Contrary to views generally held, the weight of the body generally decreased during the treatment; in only eight of the twenty-eight cases of cure was there an increase; after the completion of the cure the weight rapidly increased, often to the extent of 30 or 50 per cent. Only one death occurred during the treatment: it was that of a melancholic and anæmic woman, aged fifty-two, who fell upon her left temple, and thus brought on an effusion of blood upon the brain; it remains doubtful whether the fall was in any way due to the opium treatment.

Nasse does not look upon hyperæmia of the brain, organic disease of the heart, or atheroma, as contra-indicating opium; he has had notable cases of cure when each of these conditions has been present. Also one remarkable recovery took place where organic disease of the brain was suspected, and paralysis of the face, tongue, and pupil existed.

The author believes the beneficial results of opium to be chiefly due to its sleep-producing qualities, the narrowing of the vessels and retardation of the circulation; he also ascribes to it a tonic effect upon the brain, and an indirect influence on nutrition. He does not deny that the drug may have a beneficial action in recent cases of melancholia outside asylums, but considers its effect to be very small in pure melancholies of several months' standing. On the other hand, he strongly recommends the opium-treatment for such cases of mania as are described above.

CHARLES S. W. COBBOLD, M.D.

TOXICOLOGY.

WADDEL ON ACONITE POISONING.—In the *Cincinnati Lancet* of July is a paper by Dr. Thomas Waddel, giving an account of a case of poisoning by aconite.

Mr. J. R., aged thirty-four, married, had been under treatment for nine days for an intermittent neuralgia of the supraorbital nerve and its branches, the pain coming on at 8 A.M., and lasting until evening, then

subsiding completely until next day. Before the attack, he had been in his usual health, which was sufficiently good to enable him to pursue his occupation as a carpenter. On March 16, about the usual time, pain again came up; tincture of aconite was used for a short time, but as it did not give immediate relief, Raspail's liniment was substituted. At 4 o'clock P.M. Dr. Waddel found him sitting up in bed; he had been sleeping a little; pulse 70, and regular; in answer to inquiry as to pain, he replied that he was 'perfectly easy.' At about fifteen minutes to eight P.M., Dr. Waddel was called in great haste to see the patient. The wife informed him that she believed she had, by mistake, given him one-third of a teaspoonful of the tincture of aconite root (which had been ordered as a local application) instead of his bitters (tincture of calumba and lupulin), about twenty minutes to half an hour before, and that he had since eaten a light supper; the patient himself calling her attention or the mistake by referring to the numbness of the lips, tongue, and throat, a few minutes before. Dr. Waddel found him sitting up in bed, considerably excited, but very rational. He said his feet were prickling and numb, as well as his throat, which had lost all feeling; pulse about 80, considerably weaker than normal; he had profuse sweating; disturbed respiration, and complained of nausea. Without any delay, an ipecacuanha emetic was given, followed by free draughts of warm water. About seven minutes later he was quietly reclining in bed, awake, and had not vomited. A catheter was passed into the oesophagus, when free vomiting took place. Warm water was again given, which was quickly followed by vomiting. This was repeated the third time. The food he had eaten was ejected with the vomited matter. The time consumed until the third act of vomiting, was about twenty minutes after Dr. Waddel first saw him. At this time his pulse became very weak, and he complained of numbness over his entire body; became delirious, and said he was dying; was very restless, jerking and jumping about; was with difficulty kept upon the bed. His symptoms were so alarming that Dr. Waddel, believing the stomach to be cleared, now gave him, at short intervals, four wine glassfuls of whisky, which he swallowed with a little difficulty, assisting in raising the glass to his lips with the back of his hand, as if his fingers were paralysed. In about twenty minutes after this, his pulse became almost normal, except stronger and fuller. The apparent anxiety and restlessness ceased to some extent, although he was still delirious, with symptoms of alcoholic stimulation, sitting up in the bed singing English ditties loudly. Pulse 70, full and strong; skin moist; respiration disturbed and shallow. This was the condition at nine P.M., about one and a half hours after taking the aconite. Dr. Waddel now left him for a short time (as his symptoms were much improved) to respond to an urgent call. On returning, about fifteen minutes to ten, he found him lying on the bed, very quiet, the nurse remarking that he thought his pulse better. On examination, Dr. Waddel found it about 50, strong and full; but was surprised to find it intermitting one of every four beats. On looking for the cause of this change, he immediately glanced at the respiration, and found scarcely any perceptible. The head was thrown back; the mouth open; there was frothy mucus on the lips; the head was cool; the eyelids closed; the whole surface was covered by profuse sweat. On inquiry, Dr. Waddel learned that he had been fully

conscious until ten minutes before his arrival, talking with the nurse in a rational manner regarding the accident, and expressing the conviction that he would not survive it; this last he spoke just before losing consciousness, and since then was unable to swallow. During Dr. Waddel's absence he took more stimulants; as nearly as could be ascertained, the amount was less than four ounces. Since being unconscious, there had been involuntary evacuations from the bowels, and reflex attempts at vomiting.

While Dr. Waddel was rapidly examining these symptoms, he gave a short gasp and ceased to breathe. The lips and face became livid, the pulse remaining the same. The patient was rolled over on the side, and artificial respiration (by compression of the chest) was made. After a minute he gasped, and under this stimulus resumed a weak spasmodic respiration, which would cease, if left to itself, for half a minute at a time. At half-past ten o'clock the pulse became very weak and intermitting. Whisky enemata were now given, while an assistant sustained the respiration. The sphincters were so relaxed that continuous pressure over the anus only succeeded in retaining a small portion of the stimulants, yet sufficient to materially strengthen the pulse.

This condition of things continued until eleven o'clock, P.M., when Dr. Thom saw the patient in counsel. So unceasing was the vigilance required to keep the patient from dying up to this time, that no accurate record could be kept of the pulse, respiration, or condition of the pupils. The latter were, however, noticed to be enormously dilated.

His pulse, at this time, counted 80 and full, with a strong tendency to intermit. The surface was moist, hands cold, respirations the same as for the past hour, only sustained artificially. After the arrival of Dr. Thom the patient was moved to the front side of the bed; while this was being done, although it took less than a minute, the respiration again ceased, and it was only by the greatest exertion that it was resumed. During this suspension of respiration, he presented all the characteristics of a dead man. Fifteen minims of tincture of nuxvomica, and thirty minims of tincture of digitalis, were given hypodermically during the next half hour; after which there was considerable improvement in the pulse and respirations. Whisky was also injected subcutaneously. At twelve o'clock it seemed for the first time safe to leave the respiration to itself, being still spasmodic, and superficial at 40 per minute. Pulse 75 and pretty regular; the skin was moist, head cool, pupils still much dilated and nonsensitive. During the past two hours he had had several involuntary evacuations from the bowels. From twelve to two o'clock there was little change in pulse or respiration, both were somewhat more frequent. An enema of carbonate of ammonia was given, but little was retained. The skin was more dry, the pupils were not so largely dilated, and the left was recovering sensibility. Inability to swallow still continued. Not the slightest muscular movement had been perceptible since ten o'clock.

At two and a half A.M., the respirations were 40, shallow and jerky, with mucous rales; pulse 88, very full and regular. The left pupil was more sensitive and nearly normal; the right largely dilated and immovable. There were more involuntary evacuations; no muscular movement.

Four A.M. Pulse 90, not strong, but regular; respirations 42, regular; the left pupil readily re-

sponded to light, the right was much less sensitive; he had hiccups, and involuntary evacuations.

Five A.M. Pulse and respirations faster, left pupil normal in size, right nearly so, skin dry.

Six A.M. Pulse 108 stronger and harder; respirations 36, pretty regular; no moist rales; pupils the same.

Seven A.M. Pulse 110; respirations 48 and jerky; both pupils were alike and normal in size for the first time, responding slightly to light.

Seven and a half A.M. Pulse same, but very weak; respirations 50. Twenty minims of fluid extract of digitalis were injected subcutaneously; and carbonate of ammonia was given. About nine A.M. the pulse was scarcely perceptible at the wrist. Respirations were frequent; the skin was covered by a clammy sweat. Twenty minims of fluid extract of digitalis were again injected, and a catheter was passed into the œsophagus, through which carbonate of ammonia, whisky, and water were slowly passed with a syringe. These were all retained and excited no reflex action except a slight movement of the corners of the mouth. In about twenty minutes a slight improvement could be noticed in the condition of pulse and respiration; still it was evident that a fatal issue could not long be averted. The pupils were now partly exposed; the eyeballs could be touched without exciting any reflex action; the whole surface was becoming more cyanotic.

At ten o'clock, Dr. Thom again saw the patient, and expressed surprise at the change in the patient's condition, concurring in the now hopeless prognosis. Still carbonate of ammonia, whisky, and milk were injected through the tube into the œsophagus every fifteen minutes, while digitalis and nuxvomica were given by the anus, but with little result beyond delaying the fatal issue, which took place at twenty minutes to two o'clock P.M., the respirations continuing pretty regular until within a few minutes before death. No pulse had been perceptible at the wrist since twelve o'clock.

Several times between the injections into the stomach, 'coffee-ground' fluid poured from the tubing depending from the mouth, staining the bedding and carpet a deep brown, evidently thrown up by reflex action of the stomach.

J. MILNER FOTHERGILL, M.D.

SANDERS ON DHATURA POISONING.—Dr. R. C. Sanders, civil surgeon at Muzuffernugger, relates the following cases in the *Indian Medical Gazette* for June.

These two cases of poisoning are interesting, from the *post mortem* appearances being exactly similar, and from the peculiarity of most marked venous congestion extending from the lips, along the larynx and trachea to the bifurcations of the bronchial tubes. This congestion was most marked, was uniform in its whole extent, but did not pass down the œsophagus. Their history is as follows. A sweeper, and his two children, aged nineteen and nine, were sitting near their house, when they were accosted by a traveller (a Mussulman) who, after talking to them for some time, gave them some coarse sugar to eat with their rice, and left. The father ate a small quantity, and gave the greater part to his two children; he quickly became insensible, and remained so until evening, when consciousness returned, and he found the two children dead. The bodies were sent in for examination by the police.

I.—Mussamat Badamo, a young, fat, well-deve-

loped woman, nineteen years of age, had a large number of zinc ornaments on the body. The face was swollen and congested; the eyes were intensely congested, chemosed, the pupils widely dilated. Bloody froth issued from the nose; the mouth and tongue were dark blue from congestion; the hands were clenched, the nails blue; on the left buttock and right leg the skin was rubbed off in large patches; the wounds were discoloured by dirt. Rigor mortis was persistent. The scalp was much congested, and blood was effused over the occipital region. The brain-membranes were gorged with blood; the sinuses were full of dark blood. The brain-substance was much congested. Each lateral ventricle contained one drachm of serum. The choroid plexus was turgid from congestion; the medulla oblongata was much congested. The right lung was adherent and much congested posteriorly; the tongue, fauces, larynx, and trachea were blue from congestion, which extended to the smaller bronchial tubes. The heart was healthy; its substance was extremely flabby. The stomach contained a little food, mixed with which were seeds of the dhatura alba. All the other organs were healthy.

2.—Buju, a young, healthy, well developed boy, about nine years old, had bloody froth issuing from his nostrils. The face was congested, the eyes chemosed, the pupils widely dilated, the lips livid. The body was covered with fine dirt; on the left buttock and calf of the left leg, as also on the right leg, the skin was rubbed off in large patches; the wounds were dirty; hands clenched; nails blue. Rigor mortis was persistent. The scalp was much congested; blood was effused posteriorly; the membranes of the brain were much congested; the brain was congested. Each lateral ventricle contained serum; the choroid plexus was intensely congested, erect, and turgid. The lungs were congested posteriorly. The mouth, tongue, fauces, larynx, and trachea were much congested, blue in colour. The congestion extended, without intermission, from the lips to the smaller bronchial tubes. The heart was empty and flabby. The stomach contained semi-digested food, and dhatura seeds mixed with it; it was healthy. All the other organs were healthy.

These two bodies were examined within twenty-four hours of death; in each, large swollen seeds were found in the stomach, and it was not until they had dried that they were recognised as dhatura, when they exactly resembled the figures, in Taylor's work, of 'Dhatura alba.' The girl's stomach contained seventeen, and the boy's eleven seeds.

Urgent thirst is mentioned as one of the symptoms of dhatura poisoning. This might be accounted for by the extraordinary congestion of the mouth, throat, and respiratory tract shown in the above cases, but I have not in any work seen an account of this symptom; I should be glad, therefore, if in future cases of dhatura poisoning it were specially looked for; so that, if constant, it might be placed on record.

The seeds were verified by the chemical examiner.

I accounted for the large superficial wounds on the buttock and legs, in each case, and for the blood being effused beneath the scalp posteriorly, by the bodies having been violently convulsed. The clothes of the woman, as also the body of the boy, being covered with fine dust, would also point to the conclusion that they had rolled over and over upon the ground.

SCHUMACHER AND SPÄGLER ON A CASE OF FATAL POISONING WITH NITRO-BENZOL.—The authors describe in the *Wiener Medicinische Wochenschrift*, no. 12, 1875, the case of a boy, seven years old, who took an unascertained quantity of nitro-benzol. At the end of two hours (which had been spent in the open air) vomiting and torpor set in, and continued till death, eight hours later. The vomited matter had a smell of bitter almonds; and the same odour was perceived at the necropsy (about sixty hours after death). The blood was found to be thin and dark-coloured; but on exposure to the air assumed a clearer red colour. The right side of the heart and the large veins were distended with blood. The brain and the sinuses of the dura mater were congested, as were also the lungs, which presented subpleural ecchymoses. There were also small effusions of blood in the mucous membrane of the stomach and small intestine.

A. HENRY, M.D.

DERMATOLOGY.

KAPOSI ON RECURRENT ZONA.—Dr. Kaposi [Moritz Kohn] relates in the *Wiener Medizinische Wochenschrift* (no. 22) the occurrence of this disorder for a third time in the same patient. The two former attacks were narrated in the same journal last year (nos. 25 and 26), and an abstract was given in the LONDON MEDICAL RECORD for November 25, 1874.

The patient, Marie Poje, a hospital nurse, was first attacked by severe zona of the left arm and shoulder in the spring of last year, and recovered by July; two months later a similar eruption appeared on the right arm, and on January 15 following the third began. Numerous scars, some slight and pale, others darkly coloured, and others again thick, large, and almost cheloid in appearance, the remains of the first attack, were seen scattered over the right arm, shoulder, and breast. The new eruption consisted of two large circular patches which occupied the dorsal aspect of the right forearm from the wrist to a third of the distance to the elbow. That covering the ulnar side was red, swollen and smooth [erythema exudativum]; that on the radial side was brown or yellowish in the central part, while the edge was of a bright scarlet colour. Both patches were painful, and the patient was somewhat feverish. Next day the radial disk had grown much darker and flatter; the other one, which had become the site of some subcutaneous hæmorrhage, was also dark and depressed, but the red edge was now covered with eight or ten clear vesicles, each as big as a hempseed. Besides these two large patches, there were now apparent two streaks of red and yellowish-green (hæmorrhagic) discoloration, running obliquely towards the elbow on the extensor surface of the same forearm.

January 17, 1875. The first patch was dried up; the second had extended further, with a fresh outbreak of vesicles. The two streaks which appeared on the previous day were also becoming depressed, dark, and hard, but a fresh red spot had appeared close to the elbow, preceded by pain.

January 18. The two streaks on the forearm were now surrounded by a red edge, which was covered with vesicles, and fresh red spots had appeared between the old ones. These were now themselves covered with umbilicated scabs, corresponding to the pre-

vious vesicles. The area of the affection had not spread, and the patient's general condition was more comfortable.

January 20. The only fresh eruption was a crowd of vesicles on the patch (now as large as half-a-crown) upon the elbow. The other parts were undergoing involution.

January 21. Near the wrist two fresh, red, and painful patches had appeared, each with a discoloured centre from ecchymosis. No fresh vesicles had formed, and those of the previous day were drying up like the rest.

January 22. New vesicles appeared on the elbow. Scabbing was going on elsewhere. From this date no fresh eruption appeared, and the crusts gradually dried up and fell off, leaving a red and depressed surface free from ulceration. On February 15 the patient was well. The treatment was expectant throughout.

P. H. PYE-SMITH, M.D.

RAYNAUD ON THE RELATION BETWEEN EXOPHTHALMIC GOITRE AND VITILIGO.—Dr. Raynaud (*Archives Générales de Médecine*, June, 1875) gives five cases of exophthalmic goitre, culled from various sources, in the course of which patches of vitiligo appeared on various parts of the body. Beyond the observation that vitiligo is more common in men than in women, except when congenital, that it attacks by preference persons of dark complexion, that it is sometimes, though rarely, hereditary, and has a certain analogy to Addison's disease, viewed as an imperfect vitiligo, little has been made out with regard to its pathology. Mr. Hutchinson has pointed out that although no known cachexia appears to set up a predisposition to the affection, the symmetry of the cutaneous patches is suggestive of some pre-existing general fault of the circulatory or nervous systems, and is opposed to the hypothesis of a parasitic origin. Without offering any explanation of the co-existence of vitiligo with exophthalmic goitre, Dr. Raynaud thinks that the coincidence should not be allowed to pass unnoticed. [The nature of the connection between the two diseases deserves further investigation. I may state, perhaps, that although I have carefully examined a considerable number of cases of each of these two affections, I have never met with both in the same individual in a single instance.—*Rep.*] W. B. CHEADLE, M.D.

OPHTHALMOLOGY AND OTOLOGY.

WEBER-LIEL ON THE MAKING OF PERSISTENT OPENINGS IN THE TYMPANIC MEMBRANE.—In no. 4 of the *Monatsschrift für Ohrenheilkunde* of this year, Dr. Weber-Liel, of Berlin, reports three cases in which he made perforation of the tympanic membrane by the method proposed by the reporter in the *Guy's Hospital Reports* of this year, viz., making a large trepanation in the membrane and in the cicatrix formed making another perforation. Two cases were successful, the third did not continue to attend the clinique and the result could not be determined. Since Sinrock's method of perforating by means of sulphuric acid was published Dr. Weber-Liel has been using it, and proposes to make the preliminary perforation by it. [Before seeing this article of Dr. Weber-Liel's, the reporter believed that the method proposed by him in the *Guy's Hospital Reports* of this year, was his own; but it seems that Dr. Weber-Liel had proposed the method in 1871, and reported a successful case in that year. The reporter has at present several cases under observation, in which a perforation has been effected by means of sulphuric acid, and in which he waits the full formation and hardening of the cicatrix before making the second perforation.—*Rep.*]

URBANTSCHITSCH ON THE FORM AND POSITION OF THE PHARYNGEAL OPENING OF THE EUSTACHIAN TUBE IN MAN.—Dr. Victor Urbantschitsch, of Vienna, gives a short notice on the above subject in the *Archiv für Ohrenheilkunde* for July. The form and the lumen of the pharyngeal opening he finds very varied, sometimes appearing as a fissure, occasionally having the form of a pear with the base generally upwards, sometimes having an ellipsoidal or three cornered, or kidney-form figure. He considers that the formation of the opening is greatly influenced in many cases by the ligamentum salpingopalatinum described by Zuckerkandl, which runs from the pharyngeal end of the lateral cartilage downwards to the palate. In conjunction with the under portion of this ligament Dr. Urbantschitsch finds in many preparations which he has examined, a series of tendinous fibres which arise from the ligamentum salpingo-pharyngeum, and from the under end of the middle cartilage, and pass partly to the palatal muscles and partly joins with the ligamentum salpingo-pharyngeum.

The direction which the opening generally takes is an oblique one from above forwards to below backwards, only exceptionally being seen vertically or horizontally placed.

In the newly born and in the aged, an inclination to a circular opening was seen.

URBANTSCHITSCH ON A PECULIAR FORM OF EPITHELIAL DEPOSIT ON THE MEMBRANA TYMPANI AND ON THE EXTERNAL MEATUS.—In the same number of the *Archiv für Ohrenheilkunde*, the same author describes three cases in which he has seen on the tympanic membrane several white glancing, sharply circumscribed spots, as if the membrane were studded with small pearls. In one case two such spots were on the lower segment, and on the upper and posterior quadrant four such spots were grouped together. The condensation or rarefaction of the air in the meatus, though acting strongly

on the membrane, made no change on the deposits. In a second case he saw a similar accumulation forming, appearing first as a white point, which, only to be detected by careful examination at first, grew after several weeks to the size of a pinhead. Several more formed on the same membrane, and wandered gradually upwards from the spot at which they were first observed. Touching them with the sound showed that they were hard and firm; pressure could not detect any soft part. On removing one of them by a tenotome, however, this hardness was found to be confined to the covering of the tumour, while the inner part consisted of a yellow pulpy mass, easily removed from the hard periphery. The microscope showed that it was not a cholesteatomatous tumour, as no cholesterine could be discovered, and that it consisted of fragments of epithelium. Eight weeks after the removal there were no indications of a return. In another case the tumours were absorbed without any treatment. Two of the above-mentioned patients were suffering from otitis media, the third from catarrh of the tympanic cavity.

W. LAIDLAW PURVES.

PFLÜGER ON CHRONIC GLAUCOMA IN TWO BROTHERS AGED NINETEEN AND TWENTY YEARS. The *Klinische Monatsblätter* for April, 1875, contains a short account of two cases of glaucoma which occurred in two young men of the same family.

Just S., aged twenty, was brought to Dr. Pflüger in May, 1874, and it was said that his eyesight had been slowly but gradually diminishing, but without any pain, during the last two years; the symptoms had been ascribed to debility, but no good had resulted from treatment. The widely dilated pupil and the tortuous and engorged condition of the sub-conjunctival vessels pointed to glaucoma, and a closer examination left no doubt upon the subject. Central vision was lost, and the visual field of the right eye was contracted to a small and excentric space upwards and outwards. That of the left eye was very similar but rather larger in extent. The visual acuity, right = $\frac{1}{200}$ left = $\frac{200}{800}$.

The ophthalmoscope served to make the diagnosis more complete. The optic papilla was cupped in a most marked degree, and its margins were surrounded by a yellow-white ring, the outlines of a posterior staphyloma. The erect image of the scleral ring could be most clearly seen with a concave-glass—6, while the entrance of the blood-vessels and the fundus of the cupped papilla could only be clearly seen with a concave—3.

On inquiry, it appeared that the patient had a brother a year younger whose sight had deteriorated in a very similar way, and on examination his eyes were found in much the same condition although less advanced. An iridectomy was at once advised, and was submitted to by the younger of the two brothers, but the other brother and his father were too sceptical as to the nature of the disease to submit to treatment. As his vision did not improve after the operation, the younger brother consulted Professor Horner, who made the following note of the condition of his eyes.

With the right eye he could hardly see the shadow of the hand, with the left he could count fingers with difficulty; in neither eye was the tension very marked, but the arterial pulse could be readily seen. The difference in the refraction of various diameters of the eyes were very remarkable.

The eyes had remained in much the same condi-

tion since the operation; and the discrepancy between the measurements of the glaucomatous cup, as made by Dr. Pflüger with those made at a later period by Professor Horner, may be due to the fact that Dr. Pflüger did not relax his own accommodation by atropine before he made his examinations.

BOWATER J. VERNON.

REVIEWS.

Ling's Educational and Curative Exercises. By M. J. CHAPMAN, M.A. Cantab., M.D. Edin. Fourth Edition. Edited by Augustus Georgii. London: Renshaw, 1875.

It is more than sixty years since Ling first introduced the system of gymnastics with which his name is so specially connected, the Royal Gymnastic Central Institution at Stockholm having been founded on his principles in 1813. The somewhat uncouth nomenclature of his *Kinesiatic* or *Kinesitherapeutic* science was, to a certain extent, a bar to its immediate acceptance elsewhere, and the active advocacy of Dr. Chapman was only partially successful in securing for it a hearing in this country. In Sweden, however, the Government was induced to look favourably upon it, and in Germany numerous establishments have since risen all over the country in which Ling's principles are carried out.

The present pamphlet is a reprint of the late Dr. Chapman's, and is edited by Professor Georgii, one of the only two pupils Ling had that he thought capable of carrying out his idea in the way he contemplated. Ling was a poet and enthusiast, and as such was, probably, able to push his views into notice more effectually than if he had been a man of more ordinary mould; but in this, as in many other points, we are only returning to the wisdom of the ancients, who were fully alive to the necessity of gymnastic exercises for preserving the vigour, bodily and mental, of a community.

It is, however, unfortunate that unnecessarily hard names, not to mention other points, should have imparted to the method in question a certain air of quackery calculated to repel the members of the medical profession generally. It is unsatisfactory to see the successes of such quacks as professional rubbers noticed, without any mention of their numerous failures, and the great harm done in too many cases by their ignorance and audacity. What also are we to make of 'manual magnetism, or mesmerism, according to Ling, a dynamic agent, through an external mechanical vehicle'?

It is, however, quite certain, in spite of those objections, that gymnastics, or educational and curative exercises, as Ling calls them, are highly valuable, and that much may be done by their means in the hands of properly educated persons, and to Ling is due the main credit of their revival in a scientific spirit. He divides gymnastics into four sections, viz. :—

1. MEDICAL GYMNASTICS (*Kinesitherapeutics*), in which mechanical manipulation, scientifically used, is applied to supplant or supplement medical treatment.

2. EDUCATIONAL GYMNASTICS, by which the most perfect development of the frame as an instrument is aimed at.

3. MILITARY GYMNASTICS, with special regard to training for attack and defence.

4. *ÆSTHETIC GYMNASTICS* includes the true principles of elocution, with expression of emotions in action.

In the Royal Gymnastic Institution at Stockholm, training is given in all these branches, under a board of direction consisting of a physician, a military officer, and a certificated schoolmaster. Subordinate teachers require to go through a course of two years' duration, including lectures on anatomy, physiology, pathology, and hygiene, together with instruction in the theory and practice of gymnastics, educational, military, and medical.

Ling proposed that all children should be put under physical training when they were seven years old, supposing that there should be no decisive reason for commencing his exercises sooner; and certainly the ordinary experience of the benefit often obtained by the mere learning of dancing is a corroborative fact in favour of this view. As regards the curative results, a long list of cases is given of various diseases where more or less good result was obtained by Professor Georgii. They are certainly very remarkable, and include a great variety of cases, such as phthisis, paralysis, spinal complaints, cerebral congestion, neuralgia, rheumatism, skin-affections, and even in one case fistula in ano! In a table at the end the editor gives an abstract of the results in 399 cases, of which 163 were cured, ninety greatly improved, ninety-one improved, and fifty-five no results; surely an excellent return for any therapeutic method.

The effects of gymnastics have to a certain extent been seen in our own army, especially in the gymnasium at Aldershot, under the skilful management of Colonel Hammersley, where weedy lads have wonderfully improved, the chest expanding, the muscles increasing in size and power, cough and phthisical symptoms diminishing, and the general health becoming greatly ameliorated. There can be little doubt that a scientific system of gymnastics ought to form a part of the training of our army and navy, both officers and men, and above all that the medical officers should be properly instructed in it. Yet at Netley there is no gymnasium, nor any apparent likelihood of one being voted, although it was promised that one should be established there a dozen years ago.

Both Government and Parliament might take a lesson from so poor a country as Sweden, where an annual grant is made of 31,400 rix-dollars (6,500*l.*), besides a special grant of 167,000 some years ago for the necessary buildings for the Royal Gymnastic Central Institution at Stockholm.

The whole question is one of deep and vital interest, and it is to be hoped that sooner or later both Government and people will become sufficiently alive to it.

Annual Report of the Fever Hospital and House of Recovery, Cork Street, Dublin, for the year ending March 31, 1875.

This report is divided into two parts, the first giving an account of the expenditure during the year; the second being the medical report by Dr. Grimshaw, physician to the hospital.

The hospital is capable of containing 200 patients, 150 acute and 50 convalescents, but it is found that it is necessary always to have 105 beds constantly ready for use.

During the year ending March 31, 1875, 858 patients were admitted, being an excess of forty-one

over those received in the previous year. A very large proportion of these, however, were not suffering from any specific fever.

The following table will show the number and nature of the various diseases admitted into the Cork Street Fever Hospital during the past year.

TABLE NO. I.—*Showing the Number of Admissions of the Principal Diseases, and the Mortality of those Treated to a Termination, for the year ending March 31, 1875.*

	Typhus Fever	Enteric Fever	Relapsing Fever	Simple Fever	Intermittent Fever	Small-pox	Scarlatina	Measles	Pneumonia	Whooping-Cough	Diarrhoea	Erysipelas	Meningitis

Acute rheumatism, 31; chronic rheumatism, 4; bronchitis, 120; alcoholism, 10; phthisis, 6; catarrh, 6; dyspepsia, 23; pneumonia, 1; progressive muscular atrophy, 1; tonsillitis, 1; jaundice, 3; English cholera, 1; asthma, 1; puerperal mania, 1; paralysis, 2; hemiplegia, 1; influenza, 2; no disease, 4.

The report calls special attention to the fact of sixty-eight cases of pneumonia being admitted. Dr. Grimshaw says this disease prevailed in the spring and summer months, generally in the epidemic form, occurring in the same localities and under similar circumstances to enteric fever. Dr. Grimshaw thinks that he has distinctly traced its cause to a miasmatic source, and therefore names it 'pythogenic pneumonia.' Speaking of the disease he says it 'must now be fairly looked upon as a specific fever, the lung-affection bearing the same relation to the fever as the sore throat does to scarlatina, ulceration of the intestines to enteric fever, or inflammation of the membranes of the spinal cord to cerebro-spinal fever. This form of fever must, therefore, be considered a suitable one for reception into our hospital, and should not be refused admission or transferred to other hospitals in the same way as bronchitis, or other forms of chest-inflammation produced by exposure to cold.'

Several carefully prepared tables will be found in the report, comparing the monthly admissions with those of former years. ALEX. COLLIE, M.D.

On the Influence of Temperature during Child-birth, and on the Right Management of the Puerperal State. By BENJAMIN T. MOORE, M.D. Pp. 30. 1875.

This pamphlet consists of a series of letters recently published in the *British Medical Journal*.

The author cites what he considers a typical case of labour. 'A person who was occupied in baking cakes, whilst standing before a large bread oven, was suddenly taken with her first and only pain, and had barely time to kneel down in front of a chair before the child was born.' He questions 'whether precisely similar results might not as a rule be accomplished, were the mass of parturient women subject to equally favourable conditions.'

'In cases of retention of the placenta, whether arising from spasm or inertia, I have found it an excellent plan to get the patient to stand before a fire, and thus to warm and dry her body, back and front.' It would be interesting to know in how many cases he has tried this, and whether he really recommends it in all cases. He speaks of placenta previa, which 'could only be traced to anxiety of mind.'

Then follow long extracts from Dr. Leishman's *System of Midwifery*, Dr. Richardson, and Dr. Spender's essay on *Pain*, with an attempt on the part of the author to confute their statements. 'Not to the contraction of uterine muscle, but to the inordinate distension of the parts involved, and more especially to the resistance offered at the mouth of the womb and at the external orifice, may chiefly, if not entirely, be ascribed the ordinary pain of labour,' p. 28.

'This so-called physiological pain is a matter which by the simple regulation of temperature may be brought completely under control.' The extracts speak for themselves. Criticism is superfluous.

MISCELLANY.

A STATUE of Seutin, the well-known surgeon of the Saint-Pierre Hospital at Brussels, has been lately inaugurated. He is represented with a bistoury in his hand, as if about to perform an operation.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE last week held its annual meeting in Bristol, under the presidency of Sir John Hawkshaw. A number of papers were read in the Anatomical and Physiological Department of the Section of Biology, one of the most interesting being a report, by Dr. M'Kendrick of Edinburgh, and Professor Dewar of Cambridge, on the Physiological Action of Light. We intend to give a summary of this report in our next monthly number. The meeting in 1876 is to be held in Glasgow, and Sir Robert Christison has been nominated president-elect. Sir Robert is the President of the British Medical Association for the year 1875-76.

THE MEDICAL SCHOOLS.—The introductory lectures at the medical schools in Great Britain will be delivered this year as follows:—Charing Cross Hospital, Mr. Fairlie Clarke; St. George's Hospital, Dr. Barnes; Guy's Hospital, Dr. Stevenson; King's College, Dr. Curnow; London Hospital, Dr. Woodman; St. Mary's Hospital, Dr. Randall; Middlesex Hospital, Mr. Lowne; St. Thomas's Hospital, Dr. Payne; University College, Dr. Corfield; Westminster Hospital, Mr. Davy; Queen's College, Birmingham, Rev. W. H. Poulton (Warden); Leeds School of Medicine, Mr. Jessop; Owens College (Manchester Royal) School of Medicine, Mr. Lund; Liverpool Royal Infirmary School of Medicine, Dr. Dickinson; University of Durham College of Medicine, Newcastle-on-Tyne, Mr. H. E. Armstrong; Sheffield School of Medicine, Dr. J. Young; University of Edinburgh, Sir Alexander Grant, Principal; Edinburgh Extra Academic School of Medicine, Mr. Chiene; University of Glasgow, Dr. George Buchanan.

M. ALPHONSE DUBREUIL has been installed as Professor of Clinical Surgery in the Faculty of Medicine at Montpellier.

AN UNIVERSITY IN SIBERIA.—The *Union Médicale* announces that it is intended by the Russian Government to establish a university at Tornsk, in Siberia, principally with the object of educating medical men. It will comprise two faculties—medicine and law.

A NEW HOSPITAL IN PARIS.—A new hospital will be opened towards the end of the year in the north-east of Paris. It will be called the Ménilmontant Hospital, from the district in which it is situated. It will contain 150 beds, and is intended to meet the wants of a large and increasing poor population.

BOYLSTON MEDICAL PRIZE.—The Boylston Medical Committee, appointed by the President and Fellows of Harvard University, announce that the questions proposed for 1876 are the following:—1. Civil hospital construction (not of lunatic asylums); location, materials, arrangement, warming, ventilation, drainage, lighting; with designs. The author of a dissertation on this subject, considered worthy of a prize, will be entitled to a premium of three hundred dollars. 2. Do women require mental and bodily rest during menstruation, and to what extent? The author of a dissertation on this subject, considered worthy of a prize, will be entitled to a premium of two hundred dollars. Dissertations on the above subjects must be transmitted, post paid, to J. B. S. Jackson, M.D., Boston, on or before the first Wednesday in April, 1876. The following are the questions proposed for 1877. 1. Are epidemics, and so-called contagious diseases, necessarily dependent upon material agencies, acting through the stomach, or otherwise? 2. Athletic sports, training, violent exercise, etc., as now practised by young men; their temporary or permanent influence on the health. The author of a dissertation considered worthy of a prize, on either of the subjects proposed for 1877, will be entitled to a premium of two hundred and fifty dollars. Dissertations on these subjects must be transmitted as above, on or before the first Wednesday in April, 1877.

A CASE OF ABORTION.—In an article in the *Canada Lancet* for June 1, Dr. Andrews says: About twenty-five years ago a gentleman and lady called upon me to satisfy themselves whether or not she was pregnant. After due investigation, I gave a decision that she was. The lady was deeply moved, but quiet, though tears streamed down her cheeks; but I know of no word but agony that will express the emotion her husband laboured under. He called himself her murderer, entreated her pardon, and seemed beside himself. She strove to soothe and control him, and finally brought matters to the climax, by conjuring him, 'After I am gone, don't allow any woman (she was too kind to say stepmother) to ill-use my darlings—our darlings; promise, for my sake, Charles.' The scene was harrowing, and I gave way under it. I learned that she had already borne three children, then living, under circumstances of extreme peril, and that her medical attendant had assured them both, that if subjected to the same ordeal again, it was impossible she should survive. I saw and verified a letter from her former attendant, in which he urged that abortion was the sole means of averting otherwise inevitable death. The writer was a man of considerable wealth, of a social standing far above any that I have ever attained, and of great professional repute; but all these are not absolute proof of real ability. Great men are not always wise. I was not satisfied of the absolute necessity of the act, and yet I assumed the responsibility—undertook and effected abortion. '*Mea culpa!*' I was wrong, very wrong; responsibility cannot be delegated. Upon a subsequent occasion, when I came to know the lady better, I cheered her spirits, raised her hopes, and safely delivered her at term of a living child, with much less difficulty, danger or suffering than I have encountered in scores of cases.

HIS ROYAL HIGHNESS THE LATE PRINCE KARL OF BAVARIA has left a bequest of 20,000 gulden (about 2,000*l.*) to the Pension Society for the benefit of widows and orphans of Bavarian medical men.

NUMERICAL RATES OF DISEASES.—At the recent meeting of the British Medical Association in Edinburgh, Dr. Walter Dickson, Medical Inspector of Her Majesty's Customs, read, in the section of Public Medicine, a paper on the numerical rates of disease in the adult male community, deduced from the sanitary statistics of the *employés* at the Custom House from the years 1857 to 1874. He said that in these statistics would, he believed, be found a fairly correct estimate of the health-condition of the middle-class, middle-aged male population. The Custom House officers are, for the most part, resident in London, and occupied from eight to twelve hours in daily labour, attended, in most instances, with much fatigue and exposure to the weather. They form a permanent force, leaving it seldom except on promotion, death, or invaliding; and resemble in all essentials the majority of the well doing industrious section of the community. These officers are all under medical surveillance during their service of thirty or forty years, and the records of their sickness and results have been kept with as much fulness and accuracy as the nature of the subject will allow. Their age ranges from twenty-one to sixty-five; the mean age at present is thirty-eight. Although embracing a limited number, the records extend over so long a period that they may be considered as typical of a large force. The numerical ratios of twenty-eight years (which is equivalent to that for one year of 32,000 men), are mean daily number incapacitated, 27 per 1,000; admissions to sick-list in year, 70 per 1,000; mean duration of each case, 15.5 days; time lost per man annually, eleven days, exclusive of Sunday, 9.5 days; mortality from disease, 11.5 per 1,000, and from accident, 1.3 per 1,000; in all, the deaths are 12.8 per 1,000; superannuations or invalidings, 8 per 1,000; death and invaliding combined, 21 per 1,000; recoveries so as to resume duty, 979 per 1,000. Of the various classes of disease, the ratio of those of the respiratory organs amounts to 27 per cent. of all the cases, 20 per cent. of the time lost, 11 per cent. of deaths, and 18 per cent. of the superannuations; phthisis yields 1.4 per cent. of cases, 8 per cent. of the time lost, 31 per cent. of deaths, and 9 per cent. of superannuation; rheumatism and gout show 14 per cent. of sickness, only 0.4 per cent. of death, but 33 per cent. of superannuation; diseases of the heart exhibit 1 per cent. of cases, 2 per cent. of time lost, 13 per cent. of the deaths, and 1.5 per cent. of superannuations; diseases of the digestive organs give 17 per cent. of cases, 13 per cent. of time lost, 9 per cent. of deaths, and 7½ per cent. of superannuations; diseases of the nervous system amount to 7.5 per cent. of the cases, 9 per cent. of time lost, 9 per cent. of deaths, and 20 per cent. of superannuations, 10 per cent. being for insanity; skin and other surgical diseases give 11.5 per cent. of cases, 10 per cent. of time lost, but hardly any death or superannuation. Zymotic diseases occur in the small proportion of 6 per cent. of the whole amount of sickness, and 7 per cent. of the whole mortality; and no instance has occurred in many years of any officer having contracted such illness on board ship, a remarkable proof of the extreme healthiness of the Port of London in regard to its vast foreign traffic, and of the satisfactory health of the Customs' force. Phthisis and heart-disease are the most fatal diseases, causing one half of the whole mortality. The former claims 4 per 1,000 men as its annual victims, of the mean age of forty-one years. Heart-disease destroys 1.5 per 1,000, at the average age of forty-eight years. Accidental injuries constitute 10 per cent. of the cases, 11 per cent. of the time lost, and 9.5 per cent. of the mortality. Drowning causes 4.7 per cent.; fractures, etc., 3 per cent.; and suicide, 1.8 per cent. of the whole number of deaths. These deaths from violence amount in all to the rate of 1 per 1,000 of the force.

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

EDUCATIONAL INTELLIGENCE.

We give this month the regulations of some of the principal Continental Universities relating to Degrees of Medicine, together with lists of the professors and the subjects which they teach.

FACULTY OF MEDICINE OF PARIS.

The winter courses of the Faculty will be given in the following, commencing on November 3.

Medical Physics.—M. Gavarret : General Physics—Heat, Electricity, Light, Wednesdays, and Fridays, at noon. Biological Physics : Physical Phenomena of Hearing and of Phonation, Mondays, 5 P.M.

Medical Pathology.—M. Axenfeld, deputy, M. Duguet, *agrégé* : Diseases of the Genital Organs of Men and Women, Mondays, Wednesdays, and Fridays, 3 P.M.

Anatomy.—M. Sappey : the Principal Systems and Principal Organs of the Body, Mondays, Wednesdays, and Fridays, 4 P.M.

Pathology and General Therapeutics.—M. Chaufard : on Acute and Chronic Disease, General Study of the Symptomatology and Etiology of these two Orders of Disease, Mondays, Wednesdays, and Fridays, 5 P.M.

Chemistry.—M. Wurtz : Biological Chemistry, Chemical Study of the Blood, Chemical Phenomena of Respiration and Nutrition, Tuesdays, 4 P.M. ; Medical Chemistry, Thursdays and Saturdays, noon.

Surgical Pathology.—M. Dolbeau, General Surgical Pathology, Tuesdays, Thursdays, and Saturdays, 3 P.M.

Operations and Apparatus.—M. Léon le Fort : Therapeutics of the Affections of the Circulatory Apparatus, Special Operations (Diseases of the Eyes, Mouth, Thorax, Hernia, etc.), Tuesdays, Thursdays, and Saturdays, 4 P.M.

Histology.—M. Robin : Histology properly so-called ; Special Study of the Organic Tissues and Systems, Tuesdays, Thursdays, and Saturdays, 5 P.M.

History of Medicine and Surgery.—M. Lorain : Historical Studies on some Epidemic and Contagious Diseases, Variola, Syphilis, etc., Tuesdays, Thursdays, and Saturdays, 5 P.M.

Medical Clinic.—M. G. Sée, at the Charité. M. Béhier, at the Hôtel-Dieu. M. Lasègue, at La Pitié. Every day, from 8 to 10 A.M.

Surgical Clinic.—M. Richet, at the Hôtel-Dieu. M. Verneuil, at La Pitié. M. Broca, at the Hôpital des Cliniques of the Faculty. Every day, from 8 to 10 A.M.

Obstetric Clinic.—M. Depaul, at the Hôpital des Cliniques. Every day, from 8 to 10 A.M.

Diseases of Children.—M. Blachez, *agrégé*, at the

Children's Hospital, Mondays, Thursdays, and Saturdays, 8.30 A.M.

The work of dissection will commence at the École Pratique, on Monday, October 18. M. Sée, Superintendent of Anatomy, will open his course on November 3.

Division of Studies.—First year : Medical Chemistry, Medical Physics. Second year : Anatomy, Histology, Dissections. Third year : Anatomy, Histology, Dissections, Operations and Apparatus, Internal and External Pathology, Medical and Surgical Clinics. Fourth year : Internal and External Pathology, Practical Exercise in Operative Surgery, Medical and Surgical Clinics.

Students are informed : 1. That entries for practical study, and for examinations may be made from October 14, on Fridays and Saturdays, from 1 to 4 P.M. ; 2. That the register for inscriptions of the first trimester of the scholastic year 1875-1876 will be open from Wednesday, November 3 to Thursday November 25, on Mondays, Tuesdays, Wednesdays and Thursdays, from 1 to 4 P.M. Pupils who are about to commence their course of study will not be admitted to take their first inscription unless they present and leave at the Secretary's office on November 15 at the latest : (1) Their certificate of birth ; (2) A certificate of good conduct and morality ; (3) The diploma of Bachelor of Arts ; (4) If they are minors, the consent of their parents or guardians. Those who do not reside in Paris must be introduced by a person domiciled at Paris, who will be required to enter his name and address in a register opened for the purpose. Before taking their third inscription, students must show the diploma of Bachelor of Sciences (limited curriculum).

Aspirants for the title of *Officier de Santé* are dispensed from producing the diploma of Bachelor of Sciences or Arts ; but they must produce the 'Certificate of Grammar' obtained according to the provision of Article 6 of the *Decret* of December 23, 1854.

Foreign students desiring only to follow the Courses of the Faculty without seeking a diploma of the University are, with great liberality, admitted free to the Courses of the Faculty.

UNIVERSITY OF BERLIN.

The following are the conditions under which foreigners may attain the degree of Doctor of Medicine in this University.

The candidate must produce attested evidence that he has received a scientific education, and that he has studied medicine during four years. He is then examined in anatomy, physiology, chemistry, general and special pathology and therapeutics, surgery, *materia medica*, pathological anatomy, and midwifery. The examination is conducted in German or Latin. The fees for examination and graduation amount to 440 *reichsmark* (about 22*l.*) Before graduation the candidate must lay before the Faculty of Medicine a dissertation on a medical subject, which is printed at his own expense, and which, together with a series of medical theses, he has to defend against opponents chosen by himself. The dissertations are carried on in the German or the Latin language.

The courses to be delivered in the University during the winter session 1875-76 are.—Ordinary professors : Dr. Bardeleben, Wounds and Clinical Surgery ; Dr. du Bois-Reymond, Physical Anthropology and Physiology ; Dr. Frerichs, Medicine ; Dr. Hirsch, Medicine ;

Dr. Ivengken, Herniæ and General Surgery; Dr. von Langenbeck, Surgery; Dr. O. Liebreich, Chemistry of the Urine, and Materia Medica; Dr. Martin, Obstetrics and Gynæcology; Dr. Reichert, Histology and Anatomy; Dr. Schweigger, Diseases of the Eye; Dr. Traube, Clinical Medicine; Dr. Virchow, General Pathology and Therapeutics; Dr. Westphal, Diseases of the Nervous System. Extraordinary Professors: Dr. Albrecht, Dentistry; Dr. Fritsch, Human Parasites, and the Use of the Microscope; Dr. Gurlt, Fractures and Dislocations, and Operative Surgery; Dr. Hartmann, Anatomy of the Organs of Senses, Bones, and Ligaments; Dr. Hensch, Diseases of Children; Dr. Jacobson, Diseases of the Heart and Lungs; Dr. Lewin, Diseases of the Skin, and Syphilis; Dr. Liman, Forensic Medicine; Dr. Lucae, Diseases of the Ear; Dr. Meyer, the Art of Examining Patients, etc.; Dr. Munk, Physiology; Dr. Salkowski, Physiological Chemistry; Dr. Skrzeczka, Forensic Medicine; Dr. Waldenburg, Means of Physical Examination. There are also a number of *privatdocenten*, some of the best known of whom are Dr. Cohnstein (Gynæcology), Dr. Fasbender (Gynæcology); Dr. Senator (Diseases of Children, and General Semeiology and Diagnosis); Dr. Weber-Liel (Diseases of the Ear); Dr. Zuelzer (Medicine), etc.

UNIVERSITY OF ERLANGEN.

The following are the regulations to be observed by candidates for the degree of Doctor of Medicine in this University.

1. Candidates for the degree of Doctor must announce their intention to the Dean of the Faculty of Medicine, and present the following documents: *a.* Evidence of having gone through the curriculum in a German gymnasium, or proof of equivalent general education; *b.* Proof of having studied medicine in one of the German Universities or in a corresponding foreign medical school during at least three years; *c.* A Thesis, composed by the candidate, on some subject in medicine or natural science, with a written declaration, on word of honour, that the work is absolutely the candidate's own.

2. If the dissertation be judged by the Faculty to be of sufficient merit, the candidate is admitted to an oral examination, which is conducted in the German language. It may take place in two forms: *a.* As a colloquy, in the case of those who have passed an examination in medicine before a German examining board; *b.* As an extended examination on all departments of medical science, in the case of those who have not passed an examination before a German board.

3. After the conclusion of the oral examination, the examiners decide on the result. If the decision be favourable, the degree of Doctor is at once conferred, the fact being communicated to the candidate by the dean, and his diploma issued to him.

4. The candidate, if his dissertation be approved, must have it printed at his own expense. At the back of the title-page it must be stated that the dissertation is printed with the consent of the Faculty; and the name of the reporter (*referent*) must be given.

5. The candidate must pay a fee of 300 marks (100 thalers or 175 gulden, equal to about 15*l.* 10*s.*) for the granting of the Doctor's degree, and must also deliver 100 copies of his dissertations to the Faculty.

6. If the candidate fail to pass the examination, half of the fee is returned to him.

The Medical Faculty of this University consists of the following professors and teachers: Dr. Gerlach—Anatomy; Dr. Zenker—Pathology; Dr. Heineke—Surgery; Dr. Schröder—Midwifery; Dr. Rosenthal—Physiology; Dr. Leube—Medicine; Dr. Michel—Ophthalmology; Dr. Trott—Materia Medica and Hygiene; Dr. Wintrich—Diseases of Children; Dr. Hagen—Psychiatry; Dr. Filehne (*privatdocent*)—Materia Medica and Prescribing; Dr. Penzoldt (*privatdocent*)—Venereal Diseases and Diseases of the Larynx.

UNIVERSITY OF HEIDELBERG.

The following are the regulations to be observed for graduations in medicine in this University.

1. In applying for examinations for the degree of Doctor, no evidence of a previous course of study is required.

2. The same demands are made of all candidates; the only difference is that the oral examination is shortened if evidence be produced that the candidate has undergone, in the German empire, the *Staats-examen* for license to practise.

3. The subjects of examination are (1) Anatomy; (2) Physiology; (3) Pathological Anatomy; (4) Materia Medica (Pharmacognosics, Pharmacodynamics, and Toxicology); (5) Medicine; (6) Surgery; (7) Midwifery; (8) Ophthalmic Surgery.

4. A candidate may select one of these as the principal subject of his examination. All the other subjects then become secondary.

5. The examination is oral and written. The oral examination can only be conducted in the German language.

6. The written part of the examination consists of a medical dissertation in German or Latin, which must be given in before the oral examination. The dean of the Faculty of Medicine delivers the dissertation (or a scientific publication by the candidate, which may be substituted for it) to a reporter for his opinion. The reporter is authorised to hold a conversation with the candidate on the subject treated of in the work. In voting on the dissertation, the question is put whether it shall be allowed to be printed. If it be printed, the names of the dean for the time being, and of the reporter, must appear on the title page.

7. The oral examination comprises the principal subject chosen by the candidate, and a certain number of the secondary subjects. The number and selection of the secondary subjects varies, according as the state-examination has or has not been passed. If proof be given that a state-examination has been passed in the German empire, the candidate is examined in the principal subject, and in three of the secondary subjects, selected by himself. If there be no proof of a state-examination, he is examined in five secondary subjects. Of these, three are fixed—Anatomy, Physiology, and Pathological Anatomy; the other two may be chosen by the candidate. But if one of the three fixed subjects be chosen by the candidate as the principal subject, its place as a secondary subject is taken by another, selected by the candidate.

8. The duration of the oral examination depends on the number of subjects. The candidate is examined on the principal subject for thirty minutes, on each secondary one from fifteen to twenty minutes, according to the judgment of the examiners.

9. On the result of the entire examination, three notes are granted. The first (*summâ cum laudè*)

can only be granted when the dissertation has received the *imprimatur* of the Faculty. Even when the *imprimatur* has been received, the result of the oral examination may be such as to entitle the candidate to the second vote (*insigni cum laude*) or to the third (*cum laude*).

10. No oath is administered. When the diploma is delivered to the candidate by the dean, he has to give his hand in promise that he will bear his academical dignity with honour.

11. The cost of the examination, exclusive of that of the diploma, amounts in all to 444 marks (about 22*l.* 5*s.*), which must be paid before the commencement of the examination. Of this sum, if the oral examination be not passed, 179 marks (about 9*l.*) are returned.

12. The diploma contains a record of the principal subject, the vote on the whole examination, and the judgment on the dissertation.

The members of the Faculty of Medicine are; Dr. Lange—Midwifery; Dr. Delffs—Experimental Chemistry; Dr. Friedreich—Medicine; Dr. Gegenbaur—Anatomy; Dr. Simon—Surgery; Dr. Kühne—Experimental Physiology; Dr. Becker (Dean)—Ophthalmic Medicine; Dr. von Dusch—Diseases of Children; Dr. J. Arnold—Pathological Anatomy; Dr. Nuhn—Anatomy; Dr. Oppenheimer—Materia Medica; Dr. Moos—Diseases of the Ears; Dr. Knauff—Public Health; Dr. Erb—Electro-therapeutics and Diseases of the Nervous System; *Privat-docents*—Dr. Fehr, Dr. Lossen, Dr. Weil, Dr. Thoma, and Dr. Fischer.

The winter session commences on October 15.

UNIVERSITY OF STRASSBURG.

The following are extracts from the regulations of this University, relating to degrees in Medicine.

3. Any one desirous of obtaining the degree of Doctor of Medicine in this University can only be admitted to graduation if he fulfil the following conditions.

a. If belonging to the German empire, he must have passed through an academical four years' course as a student of medicine or of natural science. By an unanimous decision of the Faculty, one or two sessions may be remitted. Foreigners desirous of graduation are not required to pass through the four years' course in Germany, if proof be produced that they have received instruction equivalent to that given in the German medical faculties.

b. He must present a scientific dissertation, composed by himself.

c. He must undergo an examination by the Faculty.

d. He must pay the prescribed fee of 100 thalers (about 15*l.* 15*s.*)

4. In announcing to the dean his desire to graduate, the candidate must first produce the evidence referred to in *3a*, and forward a scientific memoir on some department of medicine, with a written assurance that it is absolutely his own work.

5. If the dissertation receive the approval of the Faculty, the candidate is admitted to examination.

6. This examination is conducted by the ordinary professors, and consists, as a rule, of an oral theoretical examination in all the important departments of medicine. If the candidate do not pass the oral examination, he must, in order to obtain the degree of doctor, again undergo the examination after a period of time to be determined by the Faculty; but he is not required to present a second thesis.

7. In the case of candidates who have already

passed a state examination in medicine, the oral examination may, by the unanimous consent of the Faculty, be replaced by a colloquy before three members of the Faculty.

8. Graduation does not take place in the absence of the candidate.

9. The fee of 100 thalers is to be paid to the Dean when the candidate announces his desire to graduate. If the dissertation be rejected, the whole fee is returned. If it be approved, but the candidate fail to pass the oral examination, the fee is not returned, but when the candidate is readmitted to examination, he has to pay only half the fee.

11. After the oral examination has been passed and the dissertation printed and published, a printed diploma is issued to the candidate. The names are announced on the black board.

12. The printing of the dissertations and also of the diploma is done at the candidate's expense.

14. There is no public ceremony, nor is any oath administered.

The Medical Faculty consists of: Dr. Waldeyer—Anatomy; Dr. Jössel—Anatomy; Dr. Goltz—Physiology; Dr. Hoppe-Seyler—Chemistry; Dr. Schmiedeberg—Materia Medica; Dr. von Recklinghausen—Pathology; Dr. Strohl—Forensic Medicine; Dr. Leyden (and Dr. Kohts, *privatdocent*)—Medicine; Dr. Lücke—Surgery; Dr. Gusserow—Midwifery; Dr. Aubenas—Accouchements; Dr. Wiegner, Skin Diseases, Syphilis, etc.; Dr. Jolly—Psychiatry; Dr. Laqueur—Ophthalmic Medicine; Dr. Kuhn (*privatdocent*) Diseases of the Ear; Dr. Zweifel, Operative Midwifery and Diseases of New-born Infants; Dr. Friedländer (*privatdocent*), Diseases of the Respiratory Organs, etc.

The lectures for the winter session 1875-76 begin on Monday, October 18, and the session ends on March 18, 1876. Matriculation takes place on the first four Wednesdays of the session, from twelve to one o'clock. After these four weeks, the rector can allow matriculation only on special grounds. Any one desirous of matriculating as a student and attending the lectures and other instruction given in the University, must on his arrival in Strassburg, communicate with the secretary of the University, for the purpose of being entered. Other persons desirous of attending any of the courses of lectures, must obtain permission from the respective teachers, and also communicate with the secretary of the University.

UNIVERSITY OF ZÜRICH.

The following are the regulations for the degree of Doctor of Medicine.

1. In order to obtain the degree of Doctor of Medicine, the candidate must send to the dean a written memorial, accompanied by (*a*) evidence of attendance on lectures on Physics, Chemistry, Botany, Zoology, and Medical Subjects; (*b*) a dissertation on some subject in medical science, which, after approval, the candidate must have printed at his own expense.

2. The dissertation is delivered by the dean for examination to the teacher of the subject of which it treats, or to the member of the Faculty at whose suggestion it has been composed. A recommendatory opinion of the first examiner decides its acceptance; in this case, his name appears on the title when it is printed. If the first opinion be doubtful or unfavourable, the thesis must be circulated among

all the members of the Faculty, and is only accepted if two-thirds of them give their written votes in its favour.

3. When the dissertation is approved, the candidate is admitted to examination for the degree. The first part is written, and the candidate has to answer, in a closed room, two questions drawn by lot, one on Anatomy and Physiology, the other on Pathology and Therapeutics, Surgery, or Midwifery. The answers are circulated among the members of the Faculty, who, after examining them, express in writing their determination (by a simple majority) whether the candidate shall be admitted to the second (oral) examination. The oral examination comprises the above-named subjects, and also General Anatomy, Pathological Anatomy, *Materia Medica*, and Ophthalmic Medicine. The vote of two-thirds of the members of the Faculty present is necessary for the passing of a candidate.

4. After the examination has been passed and two hundred printed copies of the dissertation have been delivered, the graduation takes place under the presidency of one of the ordinary professors of the Faculty. The ceremony consists of the following acts: *a.* Reading the candidate's *curriculum vitæ*; *b.* A contribution by the candidate on some subject in medicine or natural science; *c.* A disputation on theses on subjects in medicine or natural science, which theses the candidate has printed after their approval by the dean, and which are distributed among those present; *d.* Creation of the candidate as Doctor of Medicine, Surgery, and Midwifery.

5. To the graduate is delivered, in duplicate, an official diploma.

6. The fee consists of 350 francs (14*l.*) and 15 francs to the bedell; it is paid before the oral examination (if this be remitted, before graduation). There is no additional fee if it be necessary to repeat the examination. The fee is not returned if the candidate be definitely rejected. The sum of 100 francs is remitted to candidates who already possess a recognised diploma; and in such cases the Faculty may, by a majority of two-thirds, agree to omit the oral examination. The fees are distributed in the following manner: 300 francs (or 200 if part be remitted) to the members of the Faculty in office at the time of the examination (an ordinary professor receiving three times as much as an extraordinary), 15 francs to the Dean for sealing the diploma; 15 francs to the Faculty chest; and 20 francs to the cantonal library.

7. The Faculty has the power of granting the diploma of doctor *honoris causâ*, for distinguished service to medicine.

The members of the Medical Faculty are; Dr. H. Frey—Histology and Zoology; Dr. H. Meyer—Anatomy; Dr. E. Rose—Surgery; Dr. L. Hermann (Dean)—Physiology; Dr. J. Eberth—Pathology; Dr. F. Frankenhäuser—Midwifery; Dr. G. Huguenin—Medicine; Dr. A. Cloetta—*Materia Medica* and Forensic Medicine; Dr. F. Horner—Ophthalmic Surgery; Dr. E. Hitzig—Psychiatry and Diseases of the Nervous System; Dr. O. Wyss—Diseases of Children; Dr. H. Spöndly—Operative Midwifery; Dr. J. Billeter (*privatdocent*)—Dental Surgery; Dr. F. Goll (*privatdocent*)—Hygiene and the Art of Prescribing; Dr. R. Meyer (*privatdocent*); Dr. G. Brunner (*privatdocent*); Dr. J. Seitz (*privatdocent*).

The session begins on October 18, and ends March 18, 1876.

UNIVERSITY OF VIENNA.

Candidates for the degree of Doctor of Medicine must undergo three examinations. Before being admitted, the candidate must produce his certificate of birth or baptism, and evidence (*a.*) of having received a sufficient preliminary education in one of the institutions of the countries comprised in the empire, or, if he do not belong to any of these, evidence of having matriculated as an ordinary student in a faculty of medicine; (*b.*) of having attended lectures in a medical school during at least four sessions, and of having dissected during two sessions; (*c.*) of having passed, at one of the universities of the empire, three examinations, in botany, zoology, and mineralogy. Before being admitted to the second examination, he must produce evidence of having been engaged five years in professional study, and of having studied clinical medicine and clinical surgery, each during four sessions, and clinical ophthalmology and clinical midwifery, each during at least one session; and of having passed the first examination.

The first examination embraces physics, chemistry, anatomy, and physiology. There is a practical examination on anatomy and physiology, and a theoretical examination on all four subjects.

The second examination includes general pathology and therapeutics, pathological anatomy (histology) pharmacology (pharmacodynamics, toxicology, and prescribing), and the pathology and therapeutics of internal diseases. The candidate is examined practically in pathological anatomy (in preparation and on the dead body), and in medicine (at the bedside); and theoretically in all the subjects.

The third examination embraces surgery, ophthalmic surgery, midwifery and diseases of women, and forensic medicine. The examinations in surgery, ophthalmic surgery, and midwifery are practical; and there are theoretical examinations in all the subjects.

All the examinations are public. The fee for the first examination is 55 florins, for the second 60 florins, for the third 65 florins.

In the University of Vienna, instruction is given as follows by the professors: Human Anatomy, Drs. Voigt and Langer; Histology, Dr. Wedl; Pathological Anatomy, Dr. Heschl; Anatomy of the Nervous System, Dr. Meynert; Surgical Anatomy, Dr. von Patruban; Special Pathological Anatomy, Dr. Klob; Physiology, Dr. von Brücke; General Pathology, Dr. Stricker; Electro-Therapeutics, Dr. Benedikt; Hydro-Therapeutics, Dr. Winternitz; *Materia Medica* and Therapeutics, Dr. Vogt and Dr. von Schrott; Medicine, Drs. Duchek, Von Bamberger, and Löbel; Physical Diagnosis, Drs. Stern and Schwanda; Laryngoscopy, etc., Dr. Stöck; Surgery, Baron von Dumreicher, Drs. Billroth, Cessner, Dittel, Weinlechner, Böhm, Salzer, and Mosetig von Moorhof; Diseases of the Ear, Drs. Gruber and Politzer; Ophthalmic Surgery, Drs. von Arlt, Stellwag von Carion, Jäger; Obstetrics, Dr. Braun-Fernwald, Dr. Späth, and Dr. G. Braun; Diseases of Women, Dr. Böhm; Diseases of Children, Dr. Widerhofer and Dr. Weinlechner; Diseases of the Skin, Drs. Hebra and Kaposi; Syphilis, Dr. Sigmund von Ilanor; Diseases of the Skin and Syphilis, Drs. Neumann and Auspitz; Psychology, Drs. Meynert, Schlager, and Leidesdorf; Hygiene, Dr. Nowak; Physiological and Pathological Chemistry, Dr. Ludwig. There are also numerous teachers in the several departments.

LEADERS.

THE PHYSIOLOGICAL ACTION OF LIGHT.

BY JAMES DEWAR, M.A., F.R.S.E., JACKSONIAN PROFESSOR OF CHEMISTRY IN THE UNIVERSITY OF CAMBRIDGE, AND JOHN G. MCKENDRICK, F.R.S.E., F.R.C.P.E., LECTURER ON THE INSTITUTES OF MEDICINE, EDINBURGH.

The proceedings in the department of Anatomy and Physiology at the Meeting of the British Association for the Advancement of Science, at Bristol, on August 26, commenced by Dr. McKendrick presenting the report of the committee appointed at the meeting at Bradford in 1873 to investigate 'The Physiological Action of Light.' The members of the committee were Professor Balfour, F.R.S. (Edinburgh), Professor Dewar (Cambridge), and Dr. McKendrick, the latter being the reporter to the committee.

At the late meeting of the British Medical Association in Edinburgh, the chief facts mentioned in the following paper were demonstrated to the members.

Introductory.—Dr. McKendrick, in presenting the report, spoke as follows.

Before I enter into details regarding this report, I may make one or two observations of a preliminary character, so as, first, to show what led to the investigation, and, second, to indicate the method of research. About three years ago, Professor Dewar and I began an investigation into the physiological action of light. Some of the preliminary results were stated to this section of the British Association at the meeting at Bradford in 1873; and the Association appointed a committee and gave us a grant of money to carry on the investigation. We have been working at intervals upon this subject during the past two years, and I have now the honour of laying before you the results arrived at. The considerations which led us to undertake this investigation were partly theoretical, and partly suggested by a remarkable experiment made many years ago by Sir William Grove, now Lord Justice Grove. The

Diagram showing arrangement of apparatus and direction of current in the experiment on frog's eye. A. The eye, having one electrode, B, in contact with the cornea and another, C, touching the transverse section of the optic nerve. D. Key. G. Galvanometer. The arrows indicate the direction of the current.

theoretical considerations were, first of all, that in accordance with the principles of the law of the conservation of energy, one would expect that light would produce a specific physical effect when it acts upon the retina. Light being a mode of energy, when it impinges on the retina, must become transferred into some other kind of energy, which might be expressed and measured in some form or other. It might produce, for example, a chemical change in the structure; it might be transformed into heat; it might cause a disturbance in the electrical condition of the apparatus; or, possibly it might, as supposed by Sir Isaac Newton, be resolved into some kind of mechanical action. Various theories as to the action of light on the retina have been advanced, but these have hitherto been unsupported by experimental facts. The object of our investigation was to find out what the specific action of light was. These were the theoretical considerations. We then directed our attention to the remarkable experiment of Lord Justice Grove, made in 1838 or 1840, when he was working out the illustrations of the principle of the conservation of energy with which his name is so honourably associated. His experiment may be best described in his own words.

'A prepared daguerreotype plate is enclosed in a box filled with water, having a glass front, with a shutter over it. Between this glass and the plate is a gridiron of silver wire; the plate is connected with one extremity of a galvanometer coil, and the gridiron of wire with one extremity of a Breguet's helix—an elegant instrument, formed by a coil of two metals, the unequal expansion of which indicates slight changes in temperature; the other extremities of the galvanometer and helix are connected by a wire, and the needles brought to zero. As soon as a beam of either daylight or the oxy-hydrogen light is, by raising the shutter, permitted to impinge on the plate, the needles are deflected. Thus, light being the indicating force, we get chemical action on the plate, electricity circulating through the wires, magnetism in the coil, heat in the helix, and motion in the needles.'

A little consideration showed that in the case of the living eye, light might possibly have an action of this kind. We obtained a galvanometer, and proceeded to investigate the subject. I need not go

* Grove, 'The Correlation of the Physical Forces,' 5th ed. p. 153.

into particulars regarding the earlier experiments, which are recorded in the *Transactions of the Royal Society of Edinburgh* for 1873, but I will shortly give an idea of the general mode of carrying on the investigation, so that you may be able to follow some of the points to be presently alluded to.

Mode of Research.—We use an apparatus in these experiments, which has been long employed by physiologists for the detection of electrical currents in living animal or vegetable structures. This apparatus consists of two little troughs, made of zinc, mounted on vulcanite plates, and carefully amalgamated. Into these troughs we pour a saturated solution of pure sulphate of zinc. Into each is plunged a small pad or cushion of filter-paper, and upon each pad is placed a little bit of moist clay, to protect animal structures from the irritant action of the solution of sulphate of zinc. These two troughs are called the electrodes, and may be regarded simply as an arrangement for collecting and conducting off electrical currents from the structures under examination. Wires are conducted from the electrodes to the galvanometer (an instrument for detecting the presence of electrical currents and of measuring their strength), and a key is interposed between the electrodes and the galvanometer, for the purpose of cutting off any electrical current at pleasure. The apparatus is now ready for the experimental experiment is as follows. Remove an eye from the head of a decapitated frog as rapidly as possible, carefully clean it from all particles of muscular and areolar tissues, and place it upon the electrodes, so that one clay point is in contact with the cornea and the other with the transverse section of the optic nerve.

The moment we open the key, the needle of the galvanometer swings round, indicating the presence of an electric current. The needle in a short time will come to rest, and the amount of deflection will indicate the natural electric current passing from the cornea to the transverse section of the nerve. It can be easily shown that the surface of the cornea is positive to the transverse section of the nerve, in most instances. The detection of an electrical current from an eye, the tissues of which still retain life, of course is what anyone would expect who is acquainted with electro-physiology; because we know that nerve and muscle, and almost every variety of living animal tissue, manifests the presence of an electrical current when examined by this method. But the question remains, is this electrical current in any way affected by the action of light? To answer this question, suppose we keep the eye in the dark, the natural electrical current will keep the needle of the galvanometer in a certain position. If we now allow light to pass into the eye—light from any source—there is a movement of the galvanometer needle indicating a change in the electrical condition of the eye produced by the action of light. This experiment shows that light causes a change in the electrical state of the living eye.

That is the fundamental experiment which led to the further prosecution of this investigation. To make clear what follows, I must ask you to imagine the kind of galvanometer employed. It is the one known as 'Sir William Thomson's galvanometer,' an instrument of very delicate construction. A large number of coils of wire surround the needle; the needle is small, and the coil of wire is brought into close proximity to it, so that the current passing

round the coil is in the position where it will produce the greatest possible effect upon the needle. To render the instrument still more sensitive, a small and light mirror, about the size of a threepenny

piece, is attached to one of the needles. We then place a lamp in front of this instrument, so that rays of light from the lamp are reflected by the mirror upon a screen placed a short distance in front. The angle formed by the reflected rays being twice the angle through which the mirror and magnet are deflected, a very small angular movement of the mirror produces a great displacement of the images on the scale. The movement of the spot of light on the screen indicates a corresponding movement of the needle. We thus get extreme delicacy, and there can be no doubt that the results are due in great measure to using this sensitive instrument. It is difficult to imagine that physiologists, such as Du Bois-Reymond, Valentin, and others would have failed in detecting the action of light on the eye (which we now know they looked for) had they employed such an instrument.

Diagram indicating graphically the action of light on the frog's eye. The divisions of top and bottom indicate divisions of galvanometer scale.

To show the experiment successfully, it is well to cover the electrodes (bearing the eye in the position before mentioned) with a blackened box, having a draw-shutter on one side, by which light may be admitted or shut out at pleasure. The action of light on its impact or removal may be better understood with the aid of the above diagram (Fig. 2). Suppose the scale of the galvanometer to be a sheet of paper drawn vertically upwards, the spot of light reflected on it from the galvanometer mirror would describe the curve A H. Let the dotted line represent the position of the galvanometer acted on by the natural electrical current of the eye in the dark. The length of the line would represent a certain interval of time, say forty seconds, and the deviations of the curved line would indicate, when to the right, an increase, and when to the left a diminution of the normal current. The action is as follows: On opening the shutter at A, and admitting light to the

eye, the spot of light swerves to the right, indicating an increase in the electrical current. After reaching a maximum at B, it then slowly falls during the continued action of light, passes across the neutral point C, and reaches a position D, where the electrical current is less than what it was in the dark. On closing the shutter, so as to shut off the light at D, there is a rebound as it were. The current increases until it reaches a point, F, when it again slowly falls, and at the close of the experiment reaches G, or it may slowly rise to near the original point H. There is, therefore, first an increase in the electrical current, and this may continue for some time, or it may slowly fall as above described; then, on removing the light by closing the shutter, the galvanometer needle gives another swing, and there is again a second rise.

Comparative Physiology of the Action of Light.—At the meeting in Bradford, we were able to state that the impact of light upon the eyes of members of the following groups of animals, viz., mammalia, birds, reptiles, amphibia, fishes, and crustaceans, produced a variation amounting to from three to ten per cent. of the normal current. At that time we

found that light caused a negative variation in the case of warm-blooded animals.

Transmission of Action to Brain.—This electrical variation may be traced into the brain. Instead of severing the eye from the brain and cutting the optic nerve, simply remove the head of the frog. Then, supposing we put one of the electrodes in contact with the surface of the brain and the other in contact with the surface of the cornea, an effect is obtained from the action of light similar to that just described.

Action due to Change in Retina.—We may then proceed to prove that this action is really due to an alteration in the retina itself. This of course is necessary, because it was a legitimate criticism that the change produced by the action of light may be due to contraction of the iris; the iris being a muscular structure contracting on the action of light by a well-known reflex mechanism in normal circumstances, and even after removal of the eye from the head. A contraction of the iris might produce a negative variation or diminution of the electrical current, but it is difficult to imagine that it could cause an increase or positive variation. In order,

Diagram of eye showing direction of current when cornea + or -. A. Eye. B. Corneal surface. C. Optic nerve. This might represent surface of brain or surface of the body. D. Key. G. Galvanometer. The outer arrows show the direction of the current when the cornea is positive, and the inner when it is negative. The transverse section of the optic nerve is always negative to the corneal surface, but the surface of the brain or body may be positive to it.

however, to get rid of this difficulty, we cut off the front part of the eye altogether, and then, on placing one electrode so as to touch the surface of the vitreous humour while the other impinges on the transverse section of the optic nerve, a current is obtained—no doubt weaker, but still a current sufficiently strong for detecting any variation which light may produce. In these circumstances, light still produces the variation I have described. To make it more definite still, we pick out the retina with a fine glass point, and leave only the sclerotic and perhaps fragments of the choroid. Even then an electrical current is obtained; but this current is not affected by light. It is, therefore, proved that the variation produced by the action of light is due to some change or other occurring in the retina when light impinges upon it.

Rays of the Spectrum.—We next proceeded to work out this interesting point: Which rays of the spectrum produce the greatest effect? We know, of course, that the rays which are the most luminous to our consciousness are the yellow rays. By throwing a beam of light from a limelight through a hole in a shutter, and placing a prism in front of it, we were able to obtain the various colours of the spec-

trum. The eye was then brought into the various rays successively, and the result noted. To obtain comparative results, the operations were repeated as quickly as possible. It was found, on studying the results, that those rays which we regard as the most luminous produce the greatest variation. For instance, the low red rays at the end of the spectrum produce very little effect indeed, and if you go below the red into the heat rays there is no effect at all. But if you then go up the spectrum, the effect increases till you come to the yellow. There is the maximum, and if you go on to the violet the effect gradually becomes less and less until beyond the violet, when again there is no effect at all.

The investigation reached this point when the communication was given to the meeting at Bradford in 1873. The results were obtained by the use of a sensitive galvanometer, lent us by Professor Tait. But since that time, and mainly by the aid of the grant of the Association, we have employed a still more sensitive instrument. This instrument was made by Messrs. Elliot Brothers, of London; and it is probably as sensitive as we could desire. Those interested in the matter will appreciate at once the sensibility of this galvanometer, when we

state that at a distance of sixteen feet a variation of fifty divisions of our scale on the action of light may be obtained—a considerable variation, quite capable of being seen with great distinctness.

I now come to point out more specifically what we have been doing during the last two years. In the first place, after obtaining the new instrument, we repeated all the experiments detailed in the earlier communications, and found the same results.

Explanation of Variation in Current.—The first matter we have to bring under your notice is one which particularly attracted the attention of physiologists, and especially of those who first saw the experiments: viz., that sometimes, in the case of the eye of the frog, light produced an increase in the electrical current, and in other cases a diminution. This we could not at first account for. But we have been able to make out that the positive and negative variation, or the increase or diminution of the natural current on the action of light, depends upon the direction of the primary current. If the cornea be positive and the transverse section of the nerve be negative, then light produces an *increase* of the electrical current. If, on the other hand, the cornea be negative and the transverse section of nerve positive, light will then produce a *diminution* in the electrical current. It is thus conclusively shown that the current superadded, or if we may use the language, induced by the action of light, is always in the same direction; only in the one case it is added to, and in the other subtracted from, the primary current.

New Method of Experimenting.—One of the chief difficulties in arriving at the exact relations between the electrical variations and the different luminous and colour intensity of light, was the continually diminishing sensibility to the stimulus, owing to the abnormal conditions of the eye when removed from the head. You can easily understand how this occurs. When you begin the experiment, the eye is remarkably sensitive to light, and a large variation of current is obtained; but the amount of this current is gradually falling in consequence of the gradual change in the parts of the eye, owing to their loss of vitality and sensibility. In fact, the parts are dying—the blood is not circulating, and molecular and chemical changes are slowly occurring. In the case of the frog's eyes, however, it is a fact that the retina retains its sensibility from three to four hours, and sometimes longer. After a lapse of two hours or so, the frog's eye frequently remains in a tolerably stable condition, in which it does not lose rapidly. This condition may last for four or five hours. In order to get rid of the difficulty of gradual death of the parts, we tried various methods. In our earlier experiments, we attempted to get the eye removed as quickly as possible, and to make the observations rapidly. In the case of the warm-blooded animals, this did not lead to very good results, because the sensibility to light disappeared in a very few minutes. We also on several occasions exposed the posterior aspect of the eye in the living anaesthetised warm-blooded animal, and succeeded in bringing one electrode into contact with the severed optic nerve while the other touched the cornea. This method was troublesome and difficult.

We, however, did succeed in obtaining definite results. These experiments are now made in quite a different way. By placing a frog, rabbit, or pigeon, under the influence of *woorara*, the animal remains motionless. We then remove a small por-

tion of the surface of the cranium, so as to expose a portion of the brain. One of the electrodes is brought into contact with the surface of the cornea, and the other with the surface of the brain. The blood is still circulating. A current is obtained; and all the effects I have just mentioned may be observed with ease. The animal remains in this condition, retaining its sensibility to the action of light, for as long a period, in the case of the frog, as forty-eight hours. These observations led to the discovery made recently, that there is no necessity for even exposing the surface of the brain. That is to say, the action of light can be traced, if needful, through the whole body. If, for example, we take a frog, give it *woorara*, place it in a prone position, slightly abrade the skin on the surface of the head or back, or any

Diagram showing arrangement of apparatus in the experiment on eye of frog. A. Eye showing the electrode, E, in contact with it. B. Skin removed and subcutaneous tissue in contact with other electrode, E. K. Key. G. Galvanometer. Arrows indicate direction of current. Cornea, positive. Back, negative.

part of the body, then adjust the electrodes, one in front of the cornea and the other upon the abraded skin, we obtain an electrical current which is affected by light in the usual way. But if the electrode in contact with the cornea be shifted to some other part of the body, a current may be obtained; but this current is not sensitive to light. In order to produce the specific action of light upon the eye, the retina must be included in the circuit. This discovery enabled us to perform many experiments without injuring the animal, except to the extent of abrading or removing a small portion of skin. It at once opened up the way for making observations upon warm-blooded animals (one of the chief difficulties in our earlier investigations). For example: give a rabbit or a guinea-pig a small dose of *woorara*, and the animal remains prostrate and quiet. Then cut off a little of the hair from the surface of the head at the back of the neck, and abrade the skin so as to have a moist surface; bring the electrodes into position, placing one in contact with the abraded surface and the other in contact with the surface of the cornea, and you will at once obtain the effect.

Advantage of Chinoline over Woorara in Physiological Work.—In working with woorara, we found a difficulty arising from its interference with respiration. In these experiments with woorara, it may be necessary to maintain artificial respiration. This is a great disadvantage, because it is difficult to secure the head so firmly as to be rigid, a necessary precaution, as only a slight oscillation of the head even by the respiratory movements would cause the needle of the galvanometer to swing about and thus interfere with the investigation. We then made use of hydrochlorate of chinoline (C_9H_7N, HCl), a substance obtained by the action of caustic potash on quinine, the physiological effects of which we were then investigating. This substance has the power of producing effects somewhat similar to those of woorara, with this exception, that after a moderate dose respiration is not sensibly affected. (See *Proceedings of the Royal Society*, no. 159, 1875, p. 290.)

The Use of equal and opposite Currents.—We have performed many experiments in which equal and opposite currents were transmitted through the galvanometer at the same time, and observed the effect of light in these circumstances. By the use of resistance coils, it was not difficult to balance the current from the eye; but, owing to the inconstancy of even a Daniell's cell in such experiments as these, it was impossible to avoid fluctuations which might possibly have been mistaken for those due to the action of light. This difficulty was got over by what we term the double eye experiment, in which two similar eyes are placed in reversed positions on the electrodes, so that the current from the one neutralises that of the other. When this is accomplished, it is easy by means of a blackened box, having a shutter at each side, to allow light to fall on either the one eye or the other, and it is then shown that the galvanometer needle moves either to the right or left according to the eye affected.

Action of Light in Warm-blooded same as in Cold-blooded Animals.—By the use of chinoline we were able to make experiments of the kind just described for a considerable time, without the necessity of maintaining artificial respiration. The result of those investigations upon warm-blooded animals has been to show that in these, as in the cold-blooded, light produces first an *increase* in the electric current on impact; continued light usually causes the electrical current to diminish; and on the removal of light, there is a second rise, as described in the case of the frog. In our earlier investigations, we always observed in the case of warm-blooded animals (when the eye had either been quite removed from the body or was receiving an inadequate supply of blood), that the action of light caused a negative variation, that is, a *diminution* in the electrical current. By improved methods, however, which have the effect of placing the eye in conditions more normal, we find that light causes a *positive* variation, that is, an increase; thus agreeing with what had hitherto been observed in the eye of the frog. This is a point worthy of notice. Du Bois-Reymond showed, even in the case of sensory nerves, that physiological action caused a *negative* variation. But it appears that in the case of the retina the action of the normal stimulus is to cause a positive not a negative variation.

Experiment with the Living Lobster.—The action of light can be readily shown in this animal. Fix it loosely in a cloth, and lay it on the table in a slightly oblique position. With a small trephine remove a circular portion of the carapace, about three milli-

mètres in diameter, and expose the moist tegumentary surface. Bring one electrode into contact with this surface, while the other touches the cornea. The usual effects of light may then be noted; but in the case of the lobster, the variation caused by the impact is greater than what we have noticed in any other animal, often amounting to one-tenth of the total amount of current. Another interesting experiment, comparable with that of the two eyes I have just described, may be made on the lobster by placing an electrode in contact with each cornea. The result frequently is apparently no current, but in reality the currents neutralise each other.

Diagram showing arrangement of apparatus in experiment on living lobster. A. Corneal surface, having electrode, E, in contact with it. B. Portion of carapace removed so as to expose moist surface for electrode, E. K. Key. G. Galvanometer. Arrows indicate direction of current.

Light falling on the one eye causes the needle to move, say to the left, while if it fall on the other eye, the needle swerves to the right.

Mode of Experiment on Eye of Fish.—Recently we were enabled to perform an experiment upon the eye of a fish in a very simple way, by a method adopted in Professor Stricker's laboratory in Vienna some months ago for another purpose. Take a fish and give it a very small dose of woorara. It soon becomes almost motionless, and sinks to the bottom of the vessel in some cases. The animal would soon die in consequence of paralysis of the movement of the gills necessary for respiration. But, if we take the animal out of the water, put it upon a glass plate, introduce a little bit of cork under each gill, and then by means of an India-rubber tube placed in the mouth allow a little water to flow over the gills, the fish will live out of water in that condition for many hours. By this method we were able to perform the experiment upon the eye of a fish with the same results.

Action of Polarised Light and Colours of Spectrum.—The next point investigated recently is the action of polarised light and the various complementary colours. We arrived at the results of our earlier experiments with the colour-spectrum in various ways, such as by passing light through solutions having various absorptive powers, by the direct coloured rays of the spectrum, etc., but always with the same conclusion—namely, that the most luminous rays produce the greatest effect. For studying the action of polarised light, we have recently used the simple contrivance of a black box, having a hole on

one side of it, placed over the eye. Opposite the hole we placed two cylindrical tubes of brass, each carrying a Nicol's prism, and between the two prisms a thin plate of quartz is introduced, thus producing the various colours of polarised light on rotating one of the prisms. The general results were exactly the same as when we used the colours of the spectrum. In all cases, the impact of the yellow rays produced the greatest effect. It has also been ascertained by this method that the effect of the *impact* of light is much more regular than the effect of its removal.

Determination of Electro-motive Force.—Very soon after the first experiments were announced, certain German physiologists said, that although we had obtained the results of the action of light which I have just described as indicated by the galvanometer, we had no right to say that there was a change in the electro-motive force as stated in the earlier communications. The galvanometer is, of

course, for the purpose of measuring the *strength* of a current by its magnetic effects; it really does not measure what is known as electro-motive force. But what is meant by electro-motive force? Take a Daniell's cell; connect the copper with an insulated conductor A, and the zinc with another conductor B of the same metal as A; by means of a delicate electrometer it may be shown that the potential of A is greater than that of B. If A and B be connected by a wire, a current will pass from A to B. The difference of potentials is called the electro-motive force. In the same manner, if we had a sufficiently delicate electrometer, it might possibly be shown that the potential of the corneal surface of the eyeball is greater than that of the transverse section of the optic nerve, or of some portion of the brain, and that, when these two surfaces are connected by an insulated conductor, a current will flow from the cornea to the transverse section of the nerve.

This difference between the potentials of the two

Diagram showing arrangement of apparatus in the method of determining the electro-motive force. Modified slightly from a diagram of Professor Clerk Maxwell. The arrow on the right of D should be reversed.

surfaces is the electro-motive force, or, in other words, it is the difference in condition by which positive electricity does work in moving from the one surface to the other. Now the electro-motive force acting between the extremities is the product of the strength of the current and the resistance of the conductor. The resistance is, however, independent of the strength of the current, and depends on the molecular constitution of the conductor. The strength of the current obtained from the eye, as measured by the galvanometer, might vary on the action of light; or light might produce an alteration in the resistance of the structures. It became necessary, therefore, to measure the electro-motive force of the eye, to ascertain whether or not it varied in amount on the action of light, and thus we get rid of the difficulties as regards variations in resistance or variations in amount of current. At first, in attempting this, we used Sir William Thomson's electrometer; but found that the amount of electric discharge or electric potential to be measured was too small to enable us to get good results. We could do nothing with it in this case; so that we had to adopt another method of

determining the electro-motive force. This was the method introduced by Mr. Latimer Clarke, the eminent electrician. It is called Mr. Latimer Clarke's method of measuring two electro-motive forces by a comparison of resistances (see Fig. 6). Supposing we take a Daniell's cell, D, which is known to have a very constant electro-motive force, retaining the same amount for a considerable time. This cell has wires coming from it which are brought into connection with a platinum wire about sixteen or eighteen inches long, coiled round a piece of vulcanite, A¹ B¹ (called the potentiometer). Alongside of the wire there is a scale of say 100 or 150 divisions. The current then will, of course, travel along the platinum wire which represents a certain amount of resistance thrown in the direction of the current. Then place on the other side of this a battery consisting of say four Bunsen cells, H, connected together, and, having an electro-motive force much greater than that of a Daniell. The current from H is also sent through the potentiometer of platinum-wire, but in the opposite direction; and by the introduction of resistance coils one can balance

the two electro-motive forces so that one current, as it were, neutralises the other, that is, the electro-motive force of H is made equal to that of the electromotor D. In the circuit of the first cell, the Daniell, a galvanometer, E, is placed, and when the two electro-motive forces have been balanced, the needle of this galvanometer is stationary. Then place the eye on the electrodes at F in the way I have already described, and allow the current to pass through a second galvanometer, G, and also through the potentiometer, A¹, B¹, which represents the resistance of the Daniell's cell. The needle of the galvanometer, G, sweeps round, and takes up a certain position. We then have to move along the platinum wire one of the terminals of the eye circuit, FGB²A², until we get it to a neutral point, B², at which the galvanometer needle, G, is not affected at all, or in other words until the electro-motive force of the Daniell and of the eye balance each other. It is evident, from a consideration of the diagram, that the electro-motive force of the eye will be to the electro-motive force of the Daniell, as the resistance of the portion of the wire from one end to the neutral point is to the resistance of the whole wire, as the distance A²B² is to the distance A¹B¹. Thus the electro-motive force of D is, $E^1 = R_1 c$ where R_1 is the resistance between A¹ and B¹ and c is the strength of the current in the primary circuit. Again, the electro-motive force of the eye, F, is $E^2 = R_2 c$, where R_2 is the resistance between A² and B², and c the strength of the current in the eye-circuit. Therefore, $E_1 : E_2 :: R_1 : R_2$.* Practically we found the Daniell's cell far too strong a battery to use as a standard of comparison. A thermo-electric junction of bismuth and copper, soldered together, was substituted for it. One end of the junction was constantly heated by a current of steam passing over it, and the other was kept constantly at freezing temperature. The electro-motive force of this thermo-electric junction, as estimated many years ago by Regnault, is extremely constant, and is about the one one-hundred-and-seventy-fifth part of a Daniell's cell. By means of this arrangement we were able to come to the following conclusion—that the electro-motive force of the nerve-current we have dealt with in our experiments on the eye and the brain of a frog, varies from the $\frac{1}{300}$ th to the $\frac{1}{400}$ th of that of a Daniell's cell—an extremely small amount. It was also proved that light produced an alteration in the electro-motive force. Supposing we have determined the electro-motive force in the dark, in the manner above indicated: then let light come upon the eye, the galvanometer needle of the eye-circuit will again move, and in a short time become tolerably stationary. By readjusting the terminal on the potentiometer the needle must be brought back to its original point: the length of wire along which the terminal was moved to effect this, will represent the electro-motive force. We found this change was, in many instances, not more than the $\frac{1}{1000}$ th of a Daniell's cell. But though small, it was quite distinct, and enabled us to say positively that light produced a variation in the amount of the electro-motive force. By the same arrangement, the gastrocnemius muscle of a well-fed frog gave $\frac{1}{35}$ th of a Daniell; the same muscle from a lean frog which had been long kept, gave $\frac{1}{510}$ th of a Daniell; and the sciatic nerve of the well-fed frog $\frac{1}{280}$ th of a Daniell. Dr. Charles Bland Radcliffe states, in his *Dynamics*

of *Nerve and Muscle*, p. 16, that he obtained, by means of Sir William Thomson's quadrant electrometer, from a muscle, a positive charge equal to about the tenth of a Daniell's cell, a much greater amount than ascertained by the method I have just described. As above stated, we found the electrometer of no service, as the electrical potential was too small to affect it.

Chronometrical Observations.—The last point I wish to bring under your notice, is what we have recently been doing in the way of measuring time in this research. The electrical variation has been shown to agree with our consciousness of luminous effects, the most luminous rays producing the greatest electrical variation. It became an interesting point to ascertain whether the time occupied by the action of the light upon the eye of the frog is similar to the time occupied in its action upon the eye of man. A good many years ago, Professor Donders and his pupil, Schelske, performed a number of experiments by which they determined that the time required by the human being to observe light and to signal back the impression occupied about $\frac{1}{10}$ th of a second. That is to say, $\frac{1}{10}$ th of a second is occupied by the action of light on the eye, the transmission of nerve-current to the brain, the change induced in the brain during perception and volition, the time for the transmission of the nerve-current to the

Diagram showing the recording portion of Regnault's Chronograph. A A. Limbs of recording fork, worked by electro-magnets, G G. C. Stilette on limb of recording tuning-fork. B B. Levers in connection with armatures of electro-magnets, F F, and bearing markers D D, which, along with C, record on E, a strip of blackened paper passing over pulley.

muscles, on signalling the result, and the time occupied by muscular contraction. We found that there were considerable practical difficulties in the case of the eye of the frog, some of which we have overcome, but others still face us. This part of our investigation we still desire to carry on. The instrument we are at present employing is one made by Dr. König, of Paris, and may be called a *chronograph* or time-measurer. It consists of a large tuning-fork, A A, giving 200 vibrations a second. This is placed in an upright position, and is kept in constant vibration by an electro-magnetic apparatus,

* This method is described in Clerk Maxwell's 'Electricity and Magnetism,' vol. i. p. 413.

G G. In front of a stilette, C, placed on one of the limbs of the tuning fork, a thin strip of blackened paper, E, is drawn vertically over a pulley. The action of the tuning-fork, gives a curve down the blackened paper. Each wave-like portion of the curve represents the 200th part of a second. Then on each side of this vertical tuning-fork, and on a level with its stilette, is another electrical apparatus, consisting of an electro-magnet, F F, the armature of which is prolonged, B B, and carries a marker, D D, which is on an exact level with the stilette of the tuning-fork. When a current passes through the coil the armature descends, and the moment is indicated by a mark on the blackened paper. One marker, say the one to the left, is used for signalling automatically the moment light is put on, while the other, say the one to the right, is set in action the moment the spot of light on the galvanometer scale is seen moving.

A tracing on the smoked paper will be obtained, a portion of which, indicating one experiment, is seen in Fig. 8. Here C represents the vibrations of the tuning-fork, each vibration being the $\frac{1}{200}$ th of a second. A is the line drawn by the marker moved by the electro-magnetic apparatus on the one side, and B that made by the electro-magnetic apparatus on the other. Suppose an arrangement by means of which a flash of light is given by passing an induction

current through a Geissler vacuum tube and also through the electro-magnetic apparatus with which the marker A is connected. Let this happen at *a*. The marker passes inwards and indicates the moment of time light was thrown on the eye, the result of which is an electrical variation affecting the galvanometer. The moment the observer sees the movement of the spot of light on the galvanometer scale, he completes a circuit which works the electro-magnetic apparatus supporting the marker B. This happens at *b*. The distance of *a* from *b* indicates the time between the moment light fell on the eye of the frog and the moment the needle of the galvanometer was observed to be affected by the movement of the spot of light on the scale. On counting the number of small waves we find eight; $\frac{8}{200} = \frac{1}{25}$ of a second. This, of course, would not give the real time occupied by the action of light on the eye of the frog under examination. The time between the moment light is thrown on the eye of the frog and the moment the observer of the galvanometer telegraphs that he sees

consideration, and the experiment has been modified in various ways. *c* and *d* indicate the instants when the currents ceased to pass through the electro-magnets, and when the keepers were consequently released.

We first of all satisfied ourselves that the observations made by Donders, Schelske, and others, were quite correct—that one-tenth of a second is required to signal back the impression. It can be stated at present that the action of light upon the eye of a frog occupies very nearly the same time. The experiment of time-signalling in different individuals is extremely striking; we have had the opportunity of testing the powers of various persons, as to how quickly they can signal back, and we found that there is little variation, but that each person has his own time. He may strive as much as he will to gain a minute fraction of a second, but he cannot get faster than the particular time. It was easy to find that, even if anything slightly distracts the attention, there is a somewhat longer time required to return the signal. It was also observed that expectancy of the effect caused a slight saving of time. This chronograph is an instrument of great use in physiological investigations involving measurements of time, and it may be variously applied. It is more susceptible of varied application than the chronograph of Marey.

Conclusion.—I have to mention another matter which it is but right that I should notice. After we gave our report in a preliminary paper at the British Association meeting at Bradford, we ascertained that a Swedish physiologist, Frithiof Holmgren, had worked upon the subject several years before we had attempted the investigation. Notices of his research had escaped our observation. The instrument used by him was what was termed Wiedemann's galvanometer. Holmgren was enabled to ascertain many of the points we have investigated, but from want of delicacy in his instrument he was not able to give the quantitative results at which we have been able to arrive. On ascertaining that he had been at work upon the subject we communicated with him, and he replied with great cordiality. We have exchanged various communications, and it is gratifying to know that two researches, going on perfectly independently of each other, have arrived at the same results so far as the inquiries were directed to the same points. Holmgren has directed special attention to the static electrical condition of the eye, while we have directed our attention more especially to the specific action of light considered in its physiological and psychological aspects and to its quantitative measurement. It is, however, an example of what frequently occurs in scientific research, that two persons may be working quite independently at the same time upon the same subject, and thus truth is arrived at with a greater weight of evidence. It will matter little a few years hence who first noticed the phenomenon, so long as it is a certain step in scientific discovery.

Copy of tracing obtained by Regnault's Chronograph.

the spot of light moving on the scale includes various events. It includes the action of light on the frog's eye, the transmission of the electrical variation through the coils of the galvanometer, the time occupied in overcoming the inertia of the needle, and, finally, the time occupied by the observer in seeing the movement of light and telegraphing that he does see it. We have taken all these facts into

TEACHING IN LUNATIC ASYLUMS.—The *Journal of Mental Science* for October contains an article on the Richmond Asylum Schools by Dr. Hack Tuke, in which he strongly recommends the introduction of schools into all county asylums. The article gives a detailed account of the educational system pursued at the Richmond Asylum Schools under Dr. Lalor, and is well worthy of perusal and consideration by all having the care of the insane.

ON SUDDEN DEATH FROM ACUTE PULMONARY ŒDEMA. BY DR. CANTILENA, CHIEF PHYSICIAN OF THE HOSPITAL AT BELLUNO.*

It is not a rare event in medical practice to meet with cases of acute Œdema of the lungs which are more or less rapidly fatal. In pneumonia, it is in fact the Œdema which supervenes during the period of resolution, especially if the mucous membrane of the bronchi be in a state of catarrh, that endangers life by sudden suffocation. In these conditions, the effusion of serum into the pulmonary vesicles and smallest bronchi in a short time produces asphyxia and death. It is in like manner by acute Œdema that general catarrh of the bronchi very rapidly proves fatal; and in acute tuberculosis and acute exanthematous diseases similar events are not rare.

Rokitansky, Niemeyer, Oppolzer, and Roncati, speak of sudden death from pulmonary Œdema in persons with a large chest and short neck, without preceding disease, and after a full meal. Finally, there are some rare cases of death occurring in a few minutes from this condition, in individuals having structural disease of the heart or of the larger vessels.

It is to the consideration of this last form of acute pulmonary Œdema, with which organic lesions of the heart are connected, that my observations are directed. Before giving a description of individual cases, I think it will be useful to point out what are more especially the organic diseases of the heart or of the larger vessels in which sudden death readily supervenes, sometimes in a few moments and in the midst of every appearance of health.

It would seem that those sudden deaths occur frequently in the subjects of insufficiency of the aortic semilunar valves, the more so if there be also atheroma of the commencement of the aorta, when the force of the muscular tissue of the heart is enfeebled and wearied by excessive activity or by the degeneration of the muscular fibres. This is the way in which sudden death occurs in these cases. Physiological observation teaches us that the circulation through the heart should be effected in the following manner. At the moment of systole, by the contraction of the cardiac muscle, and especially by the raising of the aortic valves and their application to the openings of the coronary arteries, very little blood can enter these vessels; hence the supply of the viscus with arterial blood must occur during diastole, when the lowering of the semilunar valves and the relaxed state of the cardiac muscle favour the ingress of blood. In order that this circulation may be active and salutary, the cardiac systole must be strong, so that the flow of blood may take place without difficulty, and the arterial circulation may be facilitated during diastole. If the flow of arterial blood into the coronary vessels be impeded either by insufficiency of the aortic semilunar valves, or by weakness of the muscular tissue of the heart—and especially if there be also sclerosis of the aorta and coronary arteries—we shall have all the conditions in which an emotion or an effort may gravely disturb the function of the heart. The consequent pulmonary congestion and the sudden pouring out of serum into the ultimate air-passages certainly has a large share in preventing the heart from resuming its regular action, since by them the right ventricle

is prevented from emptying itself of the blood which has been poured into it by the *venæ cavæ*. Mauriac and Bucquoy (*L'Union Médicale*, 1869) approve this theory, and adduce facts in its support.

In sudden death from acute pulmonary Œdema in cases of heart-disease, two morbid conditions of the organ are to be especially recognised as favouring the fatal result—viz., insufficiency of the aortic valves, by which the circulation in the coronary arteries is impeded during diastole, and weakening of the cardiac muscle, with the consequences of a systole insufficient to sustain the venous circulation; whence arises stasis, with retardation of the arterial circulation. Atheroma of the aorta and of the coronary arteries aids in disturbing the circulation through the tissue of the heart; and it is when the circulation through the coronary arteries is impeded, that the phenomena of angina pectoris may be presented, which may end fatally in the same manner, as appears from the observations recently made by Sée.

It cannot be denied that sudden death may take place also in diseases of the aortic valves of other kinds, when there coexist morbid states of the cardiac muscle by which a cyanotic condition of the heart is kept up. In narrowing of the aortic orifice, especially when very advanced, the ischemia of the cardiac muscle may certainly determine an attack of acute pulmonary Œdema, which, if it pass beyond a certain limit, and be associated with deficient oxidation of the blood in the brain, may produce sudden death.

Finally also, in diseases of the other cardiac valves, especially the bicuspid, where the venous circulation may be retarded, and the flow through the arteries impeded, with impaired nutrition and consequent degeneration of the cardiac muscular tissue, death may occur suddenly under a strong emotional impression, or after an effort by which the movements of the heart are arrested. In this case, chronic bronchial catarrh determines and maintains chronic pulmonary Œdema, not limited to the minute bronchial tubes and alveoli of the lungs, but diffused also through the interstitial tissue of the lungs, and accompanied with general Œdema and dropsy of the serous cavities. Any slight derangements of the movements of the heart then much more readily disturb the pulmonary circulation, and to the chronic Œdema is superadded an acute one of a most dangerous character. In these circumstances sudden death more frequently occurs, when the patients have not been taught by experience to surround themselves with the greatest quiet of body and mind, and where the general dropsy does not call for absolute rest by rendering movement difficult.

Acute pulmonary Œdema, and especially that connected with lesions of the heart, is recognised by the following symptoms. The patient usually has a cyanotic turgid face; the ocular conjunctivæ are congested, and the jugulars are distended; the expiratory action is prolonged, and the breathing is accompanied with râles which may often be heard at a distance. There is more or less frequent cough, sometimes dry, or with transparent or frothy serous sputum; sometimes the sputum is turbid from admixture of epithelium, or reddish from blood. The cough may be absent if the fluid lying in the ultimate bronchi do not determine reflex phenomena, especially if the narcosis of the nervous centres hinder reflex movements. The pulse is generally small, often irregular, in very severe cases intermittent. With regard to physical signs, the percussion-

* *Giornale Veneto di Scienze Mediche*, July, 1875.

sound, apart from the special signs of the disease by which the acute œdema is accompanied (such as pneumonia, acute pulmonary tuberculosis, etc.), is either scarcely tympanic, or there is a dull tympanic sound, according to the quantity of serum effused into the alveoli and small bronchi. Auscultation sometimes detects disseminated subcrepitan râles, or these may not be heard because they are masked by large rhonchi; sometimes no râle is audible, and in rare cases a more or less blowing sound is heard. The sensorium is generally stupefied; sometimes there is subdelirium, and in very severe cases coma, according to the degree of non-oxygenation of blood or deficiency of arterial circulation in the encephalon, and of narcosis produced by carbonic acid.

This mournful array of symptoms is much more distinctly marked in the acute pulmonary œdema which supervenes in cardiac diseases, and which ends rapidly, sometimes in a few instants, in death. Cases have sometimes occurred in which individuals in a good state of nutrition, and with very little apparent disturbance, have lain down quietly in the evening, and on first awaking have been attacked with terrible agonies, which have ended in death before the medical man could come. I have three times been a spectator of a lamentable result of this kind, which in two cases it was possible to ward off in previous attacks by seasonable aid. These observations of mine furnish examples of particular interest, in regard to the fact that, without a full knowledge of the state of the heart, the appearance of perfect health, disturbed only by very slight mental emotions, or by slightly fatiguing locomotion, may deceive the physician, even when he is urgently called in and hears the history of a first slight attack, which perhaps has entirely passed off without any treatment before his arrival.

CASE I.—Cavalier M., Prefect of the province of Belluno, a little more than sixty years of age, of rather lymphatic temperament, presented, on coming to this place, vigorous nutrition and perfect health. He said that he sometimes felt very slight trouble after a rather tiring walk; for the rest, beyond some bronchial catarrh of not long duration, and a state of hypochondriasis with which he had been troubled for some time in consequence of mental anxiety, he had had no disease of importance. In the spring of 1871, without any premonitory symptoms of importance, he awoke one morning with sudden dyspnoea and failure of the heart, which passed off before my arrival. A second and more severe attack occurred a few days later, in the same condition of general health. It came on towards the morning, and still continued when I arrived. I found the patient sitting up in bed, with troubled breathing; he had a violent cough, with râles audible at a distance, and expectorated a frothy mucous fluid. His face was red and tinged; the conjunctivæ were congested, the jugulars were dilated, and a cold sweat bathed his whole body. The pulse was frequent, irregular, jerking; the sensorium was recovering from the stupor, into which it had fallen when the paroxysm set in. Under the use of cutaneous stimulants, applied before my arrival, and of ammonia internally, he soon revived.

Examination of the chest gave the following results. Auscultation detected large rhonchi, which masked every other respiratory sound. The apex of the heart beat in the seventh intercostal space; the long diameter of the heart was increased. There was a murmur accompanying the second sound,

rough at the apex, and perceptible in the second intercostal space; the first sound over the aorta was dull. The pulse only presented occasional intermittence, but the artery felt large and rather tortuous, with perceptibly jerking diastole.

The diagnosis which I made was, aortic insufficiency, hypertrophy and dilatation of the left ventricle, tendency to asystolia, with sudden attacks of acute pulmonary œdema of a most dangerous character. This diagnosis was confirmed by Professor Pinali, whom I called in consultation.

The whole of 1871 was passed through without fresh attacks; the patient daily took bromide of iron, and appeared to be in better health; he attended to his ordinary business, and could even undertake a rather long journey without inconvenience. But in the winter of the next year, on being called to the patient before daybreak one morning, I found that to the previous symptoms was added a state of amnesia; the patient, who could not be roused by any means, repeated the same word at every expiration; and a cold sweat bathed his whole body. I at once bled him to a small amount, after which he regained his mental faculties, his respiration became calm, and the movements of the heart regular: in a word, he revived, but more slowly than usual, and was obliged to keep his bed for some days in consequence of a feeling of general weakness and of the supervention of bronchial catarrh. But, beyond the bodily ailment, he was seized with mental depression from the idea that his end was approaching. He was able to resume his occupation, and to go during the next summer to Reggio in the Emilia, his native country. In September of that year, after a day in which he had suffered much from melancholy but had presented no new morbid symptom, he went to bed rather early, and on awaking in the morning was seized with a new and more terrible paroxysm, which caused his death before I could arrive. I was not allowed to make a necropsy.

CASE II.—Signora N., aged seventy-five, of lymphatic temperament, and fat, had never suffered from any disease of importance. On leaving Trivignano to reside in the Belluno district, she suffered from frequent attacks of bronchial and intestinal catarrh. She had a first attack of acute pulmonary œdema in 1872, without any premonitory symptoms beyond a little disturbance after quick locomotion; it was of very brief duration, and did not prevent her from rising from bed on the same day. She presented unmistakable signs of slight aortic insufficiency, with hypertrophy of the left ventricle. She had a second more severe attack a few months later. Having lain down one evening without feeling any symptoms, she awoke after a very short sleep with much trouble of the breathing and circulation. Hoping for relief, she rose from the bed and sat on the sofa, where the difficulty of respiration increased, and she became unconscious. When I saw her, she was beginning to regain consciousness, but soon again lost it; her face was tinged and cyanotic; the jugulars were distended; the breathing was much disturbed; she had a dry cough with sonorous râles, and a small irregular pulse. Cold water had been sprinkled over her, and sinapisms applied to the limbs. I ordered a blood-letting, after which the scene was entirely changed; she did not, however, remain altogether free, as she had an attack of broncho-pneumonia from which she did not recover for some days. She had no other morbid symptom till December, 1873, although she had been much frightened by the earth-

quake in June of that year. At the above-mentioned date, she went to bed after a very cheerful evening, and had been to sleep but a short time, when she was awakened by an attack of her unwelcome visitor. She was more terrified by the attack than usual, and got out of bed in obedience to a sudden call to pass urine, hoping to relieve herself of the distressing sensation which had seized her; she was unable to return to bed without the aid of her servants, and died before my arrival. A necropsy was not permitted in this case.

CASE III. Daniel N., aged fifty, had always had good health until 1860, although exposed to occasional inconvenience in his calling as an omnibus conductor. At that time he was seized with acute articular rheumatism, which did not leave the heart free; it recurred several times, each time affecting the circulatory centre. Notwithstanding this, he could, with slight difficulty, attend with his wife to a wine and spirit business. After her death, however, and after some domestic difficulty, he addicted himself to drinking, and became unable to bear any fatigue. Œdema of the lower limbs appeared, and on July 17, 1873, he was admitted into hospital, where he remained with physical signs of severe organic disease of the heart and anasarca, until April 17, 1874, when he was discharged in a satisfactory condition. On February 2, 1875, he was again admitted, and the following symptoms were noted the next morning:—General œdema, weak irregular pulse, temperature 100° Fahr., difficult respiration, cough with frothy mucous sputa, tongue red at the margins, slight meteorism, sero-mucous diarrhoea, urine very scanty and high-coloured. He had passed a very restless night, and complained of pains in the right hypochondriac region. Inspection of the chest during a deep inspiration detected depression of the epigastric fossa, and retraction of the lower intercostal spaces; the thorax was raised *en masse*. Percussion was clear, even over the upper part of the liver and over the heart. Auscultation detected moist râles diffused everywhere through the chest. The heart's impulse could neither be seen nor felt; on percussion, the organ was found to be increased in all its diameters. There was a harsh murmur, which replaced the first sound at the apex, and was equally strong in the second right intercostal space and in the carotids: with the diastole, there was heard at the apex a murmur, less distinct over the aorta. Over the pulmonary artery the two sounds were weak. The liver extended downwards and was hard and painful; the spleen passed behind the axillary line.

Under the use of digitalis and morphia, and with perfect rest, there was notable improvement; the cough became less troublesome, the respirations more free, the urine very abundant; the diarrhoea ceased, and the œdema disappeared. On February 6, five days after his admission, he declared himself to be in a very satisfactory state, and asked for a more liberal diet, which was allowed him. But, on being called to him scarcely a quarter of an hour afterwards, I found him in a state of stupor, with turgid purple face, distended jugulars, and irregular respiration with tracheal râles; it was impossible to rouse him by stimuli applied in various ways, and in a very short time he was a corpse.

The necropsy was made forty-eight hours after death. There was still slight œdema of the lower limbs; the subcutaneous fat was scanty, and the muscular tissue flabby. In the head there was slight

subarachnoid œdema, and the nervous pulp was slightly dotted. Both lungs were emphysematous at the margins, and presented abundant effusion of serum, which escaped on section; in the right lung were patches of hæmorrhage. The mucous membrane of the bronchi was red and turgid. There was a little limpid serum in the pericardium; the heart was hypertrophied and weak; its walls were in great part covered with fat. The left cavity was dilated; the walls of the ventricle were thick, and its parenchyma friable, of the colour of dry leaves. The endocardium covering the mitral valve was thickened, wrinkled, and rigid; the valve was contracted and funnel-shaped; the chordæ tendinæ were thick, and the papillary muscles hypertrophied. The endocardium of the aortic semilunar valves was thick and rigid, of cartilaginous appearance; the valves were fixed in the diastolic position, leaving only a small triangular aperture, capable of admitting a goose-quill; there were calcareous incrustations on the tubercles of Arantius. The right cavities were dilated, and the endocardium was opaque. The aorta, immediately above the valves, presented a slight cylindroid dilatation; the lining membrane was atheromatous, and the openings of the coronary arteries had lost their round form and had thickened and rigid edges. The degeneration was less apparent in the coronary arteries. The liver was enlarged and of nutmeg appearance; the spleen was also enlarged, and its parenchyma was hard, and of a dull red colour.

In this last case, admitting that the stenosis of the aortic valves might render their insufficiency less dangerous, the coexistence of atheroma with dilatation of the commencement of the aorta and the deformity of the openings of the coronary arteries, with the enfeebled action of the cardiac muscle, constituted so many other causes capable of disordering the arterial circulation in the heart, so that even under very trivial influences the movements of the organ were liable to become less strong and at last to stop. Again, the stasis maintained in the right ventricle by the stenosis and insufficiency of the bicuspid valve, concurred in retarding the coronary venous circulation: so that in this heart the conditions most fitted for disturbing its nutrition and action existed permanently. They were combined with defects of form and of function more than sufficient to produce sudden death.

CASE IV.—This case, the subject of which is still living, offers an example of repeated attacks of acute pulmonary œdema in an individual affected with stenosis of the aortic opening and hypertrophy of the left ventricle.

Signora N., aged sixty-three, suffered in her youth from rheumatico-catarthal affections, for which she was repeatedly bled; but her general health remained good. In the winter of 1873 she was seized for the first time, shortly after awaking, with a feeling of distress and failure of the heart's action. On my arrival, I found her sitting in bed with her face rather cyanotic, short breathing accompanied with râles, pulse small and frequent, somewhat irregular. The apex of the heart-beat in the sixth intercostal space; the impulse was feeble, but prolonged, and somewhat diffused; the longitudinal diameter of the heart was increased; a harsh murmur accompanied the first sound and was perceptible over the aorta and carotids; the second sound was dull. Up to the present time she has had many attacks of more

or less severity, but as yet, with appropriate aid, she had escaped a fatal termination.

I must not omit to mention what are the most approved remedies in a case in which the physician, suddenly called in, finds that he has to deal with so dangerous a disease. I will not speak of the more appropriate curative agents for the œdema which appears in pneumonia and bronchitis; we will imagine individuals, apparently in perfect health, suddenly seized with the terrible paroxysm; or persons with heart-disease, who enjoy health so far as to dismiss from their minds the possibility of approaching death. If there be cyanosis and distension of the jugulars, and there be evidence of collection of fluid in the thorax and the sputa be more or less sanguinolent, blood-letting is an excellent remedy, provided that the patient be not too much exhausted. Oppolzer advised that the patient should be bled in the sudden position, and recommended the commencement of fainting as the proper moment for closing the vein. This precept of the illustrious Viennese physician may be useful in many cases, but it is certainly not applicable if the œdema be connected with grave disease of the heart, in which death may very readily follow deliquium. If signs of intense œdema be present and expectoration be wanting, external and internal stimulants are useful; in my cases, I have successfully employed solution of ammonia, Marsala wine, and sinapisms. An emetic may be used, when the strength allows it, and the carbonic acid narcosis does not hinder reflex action; but it must be remembered that this remedy acts on the vagus and medulla oblongata, and produces depression of the heart and spasm of the peripheral vessels; hence it must be used with great reserve, and in every case should be accompanied by stimulants. In irritable individuals, bromides are indicated; especially the bromide of iron if there be anæmia.

From what has been already said, I believe that the following conclusions may be derived.

1. Sudden death from acute pulmonary œdema may occur in well-nourished robust individuals, with a short neck and large chest. Attacked with severe dyspnoea while at table or after a full meal, they fall senseless and cyanosed. It may occur in persons of healthy appearance, who manifest only slight disorder of the circulation and respiration from mental exertion or fatiguing locomotion, which are capable of accelerating the circulation; and even without these the individual may be suddenly attacked. Finally, sudden death may occur in the various forms of lesions of the valves and muscular tissue of the heart, even at the time when the existence of salutary compensations leads one to hope that the danger of an early end has been warded off.

2. In individuals a little advanced in years, with insufficiency of the aortic valves and hypertrophy of the left ventricle, sudden death with symptoms of acute pulmonary œdema may occur when the action of the cardiac muscle has become enfeebled; by which the circulation in the coronary arteries has been rendered difficult, not only because the insufficiency of the semilunar valves impedes the coronary arteries, but because the stasis in the coronary veins tends to produce the same effect. Atheroma of the commencement of the aorta and deformity of the openings of the coronary arteries, especially if the degeneration extend some way within these vessels, may even produce rapidly fatal paroxysms of angina pectoris.

3. Attacks of acute pulmonary œdema and syncope, even rapidly fatal, may occur in narrowing of the aortic orifice, when the flow of blood fails in the coronary vessels, and the brain and centre of cardiac innervation remain unprovided with the necessary arterial supply.*

4. Individuals who suffer from complicated lesions of the heart, attended with dropsy, catarrh, etc., although revived for a time, remain liable to die suddenly, if, in addition to the signs of enfeebled action of the cardiac muscle, the conditions be present which are capable of rendering difficult the circulation in the coronary arteries.

CONTRIBUTIONS TO THE GENERAL PATHOLOGY OF CYLINDER-EPITHELIUM. BY DR. L. GRIFFINI, OF TURIN.†

In a preliminary communication, published in the *Gazetta delle Cliniche*, for August, 1874, I enumerated the more important of the results at which I had arrived in the study of the pathological changes of cylindrical epithelium. My experiments and observations at that time had special reference to the ciliated epithelium of the larynx, trachea, and bronchi. Now, however, having explained the other forms of cylinder epithelium, and obtained new results which appear interesting, I think it opportune to give a *resumé* of the whole. I intend to publish a complete memoir on the subject as soon as certain observations have been completed.

1. *Changes in Cylinder Epithelium in Tuberculosis.*—In 1863, Förster, speaking in his treatise on pathological anatomy on inflammations of the mucous membrane of the larynx, observed that, in cases of chronic inflammation of long duration, the mucous membrane undergoes in certain points, or even generally, a special change, which he calls *dermoid metamorphosis*. That is to say, the mucous membrane, naturally destitute of papillæ, assumes a papillar structure, and appears invested with an epithelium having the character of pavement epithelium.

Dr. Wahlberg, in his work on tuberculous ulcers in the larynx, published in 1872, observes that around tuberculous ulcers of the superior vocal cords, in place of the normal stratified ciliated epithelium, there is a thin pavement epithelium; and that this change occurs even when, the epithelium not being perforated but only thinned, the tuberculous ulcer is developing itself. He observes also that the mucous membrane at some points assumes a papillar structure, and endeavours to show that these changes of the epithelium are not to be regarded as the result of an inflammatory process.

Having extended my observations to the mucous membrane of the trachea, and of the large, middle-sized, and small bronchial tubes, I have ascertained in severe cases of chronic pulmonary tuberculosis in which the larynx and trachea were affected, that not only around the ulcers on the superior vocal cords, but at every point of the mucous membrane where tuberculous nodules were present, the ciliated cylinder epithelium was transformed into pavement epithelium. To these superficial tuberculous nodules corresponds a small hemispherical elevation, which on vertical section appears to be formed of a giant-

* According to Traube, an extraordinary slowness of the pulse has sometimes been observed to indicate difficulty of the circulation in the coronary arteries.

† *Gazetta delle Cliniche*, August 3, 10, and 17.

cell with epithelioid cells, rarely perfect, and numerous lymphoid cells. The surface of the mucous membrane is covered by a hyaline layer, which is sometimes entire, and follows the elevation; sometimes it is thinned, and is entirely lost towards the summit of the elevation. These elevations are always covered, sometimes with a single layer of polygonal more or less flattened epithelial cells, especially towards the summit; sometimes with two or three layers of polygonal cells, of which the most superficial are much flattened. In proceeding from the summit of each elevation, along the two sides of a vertical section towards the normal epithelium, we find a gradual transition from pavement cells to short superficial ciliated cylinder-cells, and then to longer ones, having among them oval and round cells, as in the normal epithelium of the trachea. The tuberculous nodules in the trachea appear to be imperfect (perhaps from their age), so that it is not always easy to demonstrate the typical structure of the nodule; and sometimes, without being able to see true tuberculous nodules with giant-cells, even the circumscribed elevations of the mucous membrane above described, but only a more or less abundant infiltration of migratory cells, we find the surface of the mucous membrane covered for some distance (as far as a centimètre), with pavement epithelium. But even here there are always observed, either towards the confines or in some part of the extent of the tract of transformed epithelium, one or more tuberculous nodules undergoing granulo-fatty degeneration, some of which raise the pavement epithelium, thinning or perforating it. This explains to me why Förster referred the transformation of epithelium in the larynx to a simple chronic inflammatory process, especially when it is remembered that, when he wrote, the structure of tubercles was not so well determined as it is now. I certainly do not deny that it is possible that simple chronic inflammation may give rise to this change of the epithelium; nor that in tuberculosis the whole mucous membrane of the larynx, trachea, and bronchi, or only of the parts around the tubercles and ulcers, may be affected with inflammation; but I merely observe that, in the cases studied by me, the transformation in question was always limited to the small area corresponding to the more or less perfect tuberculous nodules, and that, when distinct nodules were wanting, there were always traces of nodules, or nodules which had undergone retrograde metamorphosis and were being absorbed. In the trachea, the epithelium, when changed over a large area, presents altogether the appearance of epidermis. It is composed of a deep layer of oval cells with a large nucleus, with their greatest diameter perpendicular to the surface of the hyaline layer on which they rest; this layer is succeeded by others (two to four) of larger polygonal cells, with round granular nucleus surrounded by abundant protoplasm; finally, there are other layers of flattened cells with their greatest diameter parallel to the surface of the mucous membrane; these flattened cells appear here and there to be partly raised, as occurs in epidermis and other forms of pavement epithelium, the superficial layers of which undergo desquamation. This transformed epithelium has a thickness equal to the normal cylinder epithelium, and is only thinned here and there, either by the existence of superficial cheesy nodules or by desquamation of its more superficial layers. The inferior surface of this epithelium presents a slight undulation, which gives a papillar

appearance to the mucous membrane. To these slight undulations of the inferior surface of the epithelium correspond equal alternate elevations and depressions of its upper surface; these are not plugs of epithelium which insinuate themselves into the connective tissue of the membrane, as there are in the skin, forming distinct papillæ. I have never been able to observe a true papillar structure, such as Förster and Wahlberg describe. This change of the typical form of the epithelium is constantly met with also around tuberculous ulcers of the trachea, some of which are covered with a false membrane which, in its physical and chemical characters, and microscopic structure, exactly resembles the fibrinous membrane of croup.

In the large bronchi (four cases), in the middle-sized and small ones (two cases), I observed circumscribed elevations of the mucous membrane, with which corresponded one or more superficial tuberculous nodules covered with pavement epithelium. Here the elements of the tuberculous nodules are in a better state of preservation, perhaps because of their more recent formation. Tuberculous ulcers are more rare in the bronchi than in the trachea and larynx.

I have met with some other changes of the epithelium in fresh preparations of tuberculosis of the larynx, trachea, and bronchi; such as, in all the cases examined by me, ciliated cylindrical cells with two, three, or even four or five nuclei. It was distinctly ascertained in every case that these cells were quite isolated, and that the appearance was not produced by two or more cells lying together with their nuclei at different levels; moreover, coloration with logwood removed all doubt as to whether they might be not true nuclei, but pus-cells which had penetrated the epithelial cells. I have not in any case found cylindrical epithelium cells containing pus-globules, but have been readily able to distinguish them by the size of the globules, and especially by colouring with hæmatoxylin, which gives the nuclei an intense tint. In some cases I have found ciliated spherules (such as are found in the mucus in coryza) and goblet-cells; but of these I will speak in treating of catarrhal inflammation.

The constant occurrence of this transformation of the epithelium corresponding with ulcers and superficial tuberculous nodules of the tracheal and bronchial mucous membrane having been thus ascertained, the desire arose to observe whether it also took place in tuberculosis of other mucous membranes with cylinder epithelium (of the uterus, Fallopian tubes, intestine, etc.). Up to the present time I have been able to examine only two cases of tuberculosis of the uterus and Fallopian tubes; one of which was obligingly placed at my disposal by Professor Bizzozero, to whose private collection it belonged; the other came into my hands from the medical clinic, through Professor Rovida.

On scraping the mucous membrane of the fundus uteri in the second case, and making preparations by teasing out the specimens, there were isolated numerous epithelial elements, very large and somewhat flattened, and among them other similar but smaller ones. They all had a shape tending to the hexagonal, and were generally furnished with two, three, or more central oval vesicular nuclei, with one or two distinct nucleoli; the cellular protoplasm was fully granular, and contained numerous spherical corpuscles of yellowish appearance and uniform size.

The appearance of these corpuscles led me at first to believe that they might be organisms which had penetrated into the cells; but there were more outside the cells, and acetic acid dissolved them, and rendered the cells which contained them pale and transparent. They were then large albuminoid granules. Besides these large elements, there were perfectly spherical bodies with large granules which prevented the nucleus from being well seen. Some (specially belonging to the Fallopian tubes) had at one point a long prolongation similar to that of the cylindrical cells, and at the other, traces of a ciliated margin, from which, however, the cilia had fallen off; they therefore seemed to be cylindrical cells which had become enormously distended and spherical through the accumulation of the large yellow granules. They resembled the so-called inflammatory corpuscles of Gluge, which are met with in catarrhal pneumonia. Acetic acid caused the fine granules to disappear, but the large and yellow ones remained, and appeared more distinctly to be fat-granules. There were also, especially in the Fallopian tubes, cylindrical cells deprived of cilia, distended or more or less misshapen, and full of granules and fat-drops. Besides these, there were fragments of pavement epithelium.

Vertical sections of the mucous membrane of the body and fundus of the uterus, in both cases, revealed the existence of numerous tuberculous nodules in various grades of development; some of which, being superficial, had produced elevations on the surface of the mucous membrane, covered sometimes with a single layer of rather flattened pavement-cells with a large protruding nucleus, sometimes with two or three layers of less flattened pavement-cells. At the points also where the tuberculous nodules had perforated the epithelium and produced microscopic ulcers, the epithelium at the side of the ulcers presented the appearance of pavement epithelium for a varying extent.

The epithelium also of the tubular glands of the uterus had undergone the same change. In almost all the sections that were made, the tubes of the glands were found enormously dilated, especially towards their blind extremities, with numerous largely granular spherical bodies, with large cells having large granules, and with mucus-corpuscles and cylindrical epithelial cells in a state of fatty degeneration. Very frequently along the wall of the tube were one or more tuberculous nodules, and the corresponding epithelium had a rather flattened prominent appearance. There was a gradual transition from the cylindrical cells (at the sides of the nodules) to the cells which gradually assumed the pavement form), being without cilia or traces of a ciliated border. It seemed, therefore, that we had not to deal with pre-existing cylindrical cells which had become crushed by pressure during the development of the tuberculous nodule. Sometimes the nodule had perforated the epithelium. At some points, where the epithelium had entirely fallen off, the surface of the mucous membrane was covered with a hyaline layer twice or three times as thick as in the normal state, and presenting constrictions here and there. Sometimes the mucous membrane at these points presented a white, shining, homogeneous appearance (sclerosis), and capillary vessels with thickened, homogeneous, white shining walls. Where the mucous membrane was transformed into a yellowish granular substance (cheesy degeneration), and the cylindrical epithelium still existed, this had a

yellowish granular appearance, and the cells were misshapen, with indistinct outlines, and without cilia and a visible nucleus.

In the Fallopian tubes the tuberculous nodules were more isolated and more recent, so that the transformation of the epithelium was most distinctly observed.

The demonstration of the change in tuberculosis of the intestinal mucous membrane was more difficult, since the epithelium becomes detached and destroyed very soon after death. But, after having examined many tuberculous ulcers of the intestine, although I have not been able to obtain such demonstrative specimens as those in tuberculosis of the mucous membrane of the air-passages, uterus, and Fallopian tubes, I have in several cases been able to ascertain that the few epithelial cells still existing near the margins of the ulcers had all the appearance of pavement epithelial cells with large nuclei. This leads me to believe that the transformation in question takes place also in the intestine.

II. *Reproduction of Cylinder Epithelium.*—The results of the experiments on the reproduction of the ciliated cylinder epithelium of the larynx and trachea of dogs, published by me last year, may be reduced to two principal ones. 1. The newly produced epithelium, instead of preserving the type of the pre-existing epithelium, has the characters of pavement epithelium with very flattened cells, granular protoplasm, and a large nucleus with distinct nucleolus. 2. If, in scraping the trachea, we use a scraper with a sharp edge, a fibrinous false membrane is produced, having all the physical and chemical characters of the false membrane of croup; but this does not occur when a scraper with a blunt edge is used.

In some new experiments made during the present year, not only on dogs but also on rabbits, I ascertained in the former that, according as the scraping, even with a blunt-edged instrument, was forcible or slight, a fibrinous false membrane was or was not produced, the extent of which corresponded with that of the scraping. In the rabbit, the mucous membrane was found to be still more delicate, and very gentle scraping was necessary in order to avoid the production of fibrinous exudation; catarrhal exudation, however, was produced. In two cases, in which the scraping was rather forcible, a fibrinous false membrane was produced, which extended above the cartilaginous rings of the trachea, and was raised a millimètre above the level of the mucous membrane.

In all the experiments (thirty) which I have hitherto made on the trachea and larynx of dogs and rabbits, I have found that the newly produced epithelium is of the pavement kind, and is formed of one or several layers of cells, according to the time allowed to elapse after the scraping. By teasing out specimens, by immersion in Müller's solution and in macerating fluids, I have been able to observe other peculiarities in the structure of the newly formed cells.

If the epithelium be detached with a bistoury from the margin of the solution of continuity, and teased out, there are found greatly enlarged ciliated cylinder cells, with turbid granular protoplasm, and having a large nucleus tending to the round form, sometimes provided with two large very distinct nuclei; in rare cases, there are two smaller round nuclei, or the nucleus is undergoing division. Ver-

tical sections show that these are the last cells of the pre-existing epithelium, which have undergone turbid tumefaction or degeneration, in consequence of the traumatic irritation. Besides these, there are epithelial cells, ciliated indeed, but shorter than the normal cylinders, and very large. These cells have an irregular form, slender and scanty cilia, a finely granular protoplasm, and a large oval nucleus, with its longer diameter parallel to the ciliated margin, and therefore lying transversely to the cell. The opposite surface of the cell is of the same dimensions as or larger than the ciliated end, and presents more or less deep hemispherical depressions, or a single depression, with the concavity always directed downwards. The cell frequently presents at one side or below a lamellar expansion of greater or less length, which, when viewed in front, appears as a thin transparent lamina of slightly granular protoplasm. This expansion is not directed perpendicularly downwards, but in a horizontal direction, with only a slight obliquity. When these cells appear still in conjunction with the neighbouring ones, these expansions are seen to be turned in the same direction. In these preparations there are also seen many other ciliated cells with the characters above described, but gradually becoming shorter, until they are reduced to a thin protoplasmic lamella with long scanty cilia and flattened oval nuclei. Fragments of epithelium are often found containing all these forms of ciliated cells, and also fragments in which there are two series of cells, an upper ciliated one (the cells gradually becoming shortened) and a lower with large roundish granular cells with one or many nuclei, which insinuate themselves more or less deeply into the protoplasm of the cells of the first series, producing the depressions in them. In a front view, these epithelial fragments at first sight seem to be formed of very granular flat cells without distinct outlines; but on altering the forms, or causing the fragment to roll over, it is seen that the turbid granular appearance depends on the cilia, which, viewed in front, appear as obscure points. There are also seen spherical ciliated cells with an oval nucleus lying transversely, which have a perfect resemblance to the ciliated spherules met with in the mucous exudation of the first stage of acute coryza. Finally, there are non-ciliated pavement-cells, rather flat, with a large granular nucleus. These cells, when viewed in front, whether isolated or united in patches, appear to be of various shapes, but having a tendency to an elongated lozenge shape, with slender and long prolongations which are insinuated among the other cells; their protoplasm is finely granular, and their outlines pretty distinct; they have a very large round or oval nucleus, and some have two nuclei. From these patches of pavement epithelium proceed prolongations which narrow to a point, but never have their free extremities enlarged, and containing clear spherules, like the pseudopodia which Klebs, in the reproduction of epithelium in the frog's web, has seen emitted from the pre-existing cells, which become contracted, and to which he attaches much importance in the reproduction of pavement epithelium. These prolongations are nothing but the elongated extremities of marginal cells; and if the fact observed by Klebs were verified here, there should be no difficulty in finding cells which have emitted pseudopodia.

Transverse sections of the trachea corresponding to solutions of continuity in course of repair show that in rabbits a good quantity of epithelial tissue is

already produced fourteen days after the removal of the epithelium. Not being able to enter here into minute particulars, I will briefly describe the appearance which these sections generally present. In the normal vibratile cylinder epithelium at the margin of the solution of continuity, a copious infiltration of migratory cells takes place, which insinuate themselves into the turbid granular protoplasm of the swollen cylinder cells (this is observed a few hours after stripping off the epithelium.) Further inwards there are still ciliated epithelial cells; but among these, in the deep layers of the epithelium, there is a great increase of the number of round and oval cells which are normally present. In proceeding gradually from this point, the number of round cells increases, while in the superficial layer the ciliated cells become gradually shorter than the true cylinders. This new epithelium, immediately on leaving that already existing, begins to diminish in thickness and gradually becomes thinner; so that at last it comes to be formed of two layers of cells, then of a single layer of rather short ciliated cells with large nuclei, and finally of flattish non-ciliated cells with large round or oval nuclei, very like epithelioid cells. In two preparations from the trachea of the rabbit forty-three and forty-eight hours after removing the epithelium, in which a false membrane was produced, the newly produced epithelium, in uninterrupted continuity with that already existing, passes on to the false membrane, and lines its lateral walls and a good part of its upper surface. In the subjacent mucous membrane there are at first abundant extravasation of blood, which later become absorbed, and an infiltration of wandering cells, abundant at first, but becoming scanty after one or two days. It is not possible to make out any relation between the elements of the mucous membrane and the newly formed epithelium.

I have studied the reproduction of cylinder epithelium, ciliated and non-ciliated, in the mucous membrane of the cornua uteri of the dog, of the intestine, stomach, and gall-bladder; but, as my observations are not yet complete, I reserve further communication regarding them.

III. *Croupous Inflammation*.—By many clinical and pathological observers, croupous inflammation is placed among specific inflammations; and it is maintained that the false membranes produced in croup and diphtheria are not common exudations arising from violent simple irritation, but that they are characteristic of croup and diphtheria. But, in 1826, Bretonneau produced false membrane by injecting oil and tincture of cantharides into the trachea of dogs; and more lately Carbonaro of Naples, Delafond, and others have obtained the same result with oil of turpentine, dilute sulphuric acid, nitrate of silver, chlorine, corrosive sublimate, ammonia, etc. Croup has also been observed in children after the inhalation of chlorine and after the entrance of boiling water into the larynx. In all these observations microscopic examination was wanting, and it is only recently that more definite results have been obtained by the labours of Reitz, Trendelenburg, Oertel, and others. They have shown that false membranes exactly resembling those of croup may be produced by the introduction of diluted ammonia into the trachea of rabbits. It proved that these results must strike a severe blow at the prevailing ideas regarding the specific nature of croup; when Bayer

and Mayer, having repeated the experiments, alleged that true croupal false membrane was not produced by ammonia, but only a dense catarrhal exudation. It therefore seemed to me of great interest to ascertain how much truth there was in these contradictory observations. During the past year I have made numerous experiments on dogs, first with weak, and then with pure, ammonia, waiting for the death of the animals, or killing them at various times after the instillation of four to eight drops of ammonia into the trachea. Without entering into minute particulars, the following are the results to which my experiments have led me.

1. If very weak or diluted ammonia be introduced through a tracheal fistula into the air-passages of a dog, the only result is excessive hyperæmia with abundant mucous exudation (acute catarrhal inflammation).

2. If strong ammonia be introduced, the animal dies after a period varying from twenty-eight to sixty hours, and in the trachea are found greyish-white false membranes of varying thickness, sometimes amounting to 0.08 inch, which sometimes line the trachea like a tube, and sometimes appear as large patches scattered here and there. When examined in the fresh state under the microscope, they are seen to consist of a network of glistening white fibres, with wandering cells in the meshes. Strong acetic acid causes the fibrous network to disappear. There is therefore not a catarrhal exudation, but real fibrinous false membrane, which behaves with acetic acid and solution of chloride of sodium just like croupous false membranes in man. Vertical sections of the larynx and trachea corresponding to the artificially produced false membranes, revealed other points of resemblance to ordinary human croup, viz., the shedding of the epithelium, of which only a few cells remained around the openings of the gland-ducts; the raising of the false membranes at points corresponding to the gland-ducts by the mucous secretion which could not be poured out on the mucous membrane; and finally the peculiar glistening appearance of the membrane and its intimate structure, especially in the stratified arrangement of the network, which consisted of large trabeculæ lying parallel to the mucous membrane, and giving off smaller anastomosing trabeculæ upwards and downwards.

3. In one case I observed abundant bacteria and micrococci, which could be seen by the naked eye in the form of small white patches scattered here and there over the false membrane, and over the trachea and bronchi, where there was no false membrane. But in this case the dog had been dead some hours; while in other cases these organisms were quite absent. I therefore fully believe that the coincidence was accidental; and this still further proves how, in a favourable soil, micrococci and bacteria introduced with the inspired air multiply prodigiously. It cannot be said, then, that they existed from the first, and that they, and not the ammonia, produced the croup.

I also produced large fibrinous false membranes by injecting into the trachea of dogs, by a cannula and syringe, a drachm or a drachm and a half of a four per cent. solution of tartar emetic; while in other experiments the injection of ten or fifteen drops of the same solution produced simple inflammation without false membrane.

Not only by chemical means, but by mechanical—that is, by scraping the mucous membrane of the

trachea—have I been able to produce croupous false membranes. According as the scraping was forcible or gentle, and was made with a sharp or blunt-edged instrument, the exudation produced was simply catarrhal or croupous. I have no doubt whatever of the nature of the false membranes produced by chemical or mechanical means, inasmuch as they present in all respects the naked eye appearance, the chemical reaction, and the microscopic structure of the false membrane of croup.

I have obtained fibrinous false membranes perfectly similar to those in the trachea, by the action of ammonia on the mucous membrane of the nares.

If, then, a true form of croupous inflammation can be produced artificially by a common irritant—ammonia—and if the same substance, used in the diluted state, produces in dogs common catarrhal inflammation, there ought to be no hesitation in abandoning all idea of the specific nature of croup. The production of a croupous or of a catarrhal exudation by forcible or by gentle scraping, or by the use of a sharp or blunt scraper, shows further that, independently of chemical action, the nature of the exudation is in relation to the irritation; weak irritation producing catarrhal, and strong, croupous exudation.

4. *Catarrhal Inflammation.*—It is commonly believed by pathologists that in every case of inflammation of cylinder epithelium there is an abundant production of mucus, which is derived not only from the muciparous glands, but in great part from the cylindrical cells, which, in the normal state, may be considered as unicellular muciparous glands. I have observed, in some cases of inflammation artificially produced by the injection of tincture of iodine or tartar emetic into the trachea of dogs, that sometimes the cells, instead of producing mucus, become tumid with turbid protoplasm, formed of large highly refractive granules, which often completely hide the nucleus. On treatment with acetic acid, the large granules entirely disappear, the cells become pale, homogeneous and transparent, and the nucleus appears. Here, then, there is not precipitated mucus, but large albuminoid granules—the albuminoid degeneration of Virchow. Treatment with Müller's solution causes the protoplasm to swell up, and the cells burst and are transformed into goblet-cells. I have met with this change in natural pathological processes, as in a case of tuberculosis of the uterus and Fallopian tubes, and in catarrhal bronchitis.

In other cases of artificial inflammation of the larynx and trachea, I have found many of the vibratile cylinder cells rather enlarged, with two generally oval nuclei, one of which lies in the upper part of the cell near the ciliated border, and has its greater diameter perpendicular to that of the cell. A few others present the ciliated border, detached and raised from the margins of the cells, but united to a certain portion of nucleated granular protoplasm, of a form tending to spherical; this protoplasm being sharply defined from the remainder of the cell by a clear line. This is, perhaps, a mode or production of the so-called ciliated spherules, a goblet-cell being left remaining. But it is very probable that the greater number of ciliated spherules observed in catarrhal exudations proceed from the spherical and oval cells of the deep layers, which, as we have seen in cases of reproduction of epithelium, being capable of becoming ciliated before assuming the cylindrical form, are pushed up first to take the place of the cylindrical cells which have

fallen off, and then are eliminated, the subjacent cells continuing to grow, and a copious infiltration of migratory cells taking place. In vertical sections there are found ciliated spherules with an oval nucleus lying transversely, lying at the level of the free ciliated extremity of the neighbouring cylindrical cells, there being below the spherules no portion whatever of cylindrical cell, which would be seen if the ciliated spherules arose, as Ranvier asserts, from the division of the cylinders. Besides this, I have never been able to observe a cylindrical cell in course of fission. The goblet-cells are formed independently of the production of ciliated spherules by the mucous transformation of a portion of their protoplasm and the elimination of the mucus in the form of drops, to which the plateau of the cell, deprived of cilia, frequently adheres.

In a case of inflammation of the trachea, induced by tartar emetic, the cylindrical cells which produced mucus and were transformed into goblet-cells, were united in groups at various points, separated by a considerable interval from the ciliated cells, which were only tumid and granular.

I have also observed in the deep layers of the epithelium of the trachea round cells reduced to a large transparent vesicle with an oval nucleus, pushed towards the periphery, and having scanty protoplasm at its ends. Hæmatoxylin, which precipitates and colours mucus, renders the clear part of the cell granular and strongly coloured. Here, then, there is not cellular dropsy, but mucous degeneration.

SATTLETON ON CONJUNCTIVAL DIPHTHERIA.

In the *New York Medical Record* for August 7, is a communication by Dr. Robert Sattler on diphtheria of the conjunctiva. He writes:

Within the last few months a number of patients have presented themselves at the clinics of the Ophthalmic and Aural Institute, suffering from conjunctivitis diphtheritica, the disease assuming somewhat of an epidemic character. The comparatively infrequent occurrence of this disease in America has been a sufficient inducement for the publication of some of the cases, and for a review of the clinical history and literature of conjunctivitis diphtheritica.

Diphtheritic conjunctivitis is of frequent occurrence in Germany, especially in the northern part. In some of the cities, particularly Berlin, the disease has repeatedly assumed the character of an epidemic. In Berlin, epidemics were described by Von Graefe and Hirschberg in 1852-54, and also in 1866-70; commonly in the spring and autumn months. A small epidemic is reported by Horner, of Zürich, in 1869. During a period of five years, Jacobson of Königsberg observed, among 10,000 eye patients, forty cases of sporadic and twenty-two cases of epidemic diphtheritic conjunctivitis. In Switzerland, Belgium, England, France, Russia, and America, only isolated cases have occurred, and the disease has never assumed the character of an epidemic.

Diphtheritic conjunctivitis usually develops acutely in most of the cases. It occurs as 1, an idiopathic affection of the conjunctiva, or as 2, a complication of other affections of the conjunctival membrane (catarrhal and trachomatous conjunctivitis), or 3, it complicates diphtheritic affections of the pharynx or larynx, which, however, happens very rarely.

In the cases enumerated below, the disease occurred as a complication in four cases; in two cases

the disease manifested itself without any antecedent ocular trouble or constitutional affection. In one of the last cases, the history was obtained from the brother, who stated that the patient, for several days before the disease manifested itself, was permitted to play with a child affected with diphtheritic sore throat, and that this child had frequent attacks of violent coughing.

The disease seems to attack children more frequently than adults, and occurs as frequently as an affection of one eye as of both. Those of a scrofulous or tainted constitution, and especially those suffering or having suffered from antecedent ocular trouble, dependent upon a constitutional taint, are more prone to this disease. The disease may limit itself to certain portions of the conjunctiva, or it may involve the entire conjunctival membrane.

Several varieties or forms of the disease have been described by Von Graefe and Hirschberg. The latter mentions three varieties:

1. The disseminate or partial form.
2. The confluent form.
3. The diffuse form. (Von Graefe has described this as the confluent.)

The disease may be commonly divided into four stages: 1. An initiatory or catarrhal stage, which, however, is not always present, and if present is generally of short duration; 2. the stage of deposition and diphtheritic infiltration; 3. blennorrhœal; and 4, the stage of cicatrisation.

The disease usually commences abruptly, with marked and rapidly progressing swelling, and a feeling of heaviness and stiffness of the eyelids. The lids are excessively painful to pressure. The local temperature is generally very decidedly increased. On opening the eyelids a thin, hot, yellowish fluid exudes. These symptoms become rapidly more pronounced, the disease often reaching its maximum intensity in the course of one or two days.

The swelling of the eyelids, as the disease advances, becomes more tense and harder, and excessively hot and painful. The cutaneous surface presents a stretched and shining appearance. The discharge is moderate, as compared with a case of acute blennorrhœa. Every attempt to open the lids is followed by a gush of thin yellowish fluid containing flocculi.

On examination of the conjunctiva, at the commencement, it will generally be found that the diseased process commences in some portion of the conjunctiva tarsi, and there limits itself, or it extends over the fornix to the conjunctiva of the sclerotic, thus infiltrating the conjunctival membrane in its totality, and even overlapping the cornea to a certain extent. The diseased conjunctiva, instead of presenting its natural pale red colour, now is pale white or yellowish, the result of an infiltration of a fibrinous product in the subepithelial, tunica propria, and subconjunctival layers. The conjunctiva is more or less elevated or thickened; its surface is very finely granular. At different points it presents a drawn-in or puckered appearance. The colour of the diseased conjunctiva varies from a pale yellowish to a blanched or glistening white.

As the disease advances, the swelling of the lids becomes more and more tense, red, and painful. The chemosis of the ocular conjunctiva becomes more pronounced, it often encircling the cornea like a hard and unyielding wall. The discharge also increases; it is straw-coloured, and contains more flocculi. Constitutional disturbance usually is present

at this time, if it has not manifested itself before. There is an increased bodily temperature, the thermometer ranging from 100° to $103\frac{1}{2}^{\circ}$, accompanied by the usual symptoms of fever, anorexia, malaise, prostration, etc.

After the disease has existed from four to eight or nine days, the transition into the third or blennorrhœal stage takes place. The swelling, redness, and tenderness of the lids diminish. The external surface of the lid has lost its tense and glossy appearance, and the eyelids are soft and wrinkled. The thin flocculent discharge changes into a creamy pus. On examination of the eyelids, they are more readily everted, and the diseased conjunctival surface is now changed; it is no longer white and shining, but red and somewhat irregular. At the places of the white and somewhat raised infiltration we see ulcers, with an irregular base and ragged outline, the result of the necrosis of the tissue. Conjunctival hæmorrhages are now apt to occur.

In the conjunctiva tarsi, deep cicatrices most frequently result. The scars which form in this locality leave more unfavourable consequences (entropion, trichiasis, etc.) than those occurring in the fornix or lower lid.

The third or blennorrhœal stage varies in duration from two to eight or ten weeks, a partial relapse often taking place in this stage.

The fourth, or stage of cicatrisation, is also of variable duration, and the boundary line between it and the third stage is not sharply defined. In this stage of the disease cicatrisation goes on, and cicatrices of greater or less extent and depth result. Often the cicatrices, especially in children, are superficial and of no considerable depth, escaping observation in many cases. The cicatrices, as before stated, are generally confined to the tarsal conjunctiva of the upper lid, serious deformities of the lid resulting in many cases.

Complications of the cornea may occur at any stage of the disease, assuming the character of central and marginal ulcerations. The most destructive and rapidly progressing corneal complications are met with in the second stage of the disease.

Complication of the cornea manifests itself by objective and subjective symptoms.

A slight circumscribed and uniform haziness of the cornea appears, usually in its central portion, or it may occur at the margin or at any part of the cornea; in some cases the whole cornea becomes uniformly hazy and infiltrated.

When this condition is once present, its course is generally rapid. The ulcerative process advances rapidly and leads to partial or total destruction of the cornea. When the destructive process reaches the membrane of Descemet, the ulceration is in some cases temporarily arrested; this layer bulges, and the centre of the ulcer now presents a shining or bead-like appearance, after which, perforation almost invariably follows. Corneal complications in this stage (second) almost inevitably result in perforation.

The central ulcers are commonly deep and circumscribed, whereas the peripheral ulcers are more superficial and extensive.

Corneal complications occurring in the third stage are much less destructive and less rapid in their course, the ulceration much resembling the corneal complication in conjunctivitis blennorrhœica. In the last stage (cicatrisation) corneal complications

are rare, and, if they occur, are dependent on the mechanical irritation of the cicatrices.

Mention is made by Samisch of an implication of the lower lid, the inflammation there assuming a diphtheritic character and resulting in the formation of abscesses. He ascribes this in part to a propagation of the diphtheritic process from the conjunctiva, and in part also to the corroding effect of the secretions, from the constant contact of the mucous membrane of the swollen and pendent upper lid with the outer marginal portion of the lower lid. A peculiar diffuse inflammation of the cellular tissue of both upper and lower lids was observed in one of my cases; small superficial abscesses resulting near the marginal portion of the lid.

Conjunctivitis diphtheritica must be considered as highly contagious. It was observed (von Graefe) that the secretion from a case of blennorrhœa developed the disease. In one case the disease evidently originated as a result of the direct conveyance of a detached portion of the diphtheritic product from a child suffering from diphtheritic sore-throat, during an attack of coughing.

In a certain number of cases, conjunctivitis diphtheritica is developed in persons suffering from constitutional disease, or diphtheria of the larynx or pharynx; whereas, in other cases, it occurs solely as a local or independent affection of the conjunctiva, or as a complication of chronic affections of the conjunctiva, in scrofulous or tainted subjects.

The prognosis in all cases of diphtheritic conjunctivitis is grave; depending on the extent of conjunctiva involved, rapidity of progress, early corneal complications, age and constitution, and the hygienic surroundings of the patient. Where the cornea is affected early in the disease, the prognosis is almost invariably bad.

Von Graefe observed nine total destructions of the eyeball among forty cases affected with the disease. Hirschberg, among ninety-four cases, found that thirty-four cases proved fatal, and fifty-four resulted in recovery.

Treatment.—Before mention is made of the treatment recommended by various authorities, I will briefly mention the treatment pursued in the cases enumerated below, which consisted mainly in local and also general measures, viz., placing the patient under the most favourable hygienic and dietetic influences possible.

When one eye was affected, the other was hermetically closed. In children this was found frequently impracticable, and was therefore abandoned. In adults it was invariably practised where one eye was still unaffected. Ice compresses were constantly applied, and the most scrupulous cleanliness observed. The eyes were cleansed every ten minutes with lukewarm water, to which a small quantity of salt had been added; the salt relieved the irritant effect which even the lukewarm water would produce.

After the blennorrhœal stage had set in, the cautious application of nitrate of silver was commenced. Corneal complications were treated with atropia.

The treatment of diphtheritic conjunctivitis, owing to the extreme danger of the disease, has engaged the attention and study of many prominent oculists. The use of strong solutions of nitrate of silver in the second stage is universally condemned, on the same ground that it is injurious in all fibrinous and croupous exudations of other mucous membranes. A strict antiphlogistic treatment in the form of con-

stant ice compresses is thought, and has clinically proven to be the most efficacious method. Ice applications are well borne by almost all patients.

Local abstraction of blood has been strongly recommended by von Graefe. He applied a number of leeches to the nose and temporal region.

Scarification of the healthy portion of the affected conjunctiva has been practised; this latter plan has, however, been abandoned, for the disease would frequently propagate itself to the incisions made.

Arteriotomy, or division of the outer commissure, has been recommended. This is certainly of value in lessening the pressure of the swollen eyelids upon the globe; but here also the danger exists of a diphtheritic infiltration of the lips of the wound. If the disease be only partial and the diseased process confined to the central portion of the conjunctiva tarsi, there is less danger, and here the performance of the operation may be considered warrantable.

Mercury has been strongly recommended (von Graefe and others). Jacobson substituted the application of moist warmth, where cold compresses were not tolerated by the patient. Bertin mentions a case where it was thought to hasten the appearance of the blennorrhoeal stage, by cauterisation; but this is considered an extremely dangerous and unwarrantable proceeding.

Ice applications, frequent and absolute cleanliness, and placing the patient under the most favourable hygienic and dietetic influences, comprise the chief and most beneficial remedial measures.

Illustrative cases are given.

J. MILNER FOTHERGILL, M.D.

POPOFF ON THE CHANGES IN THE BRAIN IN TYPHOID FEVER, IN TRAUMATIC INFLAMMATION, AND IN TYPHUS FEVER.

L. Popoff (*Virchow's Arch.*, xiii. 421, and *Centralblatt*, no. 37, 1875) under von Recklinghausen's direction examined the brains of twelve individuals who died of abdominal typhus. In all there were changes of an acute active inflammatory character in the vessels, in the neuroglia, and in the ganglionic cells. In the first of these, viz., the vessels, the cells in the walls, or the fat and pigment-cells applied to them, were in a state of proliferation; in the neuroglia there was division of the nuclei, and in the ganglion-cells both active proliferation processes and penetration of wandering cells. The former manifested themselves in division and increase in number of the nuclei, then in division of the protoplasm, whereby the individual parts either did or did not possess a nucleus. With regard to the occurrence of wandering cells, it is to be remarked that they lay partly around the cells (in the so-called perivascular spaces) and partly also within the nerve-cells, and by the penetration of such cells, division of ganglion-cells was often brought about. In the preparation, these wandering cells fell out of the ganglionic cells, so that the latter appeared as if perforated. Beyond being in and around the ganglion-cells, these wandering cells were arranged in rows around the vessels, and here and there along the nerve-fibres, but still preferably on the ganglionic cells.

Essentially the same changes were to be observed in inflammatory processes, and specially in traumatic inflammations, which were produced in a variety of ways upon dogs and rabbits, only here the active changes in the nerve-elements were more pronounced;

whilst in typhoid fever the penetration of the wandering cells was in full operation before the proliferation phenomena in the ganglion-cells occurred, and in addition many granule-cells appeared which were quite absent in the case of typhoid fever. Very interesting are the experiments in which the author injected colouring matters, specially China ink, into the brain. This curious result was obtained, that a short time after the injection the chief mass of the pigment lay in the ganglion-cells, which had evidently taken it up by virtue of their own forces, as wandering cells containing colouring-matter which could have accounted for the pigment were absent, and as nothing similar could be produced in dead brains. At this time granule-cells were still absent, but they were present in large quantities, and enclosed the pigment, after the inflammation had lasted longer, whilst the pigment could not, or could only in a very slight degree, be detected in the nerve-cells. The author concludes from this that the granule-cells which generally occur in the brain in acute inflammation are (in part at least) changed nerve-cells.

In another paper in the *Centralblatt* (no. 36) the author records the results of the examination of the brains of three patients who died of exanthematous typhus, in the wards of Professor Botkin, of St. Petersburg. In this disease also the author finds the following. (1) There is such a collection of the wandering cells in the perivascular spaces, as occurs in abdominal typhus. (2) There is also penetration of the wandering cells into the ganglion-cells, and division of nuclei in the latter. (3) There is infiltration of the neuroglia with young wandering cells. (4) The proliferation phenomena in the walls of the vessels are more pronounced and extensive here than in ileo-typhus. Infiltration of fat and pigment in the vascular walls may also be observed. Capillary extravasations are sometimes to be noted. (5) An interesting, but at the same time very striking result, is the formation, in typhus, of small nodules in the substance of the brain. They were found in the cortical substance of the cerebrum, cerebellum, corpus striatum, etc., and were 0.105–0.18 millimetre long, and 0.075–0.09 millimetre broad; they often had a rounded form. These nodules, with a low power, presented appearances very similar to miliary tubercle. Like the latter, they were found generally, though not always, next the vessels. With high powers (300 diameters) these nodules were seen to consist chiefly of indifferent newly formed elements, which could not be distinguished from lymph-corpuscles or white blood-corpuscles. Sometimes they consisted of such corpuscles alone, and this specially in the peripheral finely granular layers of the cerebrum and cerebellum. Where, however, in fibrous tissue nervous cellular elements were present in considerable proportions, as in other layers of the cerebrum, in the corpus striatum, other elements, nearly as large as the nuclei of the ganglion-cells, entered into their composition. The changes already described in the nerve-cells are often very pronounced around these nodules. In the first described form of nodule, consisting of indifferent elements like white blood-corpuscles, there is never a finely granular degeneration of the central part to be observed, as is often seen in tubercle. Neither giant-cells nor a special stroma were to be observed. These nodules, from their character and origin, are apparently completely analogous to the nodules described by Wagner as occurring in some parenchymatous organs, such as the liver and kidneys in abdominal typhus.

These nodules were observed in two cases out of the three. The relation of these nodules to the brain-symptoms, owing to the epidemic being at an end, was not made out. In both cases the patient died on the fourteenth day.

W. STIRLING, D.Sc., M.D.

SCHÜLLER ON THE CHANGES IN THE CEREBRAL VESSELS UNDER THE INFLUENCE OF THE EXTERNAL APPLICATION OF WATER.

M. Schüller (*Deutsch. Arch. f. Klin. Med.*, xiv. 566, and *Centralblatt*, no. 36) trepanned the skull of rabbits, and found that an obstruction to the outflow of venous blood, disturbance of the respiration, or pressure on the abdomen, produced strong injection of the pia mater. After section of the vagi this effect was not produced, on account of the preponderance of the inspiratory movements. Fear and pinching generally produced narrowing of the vessels, sometimes after previous dilatation. Ice applied to the exposed dura mater produced marked narrowing of the vessels, which was much weaker on the side from which the cervical sympathetic and the superior ganglion were excised. Cold applied to the abdomen produced an instantaneous dilatation of the vessels of the pia mater on the uninjured side, and generally no change upon the injured side. A moist warm compress on the abdomen, on the contrary, produced narrowing, which was succeeded by dilatation upon the compress cooling. Complete immersion, as a general rule, acted like a compress. The injection of cold, and generally also of warm water into the rectum, dilated the vessels. Packing with the wet sheet, whereby the animals became sleepy, was followed by a very temporary dilatation, which gradually passed into constriction. Similar results were obtained during opium-narcosis, but not by dry packing. Rubbing of the abdomen or back was accompanied with constriction or varying changes in the calibre of the vessels, but in a weaker degree when the sympathetic and the superior ganglion were extirpated.

The changes above described occurred also in curarised animals, although in this case the filling of the vessels of the brain was somewhat less pronounced. After section of the sympathetic at the second vertebra, there was a pronounced dilatation of all the vessels of the pia mater, and the application of water was without any effect upon it. Cold directly applied to the freely exposed cutaneous sensory nervous trunks which issue upon the back produced constriction; heat, dilatation of the vessels of the pia mater on the same side. Section of individual cutaneous nervous trunks was accompanied by a temporary dilatation of the vessels of the pia mater on the same side.

The blood-pressure in the carotid, from manometric observations, rose rapidly when cold water was applied to the abdomen, and then fell considerably; with warm water applications, it was just the reverse, with slight variations.

The occurrence of all these phenomena is explained by the author through the changes in the supply of blood to the vessels of the pia mater in consequence of a constriction or dilatation of the peripheral current-areas in the skin. The movements of the heart and respiration are only indirectly concerned in the result, at one time assisting, at another hindering. The reflex influence of the thermal stimu-

lation of the cutaneous nerves upon the vessels of the pia mater is, according to the author, of subsidiary importance, and acts rather in an inhibitory manner. The second phenomena which occur with long duration of the stimulus, and which are exactly opposite to the initial phenomena, may be explained by the changes in the conditions in the cutaneous vessels and their consequences.

From the results of his experiments the author draws the following conclusions regarding the therapeutical employment of different applications of water to the human organism. It produces (1) a restitution of the normal vascular tonus (specially of the brain); (2) the restoration of normal blood and lymph currents in the brain; (3) diminution of overfilling of the brain with blood; (4) the restoration of the normal nutrition of the nerve-elements; and (5) of the normal reflex relation between the cutaneous nerves and the brain. In the insane a 'methodical' water-treatment is for the most part not to be recommended, because one cannot say how far the resistance of the cerebral blood-vessels is to be depended upon. WM. STIRLING, D.Sc., M.D.

ANATOMY AND PHYSIOLOGY.

HEYNSIUS ON THE COMPOUNDS OF ALBUMEN, OF BLOOD-SERUM, AND OF WHITE OF EGG.—A. Heynsius (*Pflüger's Archiv*, ix. 514, and *Centralblatt*, no. 30, 1875) in the introduction to his paper, reviews the results of Schmidt, Eichwald, Landois, etc. The author justly prefers the method of heating after the addition of acetic acid and a few cubic centimetres of a concentrated solution of common salt (or sulphate of magnesia) as the best test for the presence of traces of albumen.

1. The author attempted to obtain solutions of albumen containing the smallest possible quantity of salts, and for this purpose employed a dialyser of special construction, and with a surface of two square centimetres. Rain-water was at first employed for the dialysis. White of egg, diluted with water and saturated with a solution of common salt, was dialysed for seven days. A considerable precipitate formed in the dialyser; the fluid filtered from this became turbid at 113° Fahr., and the filtrate of this at 118.4°. If a solution of common salt were added to it, both the temperature at which coagulation took place, and the temperature at which the albumen was completely separated, rose. The albumen could not be completely removed by boiling with a smaller quantity of salt than 0.4 per cent. The filtrate from this precipitate, when further dialysed, formed again a precipitate in the dialyser, and the filtrate from this became turbid even at 28°, with a neutral reaction. An addition of salt acts just as before. The blood of oxen and horses shows similar phenomena. There is, therefore, present in blood-serum and in white of egg a compound of albumen, which is decomposed at a low temperature. On the author employing distilled water instead of rain-water, he could no longer obtain this compound of albumen. From this it appeared that on using rain-water the solution of albumen in the dialyser very soon became neutral, but retained its alkaline reaction with distilled water. The same difference was shown by directly mixing the solution of albumen with water. There must, therefore, be a substance in the rain-water which fixes the alkali.

The zinc oxide contained in the rain-water was probably the substance. The experiments to prevent this action by careful acidulation failed. The author then reviews the results of Schmidt and Aronstein. The solution either free from or at least very poor in salts did not coagulate at 212° Fahr., and even when mixed with alcohol showed only a little turbidity, although it had constantly an alkaline reaction, which even in solutions poor in salts exercise a very disturbing influence on the coagulation. The author is of opinion that Schmidt and Aronstein overlooked this action. As they observed no coagulation in solutions acidulated with acetic acid, the author ascribes this to too strong acidulation. The author records experiments which show the disturbing influence of alkalies and acids in solutions poor in salts.

2. A solution of albumen, which became turbid at 105.8° Fahr. after dialysis was heated to 113° , and brought into solution by the addition of a little alkali in solution (four cubic centimetre of a one-tenth normal solution of potash to 0.568 albumen). A faintly turbid fluid of alkaline reaction, which showed the reactions of paraglobulin, resulted. After precipitation with acetic acid, it was only soluble in water and oxygen, as long as upon burning it left an ash which had an alkaline reaction. The author made no experiments upon the fibrino-plastic action of this solution. This precipitate in the dialyser gradually passed into insoluble albumen. The alkali-albuminates are varying bodies according to the concentration of the alkali employed for their preparation.

3. Just as the alkalies, so has the concentration of the acids an influence upon the properties of the acid albumen formed. Paraglobulin is scarcely soluble in carbonic acid; if the solution is allowed to stand, the carbonic acid disappears and the albumen is again excreted. If a stream of carbonic acid be passed through a solution of alkali albuminate, the coagulation-temperature is lowered. If a solution of white of egg be treated with varying quantities of acetic acid, then the temperature at which coagulation occurs rises. These phenomena, however, are only to be well observed when dilute acetic acid and relatively large quantities of albumen are employed.

WM. STIRLING, D.Sc., M.D.

FELTZ AND RITTER ON THE ACTION OF BILE AND ITS DIFFERENT ELEMENTS.—In Robin's *Journal de l'Anatomie et de la Physiologie* for March and April, we have the conclusion of MM. Feltz and Ritter's experimental researches on the action of bile and its different elements on the system. We avail ourselves of an abstract prepared for the *Detroit Review*.

The experiments were commenced by injecting fresh ox-bile into the veins of dogs; generally one of the veins of the neck was chosen. The experiments were made with great care. The condition of the animals subsequent to the injections was minutely noted. Analyses of the blood and urine were made, and the results arrived at were, briefly, as follows.

Fresh bile has no serious action on the economy, unless introduced in large quantities. In doses of from two to eight grammes the bile is rapidly eliminated by the kidneys, the salivary glands, and the intestines. The animal only experiences a temporary malaise. After larger doses the symptoms become more grave; bilious diarrhœa sets in, with vomiting, first of the food, then of bile and blood; the urine becomes bloody; the animal loses flesh rapidly and refuses food; the temperature is below normal. But

in spite of the gravity of the symptoms, the animal usually recovers, if the poisoning is interrupted before the nervous system is affected.

In large doses of from fifteen to twenty-five cubic centimètres bile is a violent poison, producing, first tetanic convulsions, then coma and death. In none of these experiments was any yellow colouring of either the sclerotic or mucous membranes observed. The blood did not coagulate readily; seemed more fluid than normal. The serum was coloured red, showing an escape of the colouring matter of the corpuscles. The globules themselves had lost their elasticity. If compressed by pressure of the covering glass, on a glass slide, under a microscope, they did not recover their form when the pressure was removed.

Indican was found in the urine, as well as the biliary salts, and a feeble proportion of the colouring matters of the bile.

In the next series of experiments the biliary salts obtained from ox-bile were injected into the veins. A mixture of the glyco-cholate and tauro-cholate of sodium was first used, and in subsequent experiments the salts were employed separately. It was found that the mixture of the salts was, when used in any considerable quantity, an active poison. The system re-acted vigorously in the effort to throw off the poison, and a great increase of all the secretions was the result. The intoxication manifests itself especially in the red corpuscles of the blood. These were dissolved; their colouring matter escaped largely in the urine, and in one or two instances crystals were found in the blood. This altered condition of the blood produced difficult circulation, rupture of the capillaries, and consequently hæmorrhage from the mucous surfaces.

If the action of the poison were slow, fatty degeneration of the liver and kidneys was produced. In view of the fact that these lesions of the liver, kidneys and blood, are those noted by the best authors as characteristics of severe cases of jaundice, it is suggested that the alarming accidents often arising in these cases, as hæmorrhage or convulsions, may be due to individual conditions which increase the secretion or retention of those salts.

The salts were found identical in the character of their action on the system, but not in the degree—the tauro-cholate being very much more energetic than the glyco-cholate.

The derivatives of the acids of the bile are next studied. Glyco-cholic acid breaks up into cholic acid and glycocoll; tauro-cholic acid into cholic acid and taurine. Cholic acid, by the loss of successive molecules of water, may be transformed into choloidic acid and dyslysine. Of all these substances, cholic acid alone was found to have any effect on the system. Its effects resemble those of the biliary salts, but are incomparably weaker.

The colouring matters of the bile are rapidly eliminated by the kidneys, and produce, beyond an obstinate constipation, slight lowering of the temperature and increase in the quantity of the urine, no marked effect upon the system. To produce even a slight and transient jaundice, it was necessary to inject very large doses.

From the injections made with cholesterine, it was concluded that cholesterine is not a poison in itself, but that it may accumulate in the blood beyond the maximum of its solubility, and in that case it becomes a cause of emboli, which of course depend for their gravity on their situation.

ARNOLD ON THE CONDITION OF THE WALLS OF THE VESSELS DURING THE EMIGRATION OF WHITE BLOOD-CORPUSCLES.—Dr. Jul. Arnold, of Heidelberg (Virchow's *Archiv*, vol. lxii.) has examined the conditions under which red blood-corpuscles emigrate, and the question arose whether the white blood-corpuscles leave the walls of the vessels in the same manner, or whether they penetrate the epithelial plates themselves. To decide this question, he examined the mesentery, the tongue and the bladder of the *rana temporaria* and the *rana esculenta*, and found that generally the white corpuscles leave the vessels by means of stigmata. The irritation of the organs was caused in different ways. Thus, the mesentery was exposed for a few hours to the atmosphere, while the tongue was injured and the bladder was injected by a weak solution of nitrate of silver. Infusions of cinnabar into the blood were also made with the view to colour the white blood-corpuscles. Twenty-four hours after the operation the animals were bled to death, and then the circulatory system was injected from the aortic bulb by a solution of nitrate of silver from $\frac{1}{3000}$ to $\frac{1}{3000}$. The examination of the preparation took place immediately in a three-fourths per cent. solution of chloride of soda, or after colouring with carmine in glycerine.

The white corpuscles could be observed in numerous phases of emigration. The transmigration always took place at certain points (stigmata). Had the process of emigration been stopped in time, the emigrated blood-corpuscles were to be seen in the sheath of vessels, or at a short distance from this. The form of the white corpuscles is elongated in the state of escape. Many of them have prolongations, fixed in the stigmata. Sometimes numbers of white corpuscles accumulate on the outer wall of the vessels, so that the lining epithelial membrane appears to be separated from the sheath of the vessel. The author never observed that the plates themselves were penetrated by the white corpuscles.

As a result of the disturbance in circulation, combined with the emigration of white blood-corpuscles, it was found that the borders of the cells forming the vessels are not so distinct as in a normal state. Between them are a greater number of dark spots (stigmata) than in a normal state, generally not so large that red blood-corpuscles could pass them. Dr. Arnold observed that granules of cinnabar, as well as colloid substances, may leave the vessels through the stigmata. The cause of the easier penetrability of the vessels may be found in an alteration of the condition of the cement connecting their cells.

A great number of the emigrated white corpuscles are carried off by the lymph-vessels. The author thinks that with the disturbance in circulation during emigration there are connected currents directed towards the walls of the vessels, and that they are of different strength.

EBERTH ON BACTERIA IN PERSPIRATION.—Dr. Eberth, of Zürich (Virchow's *Archiv*, vol. lxiii.) found, by aid of the microscope, in the sweat from the face, some corpuscles which he considered as bacteria. This view became confirmed when he examined the axilla, breast, and inner side of the thigh of several persons in a state of perspiration. The sweat of these parts contained nearly always enormous numbers of bacteria. In most cases they originated from minute bodies found upon the hairs in the mentioned regions, forming little nodules on them, and giving them a greyish or a brick colour.

They were recognised by the author as accumulations of micrococci. They may rapidly increase in number, are smaller than the diphtherial micrococci, and are nearly indifferent to reagents (concentrated acids, alkalies, alcohol, ether, chloroform). Iodine colours them yellow. The vegetation of bacteria on the hairs may be observed in cases where they are changed already, beginning in places which have clefts between their cells. The vegetation occupies large spaces, especially in the direction of the longest diameter of the hair. Dr. Eberth observed a mycelium and micrococci, and thinks that the latter are the fruits of the former. Other investigators observed coloured sweat, red and blue, which contained micrococci. It was difficult to decide in these cases if the colouring matter was adherent to the micrococci, or if it was a product of the vegetation.

PATHOLOGY.

BOLLING ON A CASE OF EMBOLISM AND DISINTEGRATED THROMBUS OF THE PORTAL SYSTEM.—G. Bolling (*Hygiea*, 1874; *Nordiskt Medicin. Arkiv*, Band vii. Heft 2), relates the case of a book-seller, aged thirty-seven, who, having previously had good health, was suddenly attacked in June, 1874, with vomiting and fever. The vomiting soon ceased, and was followed by constipation. On July 5 and 6 he had severe rigors, after which icterus set in. Examination of the patient on the latter of these days showed severe fever, and distension of the abdomen, in which was felt a soft tumour extending to the umbilicus, and continuous with the liver; the spleen was enlarged; the urine contained biliary colouring matter and acids. On the 7th, in the afternoon, he suddenly had violent pains in the abdomen, and diarrhoea set in; this was followed by symptoms of severe peritonitis, and he died on the morning of the 10th.

At the necropsy, the left lobe of the liver was found to be much enlarged, extending down to the umbilicus. The free border of the lobe was adherent to the transverse colon; beneath the lobe was a large encapsuled cavity filled with puriform fluid. Similar fluid escaped from two abscesses lying outside the left lobe of the liver, the peritoneal covering of which had burst. Besides this, the left lobe of the liver was filled with abscesses containing thick yellow puriform matter. Dried cheesy matter was also found. Large and small patches with a yellow centre and greenish circumference were also seen in the parenchyma of the liver. All the portal vessels in the left lobe were filled with a yellow thick matter; and in the principal branches of the portal vein was a semisolid mass, which extended into the smaller branches. The omentum was adherent by false membranes in the region of the cæcum, and in one place was rolled up into a cord two fingers thick, which at the appendix vermiformis contained an abscess with green-yellow offensive pus. The veins in the cord contained partly puriform matter, partly firm fibrin. The spleen was considerably enlarged, with dark-red loose pulp.

Bolling considers that the illness began with perityphlitis and circumscribed peritonitis, which was followed by adhesion of the omentum and formation of unhealthy pus, thrombosis, and breaking down of thrombi in the omentum, and embolism of the left lobe of the liver. The rigors he connects with the incipient breaking down of the thrombi, and the formation of multiple abscesses in the liver. The enlargement of the spleen he explains by blood-poisoning, arising from absorption of the constituents of the bile into the blood or from septicæmic infection.

LEVERTIN AND AXEL KEY ON A CASE OF PERFORATING ULCER OF THE DUODENUM.—In this case, recorded in the *Hygiea* for 1874 (*Nordiskt Medicin. Arkiv*, vol. vii.), the patient, a woman aged fifty-one years, and very fat, suffered from uterine disease, attended with periodical paroxysms of severe pain in the hypogastrium; but otherwise her general health was good. After a slight attack of pain in the abdomen and constipation, she was suddenly seized with symptoms of peritonitis, and died in forty hours.

At the necropsy, diffuse peritonitis was found; and in the anterior wall of the duodenum, about a quarter of an inch from the pylorus, was a funnel-shaped ulcer, perfectly resembling a perforating ulcer of the stomach. The peritoneum around the perforation was loosely adherent to the under surface of the liver. From the borders of the ulcer two branches proceeded forwards and backwards, so as to nearly surround the intestine as with a ring. The anterior one appeared to be nearly healed, the edges of the mucous membrane being drawn closely together; the posterior one was undergoing cicatrization in some parts, and in another part there was a smaller round loss of substance in the mucous membrane, the base of the ulcer being formed of the thickened and hardened submucous tissue, a small portion of which was loose and perforated as far as the muscular tissue, as if there were a new formation of ulcer in an imperfectly cicatrised one. In the uterus there were found a number of intraparietal myomata, varying in size from a pea to a walnut; they partly projected into the uterine cavity.

Key regards it worthy of special remark that in

this case the unusually large and extensive duodenal ulcer, which was probably of long standing, and apparently in course of healing when fresh ulceration set in, ran its course without any symptoms until perforation and its results occurred. The remarkable fatness of the patient indicated that the ulceration had not disturbed nutrition.

FRONMÜLLER ON A CASE OF TRANSPOSITION OF THE VISCERA.—A case of transposition of the viscera is recorded by Dr. Fronmüller, of Fürth, in Betz's *Memorabilien*, Jahrgang xx. The subject was a woman aged sixty-two, who died of disease of the heart. The following appearances were found at the necropsy.

The right lung had only two, the left three lobes. The heart reached far to the right of the sternum; the apex lay near the sixth and seventh right ribs, and the base behind the left border of the sternum, near the fourth and fifth ribs. The pulmonary artery crossed the aorta from left to right, and from below upwards. The auricles and ventricles were inverted. The large lobe of the liver, with the gall-bladder, lay on the left hypochondrium; the small lobe and the spleen to the right. The stomach was inverted; the cardiac orifice lay to the right of the spinal column, and the pylorus to the left; the duodenum was also inverted. The head of the pancreas lay to the left, and the tail to the right. The cæcum and vermiform appendix were found in the left lumbar region; the ascending colon was situated on the left, and the descending colon and rectum on the right side.

Dr. Fronmüller remarks that this was the second case of inversion of the viscera that he had met with in a practice of forty-one years. The case is interesting, as the individual had lived sixty-two years without any inconvenience from the anomaly of which she was the subject. She used her left hand in preference to the right in grasping objects. The other case was observed by Dr. Fronmüller, in 1858, and described at the time in the *Memorabilien*. The subject was at that time seventeen years old, and is now a strong and healthy man. Dr. Fronmüller exhibited him at a meeting of the medical profession of Middle Franconia, and at the hospital in Erlangen, where the diagnosis of inversion was confirmed. This man is right-handed. A. HENRY, M.D.

LAMÉTRIE ON PRIMARY CANCER OF THE GALL-BLADDER.—The *Journal des Connaissances Médicales* for July 30, 1875 (no. 14, année 43) remarks that primary cancer of the gall-bladder has attracted a good deal of attention since Messrs. Durand-Fardel and Cruveilhier first drew attention to the subject.* Secondary deposits of cancer in the liver are common enough. Primary malignant disease of the liver is, however, rare, though formerly regarded as common. We now know that, when nodules of cancer are found in the liver, the primary disease must generally be sought in some other part of the digestive tube, such as the pylorus, the lower end of the rectum, etc. We must not, however, regard primary cancer of the liver as a mere myth, since, although rare, there are carefully recorded cases of it, which are above suspicion. As regards cancer of

* See Villard [*Mouvement Médical*, 1870]; the article 'Biliaires' [Voies], by MM. Barth and Besnier in the *Dictionnaire Encyclopédique*; and M. Bertrand's *Thesis* [Paris, 1870], founded on work done in the laboratory of MM. Cornil and Ranvier.

the gall-bladder, one of its chief clinical and anatomical features is, that in nine-tenths of the cases it is associated with gall-stones, and with retention of bile. A case recently occurring in the wards of Dr. H. Henrot, at the Hôtel-Dieu Hospital at Reims, has many points of interest. It will be found reported at considerable length by M. Chatelain in Bulletin 13 of the Société Médicale de Reims. The patient, a woman aged forty-nine years, had never before suffered from any serious illness. In May, 1873, she became weaker, and lost appetite. In September and October she had feelings of oppression at the stomach, nausea, and vomiting. She lost flesh, had a vague feeling of pain confined to the epigastrium, and was jaundiced. On examining the abdomen, the epigastric region appeared to bulge more on the right than on the left. Palpation gave the impression of a hard and painful 'tumour' in this situation. Percussion signs were negative. Tongue whitish; anorexia; constipation. After December 14, 1873, her temperature was noted. It rose to 104.2° Fahr. that night. During the next few days she suffered intense pain in the right hypochondriac region. A violent rigor seized her suddenly. Her temperature rose to 105.8° Fahr., and her pulse to 110 (December 18); a profuse perspiration ended this crisis. Next day her pulse was 84. The sweatings had ceased, and two days afterwards the temperature had fallen to 97.8° Fahr. The left lobe of the liver, though not uneven, was manifestly greatly enlarged. On and after the 23rd, there were fresh rigors, with alternate sweatings and high temperatures. On the 28th her temperature was 106.5 Fahr., and from this time she was never quite free from a mild delirium. On the 30th there was more evident bulging of the right hypochondrium. It was clear that the tumour was enlarging. In the mammillary line the liver-dulness was nine inches in depth. The upper border of this dulness was nearly an inch higher than on the 26th. During January the still somewhat delirious patient vomited her food, with glairy mucus; diarrhoea followed, and her stools became extremely foetid, and were passed involuntarily. On the 18th she became comatose and died. At the necropsy, the whole liver was enlarged, measuring thirteen inches transversely by nine vertically. Near the suspensory ligament the left lobe had a small patch of softening, the capsule of Glisson and the peritoneum forming a little pocket here as large as a nut, containing some greenish purulent fluid. Otherwise the upper surface was healthy. The inferior surface of the liver was almost all occupied by a milk-white mass, of cauliflower-like aspect, rather firm, and on section dead white, and furnishing, when scraped, a colourless fluid. The gall-bladder and the hepatic, cystic, and common bile-ducts were all comprised within this mass. Microscopic examination showed it to consist of encephaloid cancer. The pylorus was pressed downwards, and the first and second portions of the duodenum had formed a deep channel in this mass of cancer, which had begun to invade the pancreas. Except at the pylorus, the stomach was quite free from disease, but there it was not only attached to but slightly implicated in the tumour. On the posterior wall of the descending portion of the duodenum there was an irregular opening which admitted the finger, which then found itself in a large and tortuous (*anfractuosa*) cavity in the midst of the cancerous mass, filled with a thick greenish-black, and somewhat viscid fluid. On opening this cavity, a diverticulum

was seen, containing from forty-five to fifty gall-stones, composed of nearly pure cholesterol. Here the tumour itself was somewhat reticulated, and contained some small calculi embedded in it. The bile-ducts in the liver, especially in the left lobe, were alternately dilated and contracted, presenting a beaded or rosary-like appearance. There was a little ascites. Reviewing the case, we have, first jaundice, beginning at the age of forty-five, and persisting; next fever, with enlargement of the right lobe of the liver; then a tumour. Diagnosis was difficult; it might be abscess originating in gall-stones. The presence of fever seemed at first to negative encephaloid cancer. It certainly is rare in such cases. Dr. Henrot thought the rigors due to the retention of bile. He also attributed the small calculi embedded in the mass to this retention. In many cases retention of bile (of which the rigors, the high fever, and the delirium, were signs), is due to the smaller bile-ducts. In this case the larger passages were invaded by the cancer, and caused the retention.

W. BATHURST WOODMAN, M.D.

RIEMER ON A CASE OF ARGYRIA.—B. Riemer (*Archiv der Heilkunde*, xvi. 296, and *Centralblatt für die Medicin. Wissenschaften*, no. 41, 1875) describes a case of this affection in a patient suffering from tabes. The use of the nitrate of silver in the form of pill was continued for about two years; the whole quantity swallowed was 43 grammes, corresponding to 21.6 grammes of metallic silver. The first traces of the discoloration of the skin were observed after the drug had been taken for about a year. The patient died of pulmonary phthisis. The *post mortem* appearances were the following.

Beyond the skin, which was the organ most fully investigated, there was a greyish blue varying to dark blue colouration of the lining membrane of the aorta, of the choroid plexus, of the smallest arteries of the stomach and intestines, of the connective tissue of the intestinal mucous membrane, and of the muscular coat of the intestinal tract, in the interarcinous connective tissue of the liver (slight cirrhosis); in the capsule, trabeculae, and vessels of the spleen; in the peritoneum, in the vascular loops of the glomeruli, the membrana propria of the urinary tubules, the capsule; and the connective tissue of the renal papillae; in the albuginea of the testicle and the membrana propria of the seminal tubules; in the mesenteric glands; in the intermuscular connective tissue of the heart, and in the thickened endocardium; in the dura mater; and lastly, in the perichondrium and periosteum of various parts of the body. Everywhere the pigment was generally accumulated in a finely granular, seldom in a linear or diffuse form, in the ground-substance of the connective tissue, in the homogeneous membranes, and was not combined with the cells nor with the 'cement-substance' between the cells. In the skin, specially of the face, it was the upper layers of the corium, of which the connective tissue, non-striped muscular fibres, and glands were pigmented. The epithelium of the rete mucosum on the one hand, and the subcutaneous fat on the other, formed the sharply defined limits of the silver impregnation, which here also was specially pronounced in the basement membrane of the sweat and sebaceous glands and of the hair-bulbs, whilst the epithelium of the glands and their excretory ducts remained free. The author, from the difference in the silver colouring, distinguishes two sorts of tubular glands in the palm of the hand.

and sole of the foot. The one, the narrow non-coloured sort, with alternating epithelium, he regards as physiologically equivalent to the excretory tube; whilst the wide part of the gland filled with epithelium, strongly impregnated with silver, he regards as the proper secreting part of the gland. A pathological disturbance of function is not produced by the pigmentation; but Riemer believes, from an often observed folding in the sweat-gland tube, and a dilatation of the hair-sheath, corresponding to the attachment of the muscoli arrectores pilorum, that there is a diminution in the elasticity, whose origin is to be ascribed as well to the presence of the pigment as to the cutaneous atrophy. The nervous structures of the skin do not seem to bear any relation to the argyria.

The question as to how the silver colouration arises, the author answers after the mechanical theory of Virchow.

The pigment is taken up as such, *i.e.*, as reduced silver, from the intestinal canal, is partly deposited in the lymphatics, and partly goes into the blood, whence it passes through the vascular walls into the tissues. In favour of this theory, and against that one which assumes that the silver circulates in the blood as soluble silver albuminate, and which ascribes the reduction to the tissues, there are the following facts. 1. The colouring matter is not combined with any cell, in fact is not united to any distinct tissue element. 2. It is most abundant where the strongest juice-currents exist (sweat-glands). 3. A higher degree of density of the tissues, specially in the membranæ propriæ and the cutaneous muscles, with the difficulty of the movement of the tissue-juices, produce a deposition of the colouring matter. 4. The wall of the larger vessels is pigmented, whilst the physiologically equivalent lining coat of the capillaries, which offers no important resistance to the particles of silver, is uncoloured.

WM. STIRLING, D.Sc., M.D.

FOTHERGILL ON ATHEROMA.—In the *Philadelphia Medical Times* for August 7, is an article on atheroma by Dr. Milner Fothergill. He describes it as a parenchymatous inflammation of the arterial walls, a development of connective tissue under the tunica intima. It manifests itself in two forms: in the shape of patches at certain points, and in a more general form. The localised points are less interesting than the general form, except in so far as they point to strain as the great cause of this growth of connective tissue. The most striking illustration of the causal relationship of strain to atheroma is to be found in the circumstances under which atheroma is found in the lesser or pulmonic circulation. It is only when the blood-pressure in the pulmonary artery is raised by a lesion in the mitral valve, or by induration of the lung, when there is right-side hypertrophy induced, that this change is found in extrauterine life. Still this change is but a modification of growth; it is normal nutrition run riot, rather than a morbid process *per se*. For under similar circumstances the pulmonary artery and its valves have been found strengthened and enlarged, without anything that could be called atheroma ensuing. General atheroma is most commonly found in the subjects of chronic Bright's disease, where a high blood-pressure is maintained persistently for years. It is also a consequence of the over-distension of the arteries by the contraction of the enlarged and hypertrophied

left ventricle in aortic regurgitation. Atheroma is very commonly found along with aortic valvulitis; as the over-distension which causes the atheroma closes the aortic valves violently, and so sets up parenchymatous inflammation, or excessive tissue-growth there. Wherever the position of arteries exposes them to great strain, there atheroma is most pronounced. Thus the coronary vessels at the base of the aortic column are very commonly markedly more atheromatous than other parts of the arterial system, because they are subjected to the full force of the aortic recoil. The atheromatous change shows itself in its general form as minute rice-like bodies under the tunica intima, and in time the whole arterial wall is thickened and feels like leather. At other times it shows itself in circumscribed patches, forming swellings under the tunica intima. This swelling consists of connective tissue corpuscles. This course of atheroma is varied and instructive. These patches may become infiltrated with earthy salts, and ultimately form calcareous plates; or they may rapidly degenerate, and become like purée of peas, consisting of fatty corpuscles, *débris*, and cholesterine scales. These may wash away ultimately in the blood-current, and leave the atheromatous ulcer behind. In the more general form, this tissue change may become calcareous, and the arteries feel like so many clay-pipe stems; or a merely general hardening with some elongation ensues; and in some cases the thickened arteries are soft and friable. According to the progress of the atheromatous change is the prognosis. Its progress is widely different in certain people. In some it is a slow process, almost normal to age; in others, it readily undergoes degenerative changes. Atheroma is most apt to take on degenerative change in two classes of persons—the syphilitic, and the habitual drunkard. The marked atheromatous changes seen in the arteries of comparatively young persons almost always point to syphilis. It has been too much the rule to regard atheroma as being beyond the pale of therapeutic reach. Much, however, may be done to avert or delay its occurrence. In the syphilitic, specific treatment is desirable. In the gouty, the choice of such food as shall not lead to much nitrogenised waste—the cause of the sustained high blood-pressure—is to be inculcated. Parkes found a non-nitrogenised diet to lead to a distinctly lowered blood-pressure. Here potash, colchicum, and buchu are indicated, to get rid of the excess of azotised waste.

MEDICINE.

DA COSTA ON RESPIRATORY PERCUSSION.—

Under this title, Dr. Da Costa proposes (in a paper in the *American Journal of the Medical Sciences* for July, 1875) to class the differences developed during a full and a forced expiration. There is a decided difference in the note found under either circumstances compared with the sound elicited during quiet breathing. As regard inspiration, this is more readily detected than as regards expiration; and it is also much easier for the patient, as well as more generally applicable. A large series of observations were first made on healthy men, with the following results. The resonance is increased at the apex; and the same holds good from the border of the fourth rib downwards. This is more distinct upon the right than the left side. A forced expiration lessens resonance. The quality of the note is not much affected in any case. The same results were found in women, making allowances for their anatomical differences. In disease, respiratory percussion is valuable. In bronchitis it is useful; and if the structures of the lungs be implicated, the alteration of sound on full inspiration is not found; if the bronchitis be uncomplicated, it is as marked as in the healthy chest. In lobar pneumonia the effects of full inspiration on the percussion-note are not found until resolution is setting in, and this may show itself in advance even of returning crepitation. In chronic pneumonia this plan of examination enables the percussor to determine how far the lung structure is pervious to air, and often will tell of commencing improvement. It is also useful under the following circumstances. 'We see at times puzzling cases of persons who, with organic valvular disease, have been spitting blood, are perhaps born of consumptive families, and have suspicious physical signs at the apex of a lung, have impaired breathing, somewhat prolonged expiration, râles, slight percussion dulness. Is there, or is there not, tubercular disease? Very generally not. And we find the apparent dulness, due to heavy local congestion of the lung, with possibly slight tissue consolidation, wholly, or at least very largely disappearing under full held inspiration, far more so than if, with the same physical signs, there had been tubercular deposition.' In determining the amount of lung-implication in pleurisy it is valuable. Over the seat of a marked pleuritic effusion, actually no change takes place in the flat percussion-note. At the very edge, however, percussion, practised under held inspiration, strikingly clears the sound, or rather, brings out the contrast between pulmonary resonance above and the abrupt line of dulness. Of still greater value is respiratory percussion in those instances of pleuritic effusion in which we have blowing respiration at the back of the lung, and in which the question of co-existing pneumonia arises. If the blowing respiration be due to compression or consolidation, and not to hepatisation, decided clearness takes the place of dulness. The tympanitic note of the apex in pleuritic effusion is lost by full held inspiration. In phthisis, respiratory percussion is very useful. In the very early stages of tubercular deposit, when prolonged expiration is just beginning with enfeeblement of inspiration, and ordinary percussion shows but little or a doubtful difference between the two, respiratory percussion may help us greatly by making the difference more marked. When the deposit is

more decided, it will often be a means of gauging the amount of disease in the implicated portion of the lung. When in a case of phthisis we find the dulness on percussion no longer modified by forced inspiration, we have a certain test of the malady having progressed. When cavities have formed, the information furnished by percussion is most interesting. The percussion-note in full inspiration alters to dulness, and this whether we have that mixture of dull and tympanic sound encountered in percussing over cavities, or the cracked-pot sound, or the amphoric note. Some remnant of the peculiarity of the original sound may persist; but the character of the bulk of the sound is altered. It has become dull, and there is more resistance, and usually a higher pitch. Then follow several illustrative cases. The more rigid walls of bronchial dilatation are not thus modified. In pneumothorax, Dr. Da Costa thinks that respiratory dulness will often determine whether the opening into the pleural sac is closed or not. In pulmonary emphysema it helps to establish the disease, and to form an idea of its extent. In marked emphysema the excessively clear or vesiculo-tympanic note is unchanged, and the small amount of difference in the note in ordinary and full held inspiration is the measure of the amount of emphysema.

J. MILNER FOTHERGILL, M.D

GUTTMANN ON DISEASE OF THE SYMPATHETIC NERVE IN THE NECK.—

In the *Berliner Klinische Wochenschrift* for August 9, 1875, Dr. Paul Guttmann relates a case of disease of the cervical sympathetic nerve. The patient, a man aged forty-two, up to the last two years had enjoyed good health, with the exception of some slight pulmonary disorder. For about two years he had noticed that, except when he made some excessive bodily exertion, he perspired more freely on the left side of his face than he did on the right. The parts more particularly affected were the forehead, the nose, the chin, the cheek, and the ear. If he exerted himself, this condition spread over the scalp, covering the parietal and occipital parts of the head. The median line was an invariable boundary to this condition. The sweat, which had an acid reaction, stood in large drops over these parts.

When this excessive sweating took place, which was the case on his making even slight exertion, the parts affected became redder, and the temperature in the meatus auditorius was found to be from $\frac{2}{10}$ ths to $\frac{3}{10}$ ths of a degree Centigrade ($\frac{1}{4}$ th to $\frac{1}{2}$ th deg. Fahr.) higher on the left than on the right side. Nutrition and tactile sensibility were found to be equal on both sides. In rest, these differences between the two sides were found not to exist. Still further differences between the eyes were found. The pupil on the left side was found to be larger than that on the right, and the space between the lids on the left side was also larger, there being a considerable amount of exophthalmus. The left conjunctiva was also found to be more injected than the right. These differences were constant, whether during rest or exertion. During the thermo-vascular disturbances mentioned above, the lachrymal secretion was considerably increased on the left side. The sight and power of accommodation of both eyes was normal. With the exception of these abnormalities, and a somewhat phthisical condition of the lungs there was nothing else to be observed in the patient. Nothing could be discovered from external examination indicating that there was any pressure on the

sympathetic, but the nerve on the left side was more sensitive to pressure than on the right.

Experiments on animals in which the nerve has been divided, have shown that such division of the nerve causes contraction of the pupil, and narrowing of the space between the lids with retraction of the ball of the eye. The conditions observed in the case were very similar to those observed in animals in which the cut end of the nerve has been excited electrically. This would prove that the state of the patient's eye was owing to a state of irritation of the nerve. The disturbance of the vaso-motor nerves in the patient as shown by the blushing, sweating, etc., in the opinion of the writer, tends to prove that the centres of the vaso-motor nerves affected, and of the nerves supplying the pupil are placed close together, and in this case were both affected by the same irritation.

W. HENRY KESTEVEN.

CIANCIOSI ON A CASE OF SUPPURATIVE PNEUMONIA SUCCESSFULLY TREATED BY CARBOLIC ACID AND ESSENTIAL OIL OF TURPENTINE.—Dr. Angelo Ciansiosi reports in the *Indipendente* (no. 4, 1875), a case of traumatic pneumonia following a stab in the fifth right intercostal space. At the ninth month the wound was cicatrising, but pus gradually collected in the pleural cavity, and the wound re-opened to give exit to it. Towards the middle of February 1872 pus began to escape continually, and the patient also had difficult respiration and cough, accompanied by abundant purulent expectoration, fever with slight exacerbations in the evening, diarrhoea, and progressive emaciation. In April of the same year Dr. Ciansiosi saw the patient for the first time, and, on exploring the wound, from which issued pus mixed with bubbles of air, ascertained that the lung was penetrated, and arrived at the diagnosis of suppurative pneumonia with pyopneumo-thorax, consecutive or traumatic pneumonia, with effusion of blood in the right pleural cavity. He believed that the disease had become aggravated in consequence of the bodily exertion undergone by the patient when he left hospital to return home, imagining himself to be cured.

The diarrhoea was subdued by decoction of calumba root, and the cough alleviated by morphia. Dr. Ciansiosi then gave tonics, and injected into the pleura a solution of fifty centigrammes of carbolic acid in 200 grammes of infusion of cinchona. In about a month there was marked improvement; the febrile state ceased, the expectoration diminished, and less pus escaped from the wound. Oil of turpentine was also given, both by inhalation and internally; also tannic and benzoic acids. Complete recovery took place.

A. HENRY, M.D.

LYONS ON THE SIGNIFICANCE OF INVOLUNTARY EVACUATION IN APPARENT HEALTH.—The subjoined observations are from a lecture in the *Irish Hospital Gazette*, by Dr. Lyons.

I always attach great importance to the passing involuntarily of urine and faeces after the restoration of consciousness, and for these reasons. It is only to be accounted for by some extreme depression exercised on the pneumogastric and sympathetic nerves, and that influence can only be exercised by some very limited cause acting at the base of the brain.

The passage of urine and faeces involuntarily I have known to present itself as one of the earliest symptoms in cases of slowly forming tumours at the base of the brain. I well remember one very pain-

ful, lamentable, and, indeed, tragic case, in which this was the first noticeable symptom in what proved to be a prolonged history of a case of slowly forming tumour at the base of the brain. A gentleman, who was engaged to be married, was standing up to dance in a drawing-room, when the sphincters gave way, and the involuntary passage of faeces took place, and, singular to say, he was quite unconscious of it himself. Friends standing by were shocked, and hurried him from the room. He expressed the greatest astonishment when told what had occurred. Nobody seemed able to make out what was the matter. Some thought he must have been tipsy, but it was no such thing, for he was a man of singularly abstemious habits. Curious to say, he recovered voluntary power over the sphincters, and some time elapsed before this accident occurred again. In my experience, this symptom, which is often overlooked, is one of the earliest as well as most dangerous of those occurring in slowly forming central disease of the brain. I remember another case, in the person of a member of our profession, with whom I was driving to a consultation, when the same unpleasant accident occurred. He seemed perfectly unconscious of it, and had at the time no cerebral disturbance of any kind. In about two years subsequently he died of slowly forming centric disease of the brain. In the other case there was occasional recurrence of this symptom, and then the diagnosis of deeply seated tumour in the brain was made. He then was confined to bed; paralysis slowly forming ensued, and he died at the end of two and a half years from the first incident in the ball room. On *post mortem* examination, a tumour about the size of a small walnut was found lying at the base of the brain, projecting upon the pons, pressing a little upon it, but not destroying its substance. There is no doubt that it was just at the very incipient condition of this tumour that the accident occurred, from partial irritation at the origin of the pneumogastric nerves.

BIGELOW ON HYPERIDROSIS CURED BY THE LOCAL APPLICATION OF DIACHYLON PLASTER.—Dr. J. M. Bigelow (*New York Medical Journal*, June, 1875) reports a very obstinate case of sweating of the feet that had baffled all ordinary treatment, in which a speedy cure was effected by the local application of diachylon plaster. Putting the patient in bed, he applied the plaster as follows: After cutting it in strips of convenient width, he twisted them about each toe separately, and also applied them to the interdigital spaces, completely enveloping the whole foot, so that every portion of the sole, dorsum and toes of the feet was in close and immediate contact with the plaster. These strips were removed each morning, the feet carefully and thoroughly wiped with dry, heated flannel, and new plaster strips applied. For thirteen days this treatment was continued, when the plasters were removed, and the feet presented a healthy, normal appearance, free from the troublesome hyperidrosis.

SURGERY.

LEBOUCQ ON THE REPARATION OF FRAC-TURES.—Dr. H. Leboucq, in a short contribution to the *Annales et Bulletin de la Société de Médecine de Gand*, July, 1875, points out the following facts in connection with the structure of long bones, and the reparative process in these after fracture: 1. The spongy substance of bones presents a special archite-cture in relation to the function which each bone has to fulfil. 2. The deformities of a bone pro-ducing a modification in its statical conditions would also produce a modification in the architecture of the spongy substance. 3. In the special case of re-paration of a fracture, this phenomenon would be met with in parts beyond the seat of fracture, and would even extend to parts of the bone which on superficial examination might not appear to have undergone any modification. The modifications of

these parts are due to a change which has affected the whole bone. Dr. Leboucq thinks that one may, in describing the reparative process after fracture, distinguish two categories of phenomena. Those of the first phase tend to bring about union of the osseous fragments; they may be comprised in a general formula—proliferation of the osseous tissue and consequent formation of callus. This union takes place under abnormal conditions, the frac-tured bone being kept at perfect rest. When the function of the bone is renewed after consolidation, the second phase of the phenomena of reparation commences, having for its object the adaptation of the bone to its normal function. The statical modi-fications in the callus now take place. These are not always of the same nature, and cannot be ex-pressed by the denomination of absorption of callus. Though in some cases, as in simple fractures of the diaphyses of long bone in which consolidation has taken place without displacement, the callus may be totally absorbed in the course of a few years, in other cases, on the contrary, certain parts of the callus may acquire an ulterior development and form an integral part of the repaired bone. The statical modifications are not restricted to the tissue of the callus—that is to say, to the newly-formed bone—but extend to parts of the original osseous tissue more or less remote from the seat of injury. A de-scription is given of a right femur taken from the body of a man who died at the age of fifty years. This bone had been twice fractured, once, several years before death, at the upper part of the diaphy-sis, and again, six months before death, near the lower end of the bone. The union of the upper and older fracture, though firm, was very faulty, the fragments forming a marked angle with much over-riding and twisting. The head and neck of the femur were much depressed. Dr. Leboucq examined in a section of this fracture the arrangements of the series of curved lamellæ described by Meyer and Wolff as serving in the normal bone to strengthen the head and neck; and he found that, although the direction of the head and neck of the femur had been much altered, each of the three main series of lamellæ of the spongy tissue had maintained its proper position, or rather that this arrangement had been re-established in correspondence with the sur-face of application of the pressure of the trunk.

DOLBEAU ON THE OPERATIVE TREATMENT OF PSEUDARTHROSIS OF THE HUMERUS.—Professor Dolbeau, in a contribution to the *Bulletin Général de Thérapeutique*, July 15, 1875, assumes that in most of the cases of ununited fracture supposed to have been successfully treated by simple means, con-solidation had been merely retarded, and that there had been a coincidence of the union of the frag-ments, and the application of the remedial means. The fact is insisted upon that whenever the two op-posed extremities of the osseous fragments have become eburnated, the condition cannot be cured by such means of treatment as setons, injections, acupunc-ture, electric currents, etc., and no proceeding short of resection of the fragments can assure secondary consolidation, and consequently cure of the pseudar-throsis. This condition of eburnation is indicated by extreme mobility of the fragments, by long-standing of the pseudarthrosis, and by a sensation of crepitus obtained by rubbing over each other the two extren-ities of the broken bone. To sixteen cases of pseud-arthrosis of the humerus treated by resection and

suture, in eight of which the operation failed, M. Dolbeau adds a seventeenth from his own practice, in which a false joint in the humerus of a woman aged forty years was treated four years after the fracture, by resection of the eburnated ends of the fragments and by metallic suture. The operation was successful, and in a report sent to the author three years later it was stated that the fragments of the humerus were firmly united, that the movements of all the segments of the limb could be made with freedom, and that the nutrition of the parts below the seat of injury had been well maintained. In conclusion M. Dolbeau insists upon some essential points in the operative proceeding of applying a suture in cases of pseudarthrosis of the humerus. The incision through the soft parts should be extensive, but care be taken to avoid the important organs of the brachial region, especially the musculo-spiral nerve. The pseudarthrosis having been exposed, it should be laid freely open, so that each fragment may be made to protrude through the wound. In this proceeding the surgeon would do well, according to M. Dolbeau, to isolate the bone by stripping off the periosteum, not in order to preserve this membrane with regard to osseous reproduction, but simply that he may keep his knife close to bone, and so avoid wounding the musculo-spiral nerve, the position of which in cases of pseudarthrosis of the humerus is sometimes much altered. The section of the extremities of each fragment should be made very obliquely, in order that the surfaces of contact may be extensive, and that much shortening of the whole bone may be avoided. This stage of the operation is usually very difficult, and requires much care and consideration in its performance, as it is necessary that the axis of the arm and that of the fore-arm should remain as far as possible in their normal relations. The metallic wire should be passed through the whole thickness of the shaft of the bone, and not, as some surgeons think sufficient, through the anterior wall. M. Dolbeau prefers a multiplicity of sutures. The whole extremity should, before the removal of the patient to the ward, be rendered quite immovable by means of a plaster-of-Paris splint. The extraction of the metallic suture may be attended with much difficulty, and even require a second operation. In M. Dolbeau's case the suture, which was of silver wire, was broken in an attempt at extraction, and a considerable portion of it remained in the arm for more than a year. In order that this accident may be avoided it is recommended that iron wire be used, and that the number and direction of its turns be carefully noted at the time of the operation. W. JOHNSON SMITH.

BILLROTH ON TREATMENT OF RACHITIC DEFORMITIES.—Dr. Rahsohoff writes to *The Clinic* from Vienna :

When the German nosologists christened rachitis 'Englische Krankheit,' they could only have reflected upon the fact that the disease, although known to the patriarchs of the profession, was first only recognised and described by English authors in the first half of the seventeenth century. To-day, rickety processes are as widely disseminated through South Germany and Austria, as they are in England. The distribution of identical etiological moments being the same in both countries, the effects must manifestly be analogous. These are reflections into which the observer will fall, *volens volens*, when every third case presented at the Children's Dis-

pensary, or at the ambulatorium of Professor Billroth, is one of rachitis. The surgical treatment of rachitic deformities by Professor Billroth, and a very elaborate article upon this subject by his assistant, Dr. Gussenbauer, in the *Archiv für Klinische Chirurgie*, Band xviii., have induced me to make mention of this theme. Unfortunately, it occurs only too often, that these deformities, and especially those of the lower extremities, are too long neglected, or subjected to the maltreatment of an ill-suited orthopædic apparatus. A well-contrived apparatus can doubtless overcome a deformity which has not been rendered permanent by the sclerosis consequent upon the diseased process. Indeed, the earlier operative interference is instituted, the better the result must be, for, as Dr. Gussenbauer has clearly demonstrated, the longer certain ligaments are abnormally stretched by the peculiar gait incumbent on certain deformities, the less can a *restitutio ad integrum* be expected. An outward curvature of the tibia signifies a treading upon the outer border of the foot; and an abduction of the femur. The external lateral ligaments of the ankle and the knee-joint become stretched and elongated. 'The shrinking of the internal lateral ligaments appears to supervene when the increased and constant pressure upon the inner segments of the articulating surfaces of both joints has induced their atrophy (*Druckatrophie*).' Hence, in recent cases, the deformity can generally be overcome by gradually 'straightening' the limb of the narcotised patient (*Redressment*). Should the advanced sclerosis render this manipulation impracticable, the infraction or complete fracture of the bone, should be produced at the seat of greatest curvature. The limb is then straightened, and a plaster-of-Paris bandage applied. When the latter is removed in from two to four weeks, an *ad oculos* demonstration of the efficacy of this treatment is afforded.

In the article already referred to, Dr. Gussenbauer reports six cases of deformity of the legs in which the excessive induration of the bone thwarted all manual attempts and manipulations to fracture the same. In these cases, subcutaneous osteotomy was performed with the best results. On the inner side of the tibia, at the seat of its greatest curvature, an incision varying from one-half to three-fourths of an inch in length, is made through the soft parts, the periosteum also being divided. The inner wall of the bone is then divided with a chisel, the line of division being perpendicular to the axis of the bone. The splintering of the bone must be carefully avoided, for the healing by first intention would then be interfered with. (This is one of the objections to Langenbeck's operation of subcutaneous osteotomy, the bone-dust produced by the auger and saw causing suppuration.) The division of the inner wall accomplished, the tibia can easily be fractured, manual force sufficing to overcome the resistance. The after-treatment consists in the application of a plaster-of-Paris bandage fenestrated at a point corresponding to the seat of operation. Notwithstanding the assertion of Linhart, this operation, when properly performed, does not imperil the integrity of the fibula, for the latitude of motion allowed in the superior tibio-fibular articulation, suffices to permit the fibula to sweep the angle between its abnormal and its normal position. The necropsy of one of these cases which succumbed to variola, places this beyond doubt. Unfortunately, opportunity has not yet been afforded me to witness this operation for a deformity resulting

from the disease mentioned, although two cases of genu valgum were successfully operated upon according to this method during the present semester. In these cases, the tibia was fractured one inch below the tubercle, the deformity was reduced and the extremity retained in its proper position by a plaster-of-Paris bandage. A slight hæmorrhage into the subcutaneous cellular tissue or into the medullary cavity frequently results after the operation, and may even lead to suppuration and concomitant fever, both these, however, enjoying only a very short existence. It will be seen from this that the resection of a wedge-shaped piece of bone for the removal of a deformity can very often be dispensed with. Were these lines intended for other than American readers, they might contain more or less detailed accounts of the operations of Barton, Brainard, and Gross, operations which mark an era in the surgical treatment of deformities which, though compatible with life, make life a burden.

PARONA ON A CASE OF AVULSION OF THE FOREARM, ATTENDED WITH SEVERE HÆMORRHAGE.—Dr. Parona records this case in his *Rendiconto Biennale di Clinica Chirurgica*, to show that avulsion of limbs does not always occur without hæmorrhage.

A workman in a paper-mill, aged fifty-three, had his right forearm torn off in consequence of his hand being caught in the machinery. The accident was followed by hæmorrhage, which produced syncope. A compress was applied in the axilla, and the patient was taken to the hospital, where the brachial artery was tied; and on the next day amputation was performed near the head of the humerus. There was subsequently partial sloughing of the stump; but the result was successful, and the patient left the hospital cured two months after the accident.

SYPHILOGRAPHY.

SIMMONS ON PHAGEDENIC SORES.—In the *New York Medical Record* for September 11, is an original communication on the treatment of phagedenic gangrenous venereal sores, by Dr. D. B. Simmons, in the Ken Hospital at Yokohama.

He writes: Few who have had any considerable private or hospital practice are not acquainted with the difficulties often experienced in arresting the destructive progress of what are known as phagedenic gangrenous venereal sores. Within the last two years, several cases which will admit of this classification have come into the hospital for treatment. The hot iron, nitric, chromic, and carbolic acids were all tried in turn, as well as 'Ricord's born enemy of phagedæna,' with what we believe to be the average rate of success.

The last four cases, and one especially, to which we shall refer, were almost entirely treated, however, by, if not a new process, one which was productive of such satisfactory results as to warrant us in earnestly recommending its trial. This consists in the continuous immersion of the diseased part in hot or warm water. The case referred to had been treated, before falling into our hands, by the usual means for nearly two weeks, and, though not progressing so rapidly as at first, was still advancing. Both labia, minora and majora, the fourchette, clitoris, and portions of the urethra had disappeared, and all the region occupied by the external organs of generation had been converted into an immense irregular cavity, discharging an unhealthy sanious and very fetid pus. The patient was also suffering much pain, especially if the parts became in the least dry. A sitz-bath of the ordinary size and form is what is required. In this is placed a cushion, or large bathing-sponge, to render more tolerant the long-continued position in the tub, required for obtaining the more satisfactory results. In the case referred to, the matter seemed to be increased by the use of the bath for thirty-six hours, when it began to change in character. Instead of the sanguino-serous pus which was discharged from it before, it had

assumed a more healthy, 'laudable' form. The ragged edges sloughed off, and their dark red or purple colour presented a bleached-out appearance. From this time, the progress of the disease appeared to have been arrested.

Through the dirty grey slough at the bottom granulations began to appear, and the healing up of the part, as far as the extensive loss of substance would admit, was completed in two or three weeks. Uncomfortable as the position was, the patient would not remain out of the bath for a moment longer than necessary, on account of the great relief it afforded from the burning smarting pain.

We found, after the change had commenced for the better, that it was not necessary to keep the patient so continuously in the bath, but only on alternate hours. In the interval, iodoform was sprinkled freely over the part. It is our opinion that the destructive agency is to be found in the peculiar or specific character of the discharge, and that the water simply removes or dilutes it, so as to destroy its action, the same as it would with a caustic. We do not see why this explanation is not as true and satisfactory as that the matter from a soft chancre has specific qualities, and is capable of reproducing itself, under favourable circumstances, to almost any extent.

A very bad case of multiple chancres in a female, of an inflammatory type, was treated by us in the same manner, with the same satisfactory results, about the same time.

In the male, when the organ is sufficiently large or long, we have found that its immersion in a tumbler or cup of water answered the same purpose.

We now adopt this plan in the treatment of all soft chancres that are troublesome, and are satisfied that if it is properly carried out they may often be cut materially short in their duration.

All are acquainted with the suddenness with which soft chancres often get well after long and varied modes of treatment. We believe this to be consequent upon a change in the character of the discharge, or in its irritating corrosive action, which allows of the natural healing of the wound. The same is practically effected by the dilution or removal of it by the water.

Irrigation, we have no doubt, would answer the same purpose, and could be arranged so as to subject the patient to far less inconvenience and discomfort.

We think, however, that the water should be at as high a temperature as possible in either case.

HUTCHINSON ON SOFT CHANCRES.—In the *Lancet* of September 18 and 25 is a clinical lecture by Mr. Jonathan Hutchinson on the relations of soft chancre to syphilis. A soft chancre, he asserts, is produced by pus-contagion; and a hard chancre by a specific virus. All living pus is contagious; all living pus-cells possess the power of setting up, when transferred to another home, if that home be a suitable one, a kind of inflammatory action similar to that from which they themselves have originated. Thus gonorrhœa-pus will produce gonorrhœal inflammation—but only in a favourable tissue-home. In the urethra or conjunctiva it will readily excite such inflammation, but on the skin, and possibly in the mouth, it will not live at all. The true virus of syphilis may cause inflammation, and thus result in ulceration and the formation of pus. 'Let me ask you,' he says, 'to believe that the pus so produced

is in itself contagious, and you have my theory of all soft or non-infective chancres. This pus, although produced by an inflammation caused by the specific germs of syphilis, does not necessarily contain these germs. It may contain them or it may not; just as the clover you sow in your field may or may not contain, as an accidental mixture, the seeds of the poppy as well. If the poppy-seeds be there, they will probably grow; and just so, if with the pus-cells there be also the germs of the syphilitic virus, they too may grow, and you have a mixed crop. Mixed chancres are indeed very common.' The difference, however, betwixt pus-cells and the syphilitic virus is however much greater than betwixt any two species of vegetable seeds. The soft sore is not the offspring of a specific virus, but comes as a side-result from the inflammation caused by it. Thus, if to-day all soft sores could be exterminated, and all the secretions capable of producing them by contagion, it would be found that in a few weeks they would be reproduced: whereas, if all hard chancres, and all the specific germs of syphilis were destroyed, there would be no reproduction of the disease. Mr. Hutchinson thinks that at least it is much more probable, that the pus which causes soft chancres occasionally, but not necessarily, contains the germs or virus of true syphilis, and so becomes the means of generating genuine syphilis; than that there are two specific poisons existing side by side for centuries, yet never intermixing. Soft chancres have no period of incubation. They are often multiple; and are readily reproduced by inoculation. They often occur in other parts than the genitals, and are, then, usually taken for some form of skin-disease, in which is recognised an irritable pus-secreting sore. The practical questions connected with the subject are these. 1. At what period in the course of a chancre can the surgeon venture an opinion as to its nature? 2. Are the characters of the two forms of chancre, soft and hard, often mixed? 3. Can a chancre which presented at one stage all the characters of a soft one, subsequently become indurated? The answer to the second and third questions is an affirmative one. As to the first question, it is not one always easy to decide upon. Often the soft sore will run its course and heal without any induration; and then, at the end of a month, the evidence of a hard chancre may be forthcoming: whereas, if the soft chancre be a severe and troublesome one, the true syphilitic virus may be destroyed. In this way, probably, many a soft sore does really prevent the development of a hard one. Nevertheless, as to answering the question of the patient as to the nature of a chancre, it is well ever to be guarded. It is very rare, indeed, that an infecting sore acquires any induration within three weeks of the date of contagion, and more commonly it is a month or five weeks. Until such induration takes place, nobody can tell whether it is coming or not. When soft sores heal up readily, a hard chancre not rarely follows, and the subjects of tertiary syphilis often state that the original sore healed in a week. If the sore not only ulcerate but become phagædænic, it is usually quite impossible to diagnose induration; and yet such sores are not rarely followed by secondary symptoms. All soft chancres should then be regarded very suspiciously from a diagnostic point of view. As to treatment, Mr. Hutchinson does not recommend mercury until there is induration; and then, when the need for it is unmistakable, to resort to it at once. He is in favour of further trials

of the escharotic destruction of chancres in their early stages. J. MILNER FOTHERGILL, M.D.

PETROW ON THE MORBID CHANGES IN THE SYMPATHETIC IN CONSTITUTIONAL SYPHILIS. Dr. P. Petrow, of St. Petersburg, describes (*Archiv für Path. Anatomie und Physiologie*, Band. lvii.) two kinds of changes observed in twelve cases of constitutional syphilis examined by him; some of them affected the nerve-cells, others the connective tissues.

1. In the protoplasm of the nerve-cells he observed, when the cases were not too recent, brown pigmented granules, grouped together or regularly disseminated. When the disease was more advanced, the pigment entirely filled the cell, completely concealing the nucleus. The pigment was derived from the hematin of the red corpuscles. The inner surface of the ganglionic cells had frequently undergone proliferation, so that the cells were lined with a layer of polygonal cells having round nuclei. In many of the pigmented nerve-cells the protoplasm was transformed into colloid material.

2. In the connective tissue was enormous hyperplasia, in which the nervous fibres and cells appeared to be strangled. The epithelial cells surrounding the nerve-tubules generally participated in the morbid process; they were turbid and granular, their outlines were more or less defaced, and their nuclei more distinct. In parts which had for some time undergone change, the epithelium of the inner surface of the nerve-corpuscle was replaced by a granular mass soluble in ether; the small nerve-cells were irregular, angular, and loaded with pigment, and at some points were represented only by agglomerations of pigment-granules. The sheaths of the nerve-fibres were thickened, and their nuclei proliferated; the medullary matter was finely granular, and broken up at some parts.

The author concludes that—(1) constitutional syphilis is manifested in the great sympathetic by transformation of the nerve-elements and of the interstitial connective tissue; (2) the nerve-cells become pigmented, and undergo colloid transformation; (3) there is developed in the great sympathetic, as in all the other organs, hyperplasia of the connective tissue, which atrophies the nervous elements; (4) the epithelium surrounding the proliferated nerve-cells undergoes fatty degeneration at a later period.

MATERIA MEDICA AND THERAPEUTICS.

KRUEG ON ARTIFICIAL FEEDING BY SUBCUTANEOUS INJECTIONS.—There is an article on this subject in the *Wiener Medizinische Wochenschrift* for August 21, 1875 (no. 34), detailing the case of a patient in the Ober Döbling Private Lunatic Asylum. Dr. Krueg remarks that in no. 31 of the same journal for 1869 (April 17) Menzel and Perco published some experiments on the absorption of nutrient materials by the subcutaneous connective tissue. They injected from one drachm to one ounce of oil or liquid fat in this way in dogs, and found that it was all absorbed in about forty-eight hours, without any special symptoms arising. The same occurred with solutions of sugar, milk, and even egg-albumen. Their object was practical, but the only attempt in the human subject did not exceed nine grains in quantity. They quote Stricker and Oser as to the success, at least in one case, of the injection of parapeptones. The author does not know of anything further having been done in this way. In cases of voluntary starvation, or when the stomach will not bear food, some plan in addition to our present means of forcible feeding seems very desirable. The patient referred to is a man with private property, aged fifty-seven, who has been in the asylum since 1868. He has no paralysis, but considers himself to be God, and the rightful ruler of the whole world, unjustly detained in this asylum. When visited, he generally begins with a long protest, will seldom answer questions, but asks a great many, and is familiar with everybody. Rather than wear what he considers unsuitable clothes, he will go naked. A shirt suffices for his dress-suit. He is often dirty, and implores to be destroyed that his soul may be saved. At other times, he believes that he is to undergo martyrdom. To escape this he will attempt suicide, sometimes by excessive fatigue, or often by refusing food. He was once obliged to be fed with the cesophageal tube for twenty-seven months. Of late he has been very changeable—now taking food, anon refusing it. When fed, he generally required his nose to be compressed, or he would not swallow. Towards the end of January he refused food, and attempts to feed him through a tube were frustrated by his straining and coughing till he was perfectly cyanotic and breathless. Even nutrient enemata were rejected. For ten days he took no food. One and a half grain of morphia *sub cute* did not induce sleep. Chloroform narcosis seemed counterindicated. It was thought that respiratory food was most suitable. Subcutaneous injections were therefore tried, with solution of sugar, and with olive-oil, through a syringe containing fifteen cubic centimètres (about half an ounce). In all, about one ounce of the solution was introduced daily—very slowly, and in quantities of about half a drachm at a time, or a little more—in the foot, belly, or side. Only redness was produced locally, and sometimes not even that, when the injection was slowly done. The moral effects were extremely good. He believed it to be very concentrated food; and in the first week of February ate voluntarily. From the 7th to the 25th he was again obliged to be thus injected, with exception of a few days, during which he took food. On the 25th a whole egg was thus

introduced. This was followed by a local abscess, which soon healed. This was probably due to the 'formed' elements of the egg-albumen, as it never happened with the oil. After this, he ate again voluntarily till March 25; then he refused food, and on the 27th was again injected. From April 1 he has been forcibly fed, with the nose pinched. The curious 'chloroform smell' of starvation vanished after the first injections. It is also singular that he now, for the first time, objects to fatty food, although quite ignorant of the nature of the food injected, which he believed to be 'extract of eggs.' [The reporter, at the suggestion of an eminent physician, tried this method of feeding cholera patients, in conjunction with Dr. Heckford. Whenever albuminous matters were used, there were local abscesses. In one case, unfortunately, pyæmia ensued. In his opinion, either gastrostomy or œsophagotomy is a far more feasible operation in most of the cases in which neither the tube nor nutrient enemata can be employed.—*Rep.*] W. BATHURST WOODMAN, M.D.

BRACKENRIDGE ON THE TREATMENT AND PREVENTION OF INFECTIOUS DISEASES BY THE INTERNAL ADMINISTRATION OF SODIC SULPHOCARBOLATE.—Starting from a belief in the germ-theory, the author (*Medical Times and Gazette*, July 24, 1875) has carried out two sets of clinical observations on the action of sodic sulphocarbolate in scarlet fever and diphtheria. The choice of the sulphocarbolate was determined by the statements made by Dr. Sansom in his treatise on the 'Antiseptic System.' The first series of cases bears on the remedial value of the salt, administered in doses of from twenty to thirty grains every two hours to patients suffering from scarlet fever. Fifty successive cases were thus treated in the Edinburgh Royal Infirmary. All of them recovered. Nineteen were males, thirty-one were females; their average age was 17.5 years; the average duration of the disease before treatment was commenced, 4.4 days. In three cases only was recovery long delayed by sequelæ, and in these the treatment was commenced on the sixth, tenth, and fourteenth days of the fever respectively,—too late to prevent the after-effects of the disease. In forty cases no complication interfered with the quick and quiet subsidence of the fever. By way of contrast to these favourable results, the author mentions that of twenty-four patients admitted into the scarlet fever wards during the four months immediately preceding the commencement of the treatment by sodic sulphocarbolate, no fewer than six died.

The second part of the inquiry relates to the prophylactic virtue of the sulphocarbolate when administered to healthy persons exposed to the infection of scarlet fever, diphtheria, and measles. It was given in seven families to twenty-two individuals exposed to the poison of scarlet fever; in three families, to fifteen individuals exposed to the poison of diphtheria; in three families, to eight persons exposed to the poison of measles. The dose of the salt varied, according to age, from five to thirty grains three or four times a-day, and sometimes, when well borne, more frequently. The diseases did not extend, in a single instance, beyond the individuals first affected.

BRACKENRIDGE ON QUININE AS A GARGLE IN DIPHTHERITIC, SCARLATINAL, AND OTHER FORMS OF SORE-THROAT.—The author (*Practitioner*, August, 1875) has treated a considerable number of cases of sore-throat, due to different causes, with

a gargle containing two grains of sulphate of quinine, and five minims of dilute sulphuric acid, to each ounce of water. Sometimes, when the remedy was well borne, the proportion of quinine was increased. Its employment was suggested by the experimental results of Binz and other recent inquirers. In the early stage of cynanche tonsillaris, the quinine gargle was found to be of very little use. In syphilitic ulcers it appeared to hasten the healing process, when used in conjunction with appropriate treatment of a specific kind. In non-syphilitic ulceration, and in the sore-throat of scarlatina, it proved to be of considerable value; its most brilliant success, however, was achieved in diphtheritic sore-throat—both in the milder and the more severe forms of the disease. One very severe case, which appears to illustrate the superiority of quinine to potassic permanganate as a local application, is recorded *in extenso*.

E. BUCHANAN BAXTER, M.D.

QUINTARD ON MORAL CURATIVE FORCES.—In his *Thèse de Paris*, June 2, 1875, no. 187, Dr. Quintard shows how the physician may avail himself of moral influences in the cure of disease. Dr. Quintard studies the various passions in turn; joy, grief, fear, anger, hope, friendship, and love are successively passed in review, and in each chapter Dr. Quintard shows the influence of these sentiments not only on the progress of the disease but also on its cure, by numerous examples drawn from various sources. The facts with regard to the contempt of pain are numerous, especially in the case of wounds by fire-arms.

These latter are, however, in the opinion of the reviewer in the *Bulletin Général de Thérapeutique*, Sept. 15, much less conclusive than is believed by Dr. Quintard. In these cases, in fact, the ardour of the struggle, on the one hand, and the insensibility produced by great shock on the other, explain the absence of pain better than it is explained by moral influence. Many surgeons have been in a position to observe soldiers, who, seriously wounded in action, did not seem to suffer at all, whilst the same men a few days afterwards shouted out at the least operation. M. Quintard terminates his work by the following quotation from Tissot. 'A time will come when the profession will count the mechanism of their art, the material part of their science, as nothing or as very little, and will esteem highly the philosophy of this same art, that is to say, the dual knowledge of physical and intellectual man.'

BOURNEVILLE ON THE MONOBROMIDE OF CAMPHOR.—M. Bourneville laid the results of some researches on the physiological and therapeutic action of the monobromide of camphor before the Paris Academy of Sciences at a recent meeting. He has experimented on frogs, guinea-pigs, and cats, to which the monobromide of camphor was administered in the form of subcutaneous injection. The results obtained are briefly these. 1. The monobromide of camphor diminishes the number of heart-beats, and causes contraction of the vessels of the ear. 2. It diminishes the number of the inspirations without disturbing their rhythm. 3. It lowers the temperature in a regular way: this lowering, in fatal cases, increases until the end. Thus in cats the temperature is observed to fall from 102 to 72 degrees. In the animals which recovered, the lowering of the temperature was succeeded by a rise to the normal height, but taking a longer time than that in which the lowering took place. 4. The monobromated

camphor possesses apparently incontestible sedative properties. 5. It does not produce any disturbance in the digestive functions, but its prolonged use brings on a somewhat rapid emaciation, especially in the cats and guinea-pigs. The therapeutic effects of monobromide of camphor are remarkable. The writer mentions as amongst the diseases on which he has experimented with satisfactory results, cardiac affections of nervous origin, asthma, pain of the neck of the bladder without catarrh, and finally, cases of epilepsy, in which fits and vertigos were simultaneously present.

DEBOVE ON THE PHYSIOLOGICAL ACTION OF DRUGS, AS THE RULE OF THEIR EMPLOYMENT THERAPEUTICALLY.—In order to solve this question, M. Debove studies some drugs of which the therapeutic action is best known, as quinine, mercury, and iodine, and shows how very little their physiological action is known; then he traces a rapid sketch of the results produced by experimental physiology in the study of drugs, and arrives at conclusions which the reviewer of his thesis (*Bulletin Général de Thérapeutique*, September 15) considers to be very true and equitable. The first is that, in the present state of the science, the physiological action of drugs cannot become the rule of their employment therapeutically. 2. If the physiological action of drugs cannot be the rule of their employment, it must be owned that it affords us precious indications by which clinical medicine is daily profiting. 3. The progress realised every day in the different branches of physiology warrant us in hoping that a time will come when empiricism, necessary at the present time, will give way to a rational system of therapeutics, founded on physiological teachings.

OBSTETRICS AND GYNÆCOLOGY.

INGERSLEV ON THE COMPARATIVE WEIGHT OF NEW-BORN CHILDREN.—The *Nordiskt Mediciniskt Arkiv*, vol. vii., contains an elaborate paper on the comparative weight of new-born children, by Dr. E. Ingerslev, clinical assistant in the Lying-in Institution in Copenhagen.

The author first endeavours, by a comparison of the weights of 3,450 infants born at full term, to establish the relation between the average weight of the child on the one hand, and on the other hand the age and size of the mother, and the number of pregnancies. The average weight of the infants was 3,333 grammes; the average for the males being 110 grammes more than for the females.

A classification of the births according to the ages of the mothers shows that the influence of age on the weight of the child is not so distinct as has been asserted by Dr. Matthews Duncan, if the births be arranged according to the pregnancies; but the influence of age becomes evident if the births be arranged in a single table without regard to the pregnancies; and it extends up to the fortieth year. Dr. Ingerslev's observations do not confirm Dr. Duncan's statement, that the maximum weight is found between the twenty-fifth and twenty-ninth years of the mother's age.

The influence of the number of pregnancies on the average weight of the child, observed particularly by Hecker of Munich, is evident, especially when the pregnancies are classified according to the ages of the mothers. In the tables showing this, the influence of plurality comes out more distinctly than that of age. The coincidence of pregnancy with the average of age of child-birth seems specially favourable to the weight of the child; for in the three first pregnancies the average weight of infants born in the mean years of the childbearing period exceeds that of all the children born before and afterwards.

With regard to the weight during the first days of life, the author mentions the researches of Siebold, Haake, Winckel, Gregory, Kzmarsky, Bouchaud, and Ritter, relatively to the loss of weight after birth, and enumerates the different explanations of this phenomena which have been given. He has examined more than 100 infants, which were weighed immediately after birth, and daily up to the tenth day. Excluding all cases where the children or their mothers were ill, there remained fifty healthy children born at full term. In all these, a diminution of weight was ascertained to take place after birth. In some rare cases, the weight increased or remained stationary on the first day, when the diminution due to the discharge of meconium did not take place, either because the meconium had been evacuated at the time of birth, or because it did not take place before the first weighing, and the infant had in the

interval taken the breast; but the increase was transient, and the diminution appeared on the second or third day.

The average decrease was about 222·4 grammes (one-fourteenth or one-fifteenth of the general weight); it was greatest, absolutely and relatively, in first-born children. In boys it was greater than in girls; but the loss was compensated sooner in boys. The loss was greatest, and the subsequent increase more tardy, in inverse proportion to the development of the infant. The increase generally became manifest on the fourth day. On the tenth day, thirty of the children exceeded the original weight; one had exactly reached it; and in nineteen the weight was below that at birth.

No connection can be traced between the detachment of the umbilical cord and the commencement of the increase in weight; the latter generally appears before the fall of the cord. It is necessary to take special notice of the absorbed and eliminated materials, and to compare them. The decrease of weight cannot be explained only by the evacuation of the meconium and urine, this quantity amounting to only half the loss of weight in a given time. The remainder must be eliminated by other ways. It was at first thought that the loss of weight might be explained by insufficiency of food; but from experiments where the infant was regularly fed by a healthy nurse from the time of birth, it appears that the decrease takes place just as in infants suckled by their own mothers.

The loss being relatively greater at the time nearest birth, the quantity of food should be great in proportion, in order to maintain the weight of the body; but this cannot be from the manner in which milk is secreted and children are fed for the first two or three days after birth; and, since the relations of decrease and the commencement of increase are not changed by the use of sufficient food, it must be concluded that the infant derives no benefit from this, perhaps because the assimilating power of the intestines is not yet sufficient. The consumption of material and the consequent loss of weight are hence an inevitable physiological necessity.

PIPPINGSKÖLD ON A CASE OF DOUBLE UTERUS AND VAGINA: HÆMATACOLPOS UNILATERALIS: PREGNANCY.—J. Pippingsköld (*Finska Läkare Sällsk. handlingar*, Band xvi. and *Nord. Medicin. Arkiv*, Band vii.), describes a case of double uterus. The subject was aged twenty-two, and had menstruated from the age of sixteen. Within the last four years, according to her statement, she had had severe attacks of inflammation in the abdomen. She was in the fifth month of pregnancy, but on examination the orifice of the uterus could only be reached with difficulty, and the whole anterior part of the vagina as well as the left half was occupied by a tense, fluctuating, rather painful tumour. In July, 1873, she was prematurely confined. In the beginning of October, after a difficult menstruation, the swelling was again distended, and much more prominent than it had been four weeks after labour. When she was next seen in February 1874, the swelling was lower (it had been punctured); and on examination there was found to be double uterus. The tumour was emptied by means of a Dieulafoy's aspirator, after which a broad vaginal orifice was discovered at the bottom of the cyst. The punctured opening was enlarged, and the cavity washed out; and the septum, which was four or five millimètres thick, was divided

for an extent of four or five centimètres. There was little hæmorrhage and no reaction. On March 8, an examination was made, and two uterine orifices were found; one lay backwards and to the right, less broad but more permanent, leading into an uterine cavity eight centimètres long (in which the pregnancy had taken place), the body and fundus being to the right; the other uterine orifice was lower, and was situated anteriorly and to the left; the cavity was six and a half centimètres in length. Subsequently, an examination *per rectum* detected a bifurcation between the two halves of the uterus, with considerable divergence. Menstruation had occurred normally.

A. HENRY, M.D.

BOUCHACOURT ON UTERINE HÆMORRHAGES CONSECUTIVE TO PARTURITION.—M. Bouchacourt read the first part of a paper on this subject before the National Medical Society of Lyons on July 19, 1875 (*Lyon Médical*, August 22). He considers the following to be the chief causes.

1. Retention of urine, which catheterisation arrests.
2. Laxity of the abdominal walls, which a binder prevents.
3. Too rapid change of bed. Five or six hours should at least elapse before the patient is moved.
4. The too hasty removal of the soiled linen.
5. Warmth of the bed, room, or the application of too warm things to the abdomen.
6. Frequently recurring pregnancies are an incontestable predisposing cause.
7. Fibroids; but practice has not fulfilled theoretical apprehensions.

He advocates injection, and plugging especially, with perchloride of iron, in preference to the old routine practice.

He relates a case where a patient was seized with violent endometritis on the third day of delivery from plugging the vagina and uterus with pledgets saturated with perchloride of iron. On examination three months afterwards, a circular band about three centimètres from the vulva permitted only the passage of the uterine sound with difficulty. A five months' dilatation enabled him to examine the cervix, which was almost gone, without the least trace of an os.

LAROVENNE ON A MODIFICATION OF THE ORDINARY FORCEPS TO ENABLE TRACTION TO BE APPLIED TO THE CENTRE OF THE BLADES.—The author (*Lyon Médical*, August 22), in order to carry out M. Chassagny's fundamental doctrine that 'the force should be directed on the centre of a body which has to engage and pass along a curved canal such as the pelvis,' has the ordinary forceps blades pierced at the anterior and posterior margins, corresponding to the centre of the head seized by the forceps, through which he passes a strong piece of tape, threading them from within outwards; each blade having a separate tape. The instruments are applied in the usual way; the four ends of the tape are then tied together and traction made upon them, the handles of the forceps being used as a rudder to steer the head into whatever position it is thought requisite. Its mode of action he describes as follows. The power in the middle is represented by the strings of tape, and the resistance by the diameters of the head which fix it at the contraction. If the handles of the forceps be depressed, or what is the same, let alone, the beneficial effect of the power undergoes a proportionate diminution, by the shortening of the arm of

the lever represented by the handles of the instrument. Traction can be assisted by concurrently elevating the handles of the forceps without supporting them against the pubic arch. This action, which tends to lower the portion of the head contiguous to the sacral promontory, constitutes a power of which the fulcrum is in front against the anterior wall of the pelves, and the resistance behind at the level of the promontory. By alternately drawing the strings from one side to the other, the direction of the force can be varied without the danger of doing the mischief that is apt to arise in the use of the forceps, where great care and skill is not exercised.

Clinical experience has convinced M. Laroyenne of the readiness of application of this modification, of its safety, and its advantage, and he strongly recommends its use when there is any contraction or disproportion of the pelvis needing instrumental aid.

REPORTS OF FOREIGN SOCIETIES.

ACADEMY OF MEDICINE IN PARIS.

July 27. *Attempted Suicide*.—M. Hervieux communicated the account of an attempt at suicide by a knife driven three and a half inches into the chest, near the fifth rib. There was considerable hæmorrhage, which was stopped, and cure was complete in a few days. M. Hervieux believed that the heart and the pericardium were not touched in consequence of the back of the instrument being turned towards them. The lung was, of necessity, wounded, but to a very slight depth only. However, neither cough, sanguineous expectoration, pneumonia, nor pneumothorax was present; whilst percussion and auscultation did not indicate anything abnormal. The writer of the paper cited several cases in which no pulmonary accident had been noted after more or less deep chest-wounds.

Cholera.—M. J. Guérin terminated his remarks on cholera, and examined all the systems which have been proposed to explain different choleraic epidemics. He came to the conclusion that the appearance of the scourge had always and everywhere been preceded by gastro-intestinal troubles, by diarrhoea of a more or less choleraic type: in a word, by a medical constitution which prepared for and favoured the ulterior development of the disease. With regard to this point he laid particular stress on the Jamaica epidemic, which could neither be laid to the account of importation nor to the revivification of germs. In 1873, the cholera followed the same course in India as in Europe, and there also was preceded by diarrhoea of a choleraic form. It would, therefore, be useless to go to India to combat a plague which originates spontaneously in Europe.—M. Barth reproached M. Guérin for having passed over in silence the epidemic of 1865, in which instances of importation were particularly noted.—M. Guérin replied that he had spoken of them, but had not thought it necessary to lay stress on them.

August 3. *Abdominal Tumour*.—M. Laboulbène related the sequel of a previously communicated case of Hippocratic succussion perceived in an abdominal tumour. The tumour, which was enormously developed and indolent, opened and gave issue to foetid pus and gas. A drainage-tube was inserted, and after a month of repeated washings out, the patient recovered. In all probability there was a purulent collection situated between the posterior abdominal wall and the intestinal coils, without fistulous communication with the intestine.

Cholera.—M. Woillez replied to M. Guérin's discourses on cholera, and referring to the epidemic of 1873, declared that the facts observed in no way authorised the theory of spontaneous generation.—M. Piorry asserted that this discussion on spontaneous generation and importation was utterly useless. What should be known is that cholera may be simple or compound. Simple cholera is cholera, which is not serious; compound cholera is a septicæmic complication of simple or Indian cholera. He advised that routine should be abandoned, and that a rational nomenclature, as in chemistry, should be adopted.—M. Briquet called attention to the fact that a great cholera epidemic might leave behind it germs which remain dormant and are revived

DR. DEPAUL has left Paris to go to Rio de Janeiro, in order to be present at the confinement of the Countess d'Eu, the daughter of the Emperor of Brazil.

during the summer of the next year, disappear with the cold season, and again revive the following year.

August 17. *Cholera*.—M. Guérin again referred to the question of cholera, and brought up a communication from M. Cazalas, according to which the cholera existed at Saint Germain-en-Laye and at Villeneuve l'Étang before its appearance at Havre, Rouen, and Paris. It must thence be admitted that the Parisian epidemic did not spring from that of Rouen. From the scientific point of view, said M. Guérin, M. Cazalas's memoir opened up new horizons as to the special nature of summer diarrhœas, their evolution, and the different forms assumed by them, from the most simple diarrhœa to confirmed cholera. From a practical point of view, this memoir entailed a complete remodelling of the sanitary measures hitherto adopted. He demonstrated the inutility of quarantines and of other prophylactic measures, which are only, in fact, an attack on personal liberty and injurious to the interests of commerce.—M. Briquet replied that the absence of necropsies warrants the doubt that there was any question of Asiatic cholera. He adopted the doctrine of the contagion of the original Indian and Bengal cholera, and applied it to the series of epidemics which followed each other in 1817-1828, 1854, and 1845. He wound up by affirming that ordinary cholera is a meteorological disease, the principal cause of which is the lowering of the temperature, and the secondary cause, insufficient nourishment. Epidemic cholera is a disease of Indian importation; and this doctrine of importation, according to M. Briquet, has never been met by any serious argument, either from the etiological point of view, nor from the progress of the disease.—M. Chauffard protested strongly against the similarity which M. Guérin wished to establish between cholera nostras and Asiatic cholera; and M. Barth declared that the partisans of spontaneous generation of cholera wilfully closed their eyes to the light. The few cases of choleraic diarrhœa pointed out by M. Cazalas did not prove that the epidemic of Paris had not been imported from Paris or Havre. If an African gale drove a swarm of locusts into the south of France, it could not be said that it was not an importation, because there had previously been locusts in the north of France. If even commerce suffered through measures of prophylaxis, the interest of the public health should take precedence of every other consideration.

August 24. *Diagnosis and Therapism of Asphyxia by Bronchial Foam or Angiaphrosia*.—M. Piorry read a paper on this subject. He said that angiaphrosia, or asphyxia by bronchial foam, is, as a general rule, only an epiphenomenon of a multitude of lesions; but it constitutes a special organopathic condition of itself. This disease is diagnosed by distant auscultation, which consists in applying the ear to the mouth and nostrils of the patient, so as to see if in the angaria a more or less deep rhonchus does not show itself. In this diagnosis, mediate auscultation and plessimetrist are employed, which, either by the different quality of the sounds detected by auscultation or by the differences in the sonority of the chest, allow the existence of more or less viscous mucus obstructing the bronchi to be established. In proportion as mucus accumulates, the colour of the patient's features changes more and more; it becomes specially deeper about the lips and more livid; the strength becomes enfeebled; the pulse is lower, becomes irregular; coldness comes

on; more and more hyperæmia shows itself; expectoration is more and more difficult; and axonæmia occurs sooner or later and terminates the existence of the patient. The therapeutic treatment consists in first, above all, seeking to remedy the organopathic conditions which have brought on the complication in question; finally, in treating the complication itself, it is advisable to recommend the patient to make very deep inspirations, followed immediately by a purposely violent cough, so as to bring on expectoration. The depression of the head on the chest singularly favours the exit of the sputa; it is particularly when the patient feels that the sputa bring on the need to expel them, and that he is unsuccessful in so doing, that it is well to proceed in this way to obtain the exit of these liquids. The physician should use his authority, when the strength and the will of the patient are failing, and sometimes thus succeeds in retarding the fatal ending. To prevent the accumulation of the liquids in one part of the air-passages, it is urgent to lay the patient on the other side of the chest; if the sputa be very viscous and very thick or dry, inhalations of watery vapours must be tried, or the patient must smoke cigarettes of datura stramonium or other narcotics. When the sputa are very liquid, nothing is more useful than to breathe a dry and hot air. In the early stages, emetics and purgatives may be advantageously employed, by emptying the digestive tube of the gaseous liquid or semi-solid matters it contains. Recourse must also be had to inhalations of oxygen gas, to titillations of the larynx and the top of the œsophagus, and even to the introduction of a sound into this canal. Finally, there remain the semi-surgical means in extreme cases; aspiration of liquids by means of a pump introduced into the trachea; tracheotomy, etc. These means are employed in imitation of the veterinary surgeons, who combat meteorism in animals by abdominal puncture; a practice which medicine, as applied to the human subject, will scarcely admit in analogous circumstances.

Cotton-Wool Dressing.—M. Gosselin read cases with reference to M. Guérin's cotton-wool dressing. He said that the mode of action is good; firstly, because it protects from too intense suppurative inflammation; and secondly, because it satisfies this indication by its great quality of being an uncommon dressing, which, without interruption, keeps up occlusion, protection, immobility, uniform temperature, insensibility, and mental satisfaction. These conditions, if the previous health be not too bad, and if the atmospheric hygiene be not too defective, lead to the very simple and yet very great result of rapid and uninterrupted formation of an essentially and promptly reparative granulous membrane.

September 7. *Myopia*.—M. J. Guérin called to remembrance the conclusions of a work which he had presented to the Academy of Sciences in 1841. 1. There exist two kinds of myopia, as there exist two kinds of strabismus, mechanical or muscular myopia, and optic or ocular myopia. Mechanical myopia, like strabismus of the same kind, results from the original brevity, or the active retraction, of the muscles of the eye. In mechanical myopia, the too short muscles are the four recti muscles simultaneously, or two or three only of them, but so that the shortening is proportionately equal in the muscles affected. Myopia is frequently combined with strabismus, when several of the recti muscles are retracted to greater relative shortness than one of

them, or even only one rectus muscle is retracted but to a slight extent. The characteristics of mechanical myopia resemble those of mechanical strabismus, furnished by the shape of the ocular globe, and by the movement of the eyes. The active treatment of mechanical myopia should consist in the subconjunctival section of the too short or retracted muscles. M. Guérin has several times performed this operation with success; sometimes for complicated cases of strabismus, sometimes for cases of simple myopia without strabismus. The immediate knowledge of the cause of mechanical myopia tends to demonstrate that the eye adapts itself by alternately lengthening or shortening to the means of the primary contraction of the recti muscles, at the distance of the objects at which it looks. Direct experiments prove that this is so.

M. Guérin presented to M. Arago a young man, aged twenty-eight, in whom alternate retreat and relaxation of the eye, corresponding to short and long sight, were appreciable without the help of any instrument. These facts and experiments help to show that the crystalline lens does not alter in form to adapt itself to the sight at different distances, but that it only changes its relation with the retina and the transparent cornea.

September 14.—*Myopia*. M. Giraud-Teulon continued the discussion on myopia. According to him, it is perfectly established by the modern school that the recti muscles by their contraction have no direct action on the mechanism of the adaptation of the eye to different distances. This same adaptation is realised by the single and only modification of the curvature of the surfaces of the crystalline lens, which neither changes place nor distance in relation to the cornea or the retina during this modification of form. M. Giraud-Teulon summarily enounced the experimental facts on which the two laws rest, which he called to recollection. The recti muscles (no more than the oblique) only take a direct and mechanical part in the act of accommodation. Anatomy, physiology, and experimental pathology show the same teachings. Only to cite the latter, in a case of complete paralysis of the outer muscles of the eye (*Lusitas oculi* of the ancients), Von Graefe has recorded the persistence and preservation of the faculty of accommodation. *Per contra*, it is daily observed that the instillation of a strong solution of atropia, which leaves the action of the motor muscles of the eye perfectly intact, completely paralyses the power of accommodation. On the other hand, we see the reverse effect produced under the influence of Calabar bean or its alkaloid, eserine. It is not difficult, according to M. Giraud-Teulon, to directly demonstrate that this adaptation has taken place by a modification which has supervened in the degree of curvature of the lens, and only so occurs. M. Giraud-Teulon ended by calling to mind that myopia, being one of the most serious of acquired diseases, may be prevented by prophylactic measures; by a hygiene founded on the knowledge of its real mechanism.

ACADEMY OF SCIENCES.

June 7, 1875. *Lightning Accidents*.—M. Passot sent details of three cases of accidents from lightning. 1. The two first cases were actually struck down by the stroke. 2. The portions of the body struck were of little importance with regard to nervous phenomena. 3. The effects on all three cases diminished

very rapidly from the first to the last struck. 4. In the first two cases, the lightning-stroke caused a complete resolution of the muscles; and in the third a muscular contraction.

June 14. *Phenomena of Old Age*.—M. Chevreul presented a third memoir on the explanation of the numerous phenomena consequent on old age. The first section of this memoir comprised the exposition of the sources whence the author derived the instructive and intellectual faculties of animals and man, examined in their normal condition. The object of the second section was the application of the study of those faculties, as they were seen in the first section, to the explanation of several phenomena of the decadence of the human understanding brought on by old age.

July 12. *Spontaneous Coagulation of Blood*.—M. Hénard communicated a note on the causes of the spontaneous coagulation of blood when it leaves the organism. One of the principal causes is the contact of a foreign body, as that of the palette in bleeding. If a segment of vein filled with blood be sheltered from contact with the air, coagulation does not take place; when the vessel is dry, the sanguiferous mass becomes pulverulent. Thus the blood retains its vivifying property whilst it is in contact with the vascular walls; coagulation is death of the blood.

August 2. *Recurrent Sensibility of the Nerves of the Hand*.—A note by M. A. Richet was read, on the recurrent sensibility of the peripheric nerves of the hand. In 1864 Langier made the suture of the median nerve at the level of the wrist, and having found that peripheric sensibility was re-established, he declared that conductivity had been re-established by the cicatrix. M. Richet, having had the opportunity of observing a similar fact, sought for peripheric sensibility before making a suture, and found it intact. This fact demonstrated to him that the peripheric sensibility of the median nerve is assured by the anastomoses of the terminal loops with the filaments of the radial and cubital. Besides, the nerves of each side of the hand receive from the opposite side filaments which terminate at the same part of the teguments. To resume, where at first only a fact of immediate reunion of the nerves with passage of the nervous influx across the cicatrix had only at first been seen, M. Richet had, he said, shown that on the contrary, there was nothing but the physiological manifestation of a pre-existent normal anatomical disposition of which the physiologists had taken no account, and which had but very distant relations, if any, with the facts of recurrent sensibility discovered by Magendie in the posterior radial. It is important in the interests of truth to formulate these data, which once again demonstrate that clinical observation which has fixed the attention of learned men on these remarkable facts, especially of the histologists and experimenters.

REVIEWS.

An interesting Pamphlet, printed for private circulation, contains the following 'Collected Papers,' being the various communications which emanated from the Physiological Laboratory of University College, London, during 1874-75.

1. *Note on the Excitation of the Surface of the Cerebral Hemispheres by induced Currents*. By J.

BURDON SANDERSON, M.D., F.R.S. (*Proceed. Roy. Soc.*, June 11, 1874.)—The author finds (1) that severance of the superficial convolution, without disturbing the flap, does not alter the properties of the active spots; (2) on the surface of a deeper horizontal cut, corresponding spots exist which have the same properties; (3) when the corpus striatum is reached, the same movements are produced by excitation of its upper and outer part. He concludes that the superficial convolutions do not contain organs essential to the production of certain combinations of movements.

II. *Note on the Electrical Phenomena which accompany Irritation of the Leaf of Dionæa Muscipula.* By J. BURDON SANDERSON, M.D., F.R.S. (*Proceed. Roy. Soc.*, October, 1873.)—This describes the method of detecting the electric current from the proximal to the distal end of the leaf of *Dionæa* (normal leaf current). And in the stalk a current in the opposite direction. Irritation of the sensitive hairs on the upper surface of the lamina causes the galvanometer to swing in the opposite direction (negative variation), and the leaf closes. The deflection of the needle by the stalk current is increased by the irritation of the leaf. Electrical excitation produces the same effects.

III. *Note on the Intercellular Development of Blood-Corpuscles in Mammalia.* By EDWARD ALBERT SCHÄFER. (*Proceed. Roy. Soc.*, no. 151, 1874.)—Among the cells of the subcutaneous connective tissue of the new-born rat, the author describes some as having a reddish tinge throughout, while others contain red patches varying in number, size and circumscription. Some cells are obviously filled with distinct red globules of hæmoglobin. These (connective tissue) cells become elongated and the red globules are seen in a common cavity of fusiform shape. When two or three of these cells overlap by their pointed extremities they coalesce, and their cavities become continuous. The development of these hæmopoietic cells is likened to that of the area vasculosa of embryo chick.

IV. *On the Cartilages and Synovial Membranes of the Joints.* By CARL REYHER, M.D., of Dorpat. (*Journal of Anatomy and Physiology*.)—The author details investigations into the mode of development of the surfaces of joints, by which the cells on the inner side of the capsule are shown to be continuous with those on the surface of the cartilage, and the so-called synovial processes are seen also to be derived from this layer of superficial cells, which at one time were very like epithelium.

V. *An Account of Certain Organisms occurring in the Liquor Sanguinis.* By WM. OSLER, M.D.—Changes are described as taking place, after the addition of neutral fluid and heat to 37° Cent., in certain masses of organisms found in the blood of most animals. When watched for a long time under the above circumstances the familiar granular masses become less dense at their margin, and numerous filamentous and spermatozoon-like forms are seen wandering away from the mass. In a few hours nothing but small granules are left, and at the end of six hours the original mass has nearly quite disappeared.

VI. *The Structure of the Pacinian Corpuscles considered with reference to the Homologies of the several parts composing them.* By EDWARD A. SCHÄFER, Assistant-Professor of Physiology, University College,

London.—The paper contains an accurate description of the structure of the Pacinian corpuscles which are shown to be composed of (1) central fibre, (2) core, and (3) tunics. The central fibre is continuous with the axis-cylinder of the communicating nerve. The medullary sheath stops short of the corpuscle, the primitive sheath passes around and blends with the outer layer of the core, while the neurolemma is continuous with the outer layer of the tunics.

VII. *Description of an Apparatus for Maintaining a Constant Temperature under the Microscope.* By E. A. SCHÄFER, Assistant Professor of Physiology, University College, London.—The author describes a warm stage which is heated by a circulating current of water kept at a constant temperature by means of a gas regulator, the actual temperature of preparation being determined by a thermometer passed into the central chamber of the stage. This must be removed when the preparation is to be examined.

VIII. *A simple form of Gas Regulator for Maintaining a Constant Temperature in Incubators and Air Baths, etc.* By F. J. M. PAGE, B.Sc., F.C.S.—The form of regulator here described is not affected by barometric variations, and therefore is well suited for prolonged investigations. It is, at the same time, easy to fit up.

On the Relation of Diabetes to Food, and its Application to the Treatment of Disease. By ARTHUR SCOTT DONKIN, M.D. Smith, Elder & Co., 1875, pp. 186.

Dr. Donkin is well known to the profession as an authority on the subject of diabetes, and especially in reference to its treatment by diet. Of course the conclusion arrived at is the old one of skimmed milk as the best dietary for the diabetic. According to the author milk-sugar is converted into lactic acid in the course of digestion, and therefore is of use in the economy, while it does not add to the existing glycogen. He also holds that albuminous matter in the form of casein does not readily undergo the splitting up into glycogen and nitrogenised waste, which occurs with other forms of albuminous material. Consequently in skimmed milk there is a theoretically perfect, or nearly perfect, food for the diabetic. Many persons would hold that the fat in the form of cream would be a useful addition; but Dr. Donkin, on the authority of some experiments by Salomon, holds that glycogen can be formed from fat. In this he is in opposition to most physiologists. On the whole, the work is an useful one, and from its perusal most men would gain much information on a matter very imperfectly understood, but on which more widespread information is very desirable.

NEW INVENTIONS.

BARTLETT ON PEPSIN, PANCREATIN, AND OTHER AIDS TO DIGESTION.

Mr. H. C. Bartlett, Ph.D., F.C.S., sends us the following note.

The most important of all aids to the digestion of food must be those which most nearly approach in composition and action to the solvents provided for the purpose by a healthy state of nature. A very common-sense application of scientific research has

for many years past proved the feasibility of making up for any deficiency of gastric power in the more or less dyspeptic human creature, by obtaining a supply of the needed secretion from the more powerful digestive juices of some of the domestic animals slaughtered for food.

The successful treatment of weakened digestive power by the administration of pepsin is now too much appreciated, to admit any well-founded doubt as to its invaluable application to a large section of the vast number of cases of insufficient vigour of digestion and assimilation. But a not inconsiderable proportion of failures among the indiscriminate and capricious uses, in cases where it is, perhaps, less required than some of the other equally necessary agents to carry out the digestive processes, has not unlikely tended to retard the growing confidence in the judicious employment of really good pepsin.

As I have been engaged upon some of the original investigations of the normal peptic powers of various animal digestive fluids, some rather important questions have been lately submitted to me with regard to the popular use of pepsin, pancreatin, diastase or cerealin, and other natural aids to digestion. The first is, Can the public be trusted to discriminate among the several active principles of healthy digestive fluids, so as to select those which are most required in each particular case, and can non-professional purchasers form any estimate of the purity of the different samples, or of the quantities suitable to be taken? Careful consideration leads me to the belief that a concise, yet untechnical, description of the more important components of the fluids which cause a healthy digestion of food, together with the effects produced by each in this process, could enable persons of ordinary intelligence who may require them to make beneficial use of several of these aids to digestion. Moreover, if the exact strength of each article, and the proportions in which they are combined in the more complex preparations, were stated and guaranteed by the vendors, as is not always the case at present, a little experience would usually determine the quantity best adapted to the requirement from time to time.

Food is digested in the first place by the ptyalin or animal diastase of the saliva, which is the most considerable and active agent in the transformation of the large mass of starchy matters which form, or should form, three-fifths of the ordinary solid food. It must be remembered that, unless the starch be so transformed into glucose or sugar, it cannot be digested in the stomach in any appreciable degree, the constituents of the gastric juice, including pepsin, rather preventing than favouring this change into soluble saccharin and dextrin.

However important this transforming action of the diastase of the saliva upon starch may be, and its importance can hardly be overrated, it is only upon starch that this principle has any active chemical agency; neither emulsifying fat nor assisting in dissolving albuminous substances, except in so far as its secretion with a large amount of water and oral mucus mechanically aids the previous mastication.

Pancreatin and the active principles of the secretion of the bowel-glands are the only other portions of the digestive fluids which have any transforming influence over starch; and from some experiments, which I have not yet quite completed, there appears to be a great doubt if this action can be maintained

in the presence of a sufficient proportion of fat in the food to absorb the fluids of the pancreas and bowel-glands in forming that fatty emulsion which appears to be their proper function. If this be correct, as my results at present lead me to believe it to be, a counterbalance between any discrepancy of the proportions of the carbo-hydrates to the hydrocarbons in a mixed diet may be made up, not by chemical evolution as Liebig thought, but by the ordinary processes of digestion, in which the pancreatic and similar fluids may emulsify a too small proportion of fat in the food, and then expend themselves in transforming any starch which has evaded the action of the saliva.

Pancreatin has also been supposed to dissolve albumin under certain conditions; but this is not the case when the fluid containing it is fresh; the putrefactive decomposition of the albuminous portion of food, produced by already partially putrid pancreatin, can, therefore, have no relation to the healthy formation of peptones by pepsin; on the contrary, the evidence of such decomposition proves the necessity for greater peptic power in the stomach, followed by antiseptic treatment to arrest this dangerous condition.

Hence, we must depend mainly upon diastase, ptyalin, or cerealin for the conversion of starch, and upon the bile and pancreatic fluid for the absorption of fat, and especially upon the latter as an aid from without towards digestion of this essential constituent of food.

I now come to the composition of the gastric or stomach juice; and, without referring to its minuter ingredients, it will suffice to mention that to effect the due digestion of the nitrogenous or albuminous part of food, it must consist of a sufficiency of pepsin and acid salts, and be duly diluted with saliva from the mouth.

The absolute necessity for dilution with saliva was very curiously shown on performing tracheotomy on a dog, a bone being firmly wedged so as to completely close the oesophagus. No digestion of the meat in his stomach took place, although there was an abundant solution of acid salts and pepsin; neither did digestion commence on injecting distilled water into the stomach; but directly the bone was extracted, and the saliva again trickled down into the stomach, rapid digestion began.

The quantity of acid salts requisite for the solution of albumin, and their exact composition, need not be entered upon in this paper, as, in the event of these being insufficient to cause a vigorous action of the pepsin upon the albuminoids, medical advice must be obtained, and aids to digestion must be administered with critical acumen. But of pepsin it will be found that, in many cases of impaired digestion, where cheese and the harder portions of meat are sources of pain and inconvenience, and peas, beans, some of the most highly nitrogenous of vegetable foods, occasion the most unpleasant flatulence, a little good pepsin may be of great benefit.

Pepsin, as sold, unfortunately, is not even of an average equality of strength or purity. Some will dissolve nearly a hundred times its weight of coagulated albumin; other samples are not found equal to one-tenth of this power. Almost absolute purity can be, and is, attained in a few of its preparations, but in many it is lowered by admixtures of various kinds. The following analysis of a sample recently sub-

mitted to me affords a good example of this latter class.

Percentage composition.	
Moisture	10'20
Pepsin	20'00
Animal tissue, not pepsin	7'30 liable to cause putrefaction.
Starch	57'42 { cheap arrowroot, evidently added to increase weight and bulk.
Salts	5'15
	100'07

In continuing this subject, further illustrations of the preparations of pepsin, pancreatin, and other aids to digestion will be procured as sold, and the analyses will prove how far they may be depended on.

H. CALANTE
A. PARIS.

rectum nor in the *bas-fond* of the bladder. The flexibility of this ring also allows it to change its form temporarily, but its elasticity causes it to return to its circular form as soon as the peripheric pressure no longer exists. This peripheric pressure is infinitely varied according to the full or empty condition of the reservoirs of the pelvis minor, and according to the different movements of the patients. This ring pessary is very inexpensive, and will be found useful in all uterine displacements. M. Dumontpallier has applied it in a great number of cases, and always with the greatest success. Its introduction can be effected without the knowledge of the patient.

RING PESSARY.

At the meeting of the Paris Société des Hôpitaux on August 13, 1875, M. Dumontpallier presented a ring pessary, which is a modification of that of Meigs of Philadelphia, and is also very similar to the pessary laid before the society by M. Gairal of Carignan, a description of which will be found in the *Bulletin Général de Thérapeutique*, vol. lxxxviii. p. 337. This ring pessary is composed of a very flexible, very elastic watch-spring, surrounded by a gutta percha covering. The inventor has thus obtained an extremely flexible ring pessary, which, no matter what shape it receives from pressure, always reassumes its original circular form. Hence, this ring may be introduced with the greatest ease, and when it has been placed *in situ*, its flexibility allows it to model itself on the parts with which it is in relation. Consequently it produces no annoyance, either in the

MISCELLANY.

M. BOUILLAUD has resigned his chair as Professor of Clinical Medicine in the Faculty of Paris. The eminent professor will still, however, continue to practise and to take part in the discussions of the Academy of Medicine and the Academy of Sciences.

ACCORDING to the *Academy* there exists in St. Mark's Library, at Venice, a MS. in the handwriting of John Locke, consisting of notes on medical subjects, which, our contemporary observes, is the more curious if, as has been said, Locke was averse from allowing it to be known that he once intended to practise medicine.

ANATOMICAL AND PHYSIOLOGICAL PREPARATIONS.—Messrs. Coles, Sons, of Liverpool, well known as preparers of Diatomacea, have recently undertaken the preparation of pathological and physiological sections for the microscope. We have seen some of their injected preparations, including some which have been made for Dr. Braidwood, of Birkenhead, and we can speak of them in high terms.

'MAGNA EST VERITAS.'—The latest intelligence concerning Louise Lateau, the so-called mystic of the Bois d'Haine, is that she no longer bleeds and that her stigmata have disappeared, since one of her sisters has taken up her abode with her and resolutely closed the door against all visitors. The *Presse Belge* adds that Louise Lateau, who, according to the Roman Catholic journals, took no food whatsoever, now displays a remarkably good appetite.

MEDICAL STUDENTS AT THE GERMAN UNIVERSITIES. The statistics of the German universities for the summer semester of the years 1874 and 1875 show a diminution in the numbers of the medical students for the present year. The number has fallen from 6,190 to 6,039. The *Gazette Générale*, whilst recording the fact, accounts for it by stating that at the present time the Jewish students apply themselves to the study of jurisprudence, whilst in former times, the legal career being to a great extent closed to them, a great number of them embraced the medical profession.

INFANT MORTALITY IN NEW YORK.—In the course of a discourse delivered at a Ladies' Aid Society in New York, Dr. Stephen Smith of that city made the startling statement that, on an average of years of all the persons who die annually in New York, about one half are children under five years of age. To be more exact, in 1872 32,647 deaths were recorded officially; of these 16,188 were under five years of age, the latter being 49.58 per cent. of the former. He analysed the causes of this excessive destruction of infant life in the course of his remarks, which are published in the *Sanitarian* for October. They reveal a state of things amongst the poor of New York, which Dr. Smith seeks to remedy by the help of ladies, who will visit the neglected homes of these neglected people as sanitary missionaries.

It is with regret we chronicle the death of Dr. Duchenne, of Boulogne, which took place on September 18, from the effects of an attack of apoplexy. Dr. Duchenne was well known to the medical profession by his remarkable labours on the application of electricity to the diagnosis and treatment of the diseases of the muscular and nervous systems.

A NEW SCHOOL OF ANATOMY.—We are informed that Mr. Thomas Cooke, senior assistant surgeon to Westminster Hospital, widely known as the author of the useful *Tables of Anatomy*, has opened a private school of anatomy. The school has been duly licensed for dissections, and Mr. Cooke's ability as a teacher of anatomy will, doubtless, be found of the greatest utility to those students who desire to supplement the anatomical knowledge they are required to obtain at the recognised medical schools.

MEDICAL EXAMINATIONS IN PARIS.—Preparatory conferences for the third and fourth examinations for the Doctorate, and for the first terminal annual examination (*1er examen de fin d'année*), are conducted at the Laboratory Gay-Lussac. They will be opened on October 20 at 3 P.M., and will be continued on the following Mondays, Wednesdays, and Fridays. The subjects treated are: the recognition of plants and medicines; principal reactions, and chemical experiments. Entries may be made at the Laboratory, No. 10 Rue Gay-Lussac, on Mondays, Wednesdays, and Fridays, from 2 to 3 P.M.

THE MEDICAL EDUCATION OF WOMEN.—The professors of Queen's College, Birmingham, by a majority of nine to three, have passed a resolution to the effect that they cannot undertake the medical instruction of women students. This resolution, it is stated, was based on the objection that the admission of women would endanger the college as a school for male students, many of the latter having intimated their intention to withdraw if women were admitted. The resolution of the professors was communicated to the college council, who have since unanimously resolved to decline to admit women students to the institution.

UNIVERSITY OF PENNSYLVANIA.—The late John H. Towne, of Philadelphia, in his will made a large addition to the endowment fund of the University of Pennsylvania. After making liberal provisions for his family and relatives, he bequeathed 10,000 dollars to the University Hospital; and after various other bequests to the Pennsylvania Academy of Fine Arts, to the Academy of Natural Sciences, etc., he constitutes the trustees of the University of Pennsylvania residuary legatees of the remainder of the estate—probably 300,000 dollars. The university has also a reversionary interest in the estate, which may ultimately make the total bequest upwards of one million dollars. The money thus bequeathed is to be held as a portion of the endowment fund of the university, and the income is to be applied solely to the payment of salaries of professors and other teachers in the department of science.

ORIENTAL CLEANLINESS AND WESTERN CIVILISATION.—Dr. J. H. Davidson, in an account of 'A Visit to a Turkish Lunatic Asylum,' published in the current number of the *Journal of Mental Science*, makes the following statement on this point. The physician superintendent of the asylum of Constantinople, from whom he obtained some interesting information respecting the care and treatment of the insane by the Turks more than three centuries ago, remarked to him that the love of the bath and of personal cleanliness shown by the Mahommedan patients contrasts strangely with the aversion exhibited to all ablutionary processes by the few Christian inmates of the asylum, who, by their education and knowledge, generally belong to a much superior class of society. On the other hand, personal cleanliness being strictly commanded by the laws of Islamism, the Mahommedan patients never, or very rarely, manifest the slightest reluctance to the bath, but rather the contrary.

ANATOMICAL MICRO-PHOTOGRAPHS.—The *Monthly Microscopical Journal* mentions that, at the meeting of the British Association, Mr. H. B. Brady exhibited a series of photographs, chiefly from physiological and pathological preparations, taken by a new and simple process devised by Mr. Hugh T. Barman, of Newcastle. The apparatus was also shown, and described to consist of a simple mirror of spectrum metal placed at an angle of 45° , in front of the eye-piece of the microscope directed downwards. The image was received upon a collodion plate set in the frame of a common photographic camera, and photographic copies taken in the usual way. About eleven seconds were stated to be a sufficient exposure for the purpose.

A NEW FOOD.—A society of rat-eaters has been formed at Gembloux in Belgium. The members meet once a week, and the proceedings are wound up by a grand (?) banquet, in which preparations of that delicious animal held a prominent position. This society, following the example of the Hippophagic Society, wishes to destroy the prejudice attached to the flesh of these little animals. In the furtherance of this object, a learned Belgian has been at the pains to discover that the ancient Romans formerly ate grey mice seasoned with acorns and chestnuts. Buffon relates that the inhabitants of Martinique eat mice, and are especially fond of musk-rat. A species of rat called the climbing rat likewise forms a large item of food at Cuba.

PHYSICAL EDUCATION OF THE YOUNG.—In a recent address to the pupils of Amherst College, Dr. Nathan Allen, of Boston, stated that it was almost twenty years since the question of doing something to promote the health of students in college was first agitated and discussed, at the meetings of the board of trustees. This resulted in the erection of the gymnasium in 1859, and the establishment of the department of physical culture and hygiene. Since that time fifteen classes had entered college, and more than three thousand students had taken part in these exercises. It had proved a great success, as was shown by the contrast between the health of the students at the present and their condition before the system was adopted. It has had its influence both in the discipline and in the scholarship of the college. It has been made one of the required exercises, and excellence in this department plays a part in determining the rank of the student.

A NATURAL RESULT.—The *Liverpool Courier* of September 13, states that the other day Mr. C. W. Hodgkinson, horse-slaughterer and grease-manufacturer, received at his works, near Sandhills station, a horse which had just died from an obstruction in the bowels. On a *post mortem* examination, Mr. Hodgkinson discovered in the colon the following articles; eleven hundred nails, ranging from about half to an inch and a-half in length, a quantity of small screws, buttons, curtain-hooks, and other miscellaneous items of a scarcely more digestible kind. It is not known how the horse obtained such appetising morsels, but probably from often feeding in close proximity to a nail-manufactory, or an ironmonger's establishment. That the foreign ingredients had been in the poor beast's intestines for a considerable period, was proved by the fact of their having been worn smooth and thin by the friction to which they were subjected. It appears that Hodgkinson has preserved the nails, screws, curtain hooks, etc., for the inspection of the incredulous.

THE HOPKINS UNIVERSITY.—Mr. Jonas Hopkins, a rich citizen of Baltimore, has lately died, and after providing for his relatives and leaving various minor benefactions, has bestowed the chief part of his estate to found a university with an affiliated medical school and hospital. Both the university and the hospital receive separate landed and other property, of such a substantial character that the value of the total amount is over three millions of dollars. Each institution is to be controlled by a board of nine trustees, and the same persons are to be on both boards.

The university will have no ecclesiastical or political character or supervision, and will be modelled as far as possible after all that is best in similar American and European institutions. It is intended to give the highest instruction that can be obtained, and the trustees are to act in accordance with the most enlightened experience of the day. The scientific and literary departments will first be organised, and then will follow the departments of Medicine and Law. No permanent buildings will be erected till all the Faculties are in working order and the wishes of each professor can be carried out; meanwhile a building has temporarily been secured in Baltimore, on the outskirts of which city are the grounds Mr. Hopkins has left for the hospital and university which in future will bear his name. The trustees have already selected the President of the University, and have found an admirable head in Mr. Henry Gillman, formerly the Principal of the San Francisco University. Mr. Gillman is now in England maturing his plans and gaining information from various universities in Europe. Only one chair has yet been filled, namely, that of Mathematical Physics, and to this Mr. H. A. Rowland has been appointed. It is hoped that students will be received in 1876.

UNIVERSITY OF CAMBRIDGE.—The Board of Natural Sciences Studies have issued the following notice with regard to the examination for the Natural Science Tripos for 1876 and following years. The notice is issued in lieu of the schedules dated May 15, 1871, which are withdrawn:—
'In the papers set in the first three days (in June) the questions in all the subjects will be of a comparatively elementary character, and will be such as to test a knowledge of principles rather than of details. Specimens may be exhibited for description and determination. In physics the questions will be limited to the elementary and fundamental parts of the subject, and, in particular, special attention will be paid to the definition of physical quantities, the general principles of measurement, the configuration and motion of a material system, the laws of motion, and the comparison of forces and of masses. In sound, light, heat, electricity, and magnetism, only the fundamental laws, their simpler applications, and the experiments which illustrate them, will be required. In chemistry the questions will relate to the leading principles and experimental laws of chemistry, the properties of the commoner elements and their principal inorganic compounds, the outlines of metallurgy, and simple qualitative and quantitative analysis. In mineralogy the questions will be confined to elementary crystallography, the general properties of minerals, and the special characters of those species only which are of common occurrence. In geology the questions will be limited to physical geography, the interpretation of the structure of the crust of the earth and the history of its formation, so far as to involve only the elementary parts of paleontology and lithology. In botany the questions will relate to the elementary parts of vegetable morphology, histology, and physiology, and to the principles of a natural system of classification. Candidates will be required to describe flowering plants in technical language. Questions will not be set in the first three days on vegetable paleontology, the geographical distribution of plants, or details of classification. In zoology with comparative anatomy minor details will not be included in the questions relating to classification. Geographical distribution of animals is held to be a part of zoology, and comparative anatomy includes the structure of extinct as well as of recent forms. In physiology the questions will be of a comparatively elementary character.' The range of questions in the second part of the examination for the Tripos is not defined. The Board of Medical Studies for the guidance of students proceeding to medical degrees have issued schedules defining the range of the examinations in chemistry and other branches of physics, botany, and comparative anatomy. The schedules are of considerable length, and are published in the *University Reporter*, which can be obtained of the University publishers, Deighton, Bell, and Co.

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON THE SEMEIOLOGY OF CHILDREN'S DISEASES. BY DR. A. CUZZI, ASSISTANT IN THE CLINICAL DEPARTMENT OF THE OBSTETRIC INSTITUTION OF TURIN.*

Gentlemen,—We yesterday ended the study of manual midwifery; and to-day I will satisfy the wish which you have expressed to me, by treating briefly of the general pathology of early infancy. Hufeland, in his treatise on Practical Medicine, the fruit of fifty years' experience, has said that the diseases of infancy are of the highest importance, since a third of the sick are children, and their diseases present a particular character. These diseases assume a special aspect from the great mortality which attends them; according to Roger, of five infants one dies in the first year of life; and at the end of the fifth year the mortality amounts to 33 per cent.

Hufeland divides childhood into three periods:

1. From birth to the first dentition.
2. From the first dentition to the seventh year.
3. From the seventh year to puberty.

The greatest mortality occurs in the first of these periods; the least in the last.

Another classification of the diseases of children may be derived from their nature and character. Thus we have:

1. Diseases proper to this age (umbilical erysipelas, and sclerema, hydrocephalus, tongue-tie, rickets).
2. Diseases which are rare in adults, but which on the contrary are very frequent in children (convulsions, contractions, whooping-cough, eruptive fevers, croup, scrofula, etc.)
3. Diseases which assume a particular impress (tuberculosis, which tends to become generalised, meningitis, which is granular, pneumonia, which instead of being lobar is lobular.)
4. Slight diseases which appear to be severe (ephemeral fever, with a temperature of 105° Fahr.), and severe diseases with slight symptoms (diseases of the heart, etc.)

I will divide the study which we are making into two parts; in the first I will speak of the physiological modifications which occur in the infant, and in the second of infantile semeiotics.

Physiological Modifications.—At the moment of birth, when the umbilical cord has been divided, a new and independent life commences for the child; hitherto a parasite on its mother, it now has to live an isolated life. Incapable of providing for its own wants, sensibility and the instinct of sucking are the most developed faculties which it possesses. It grows rapidly; assimilation and hæmatosis are carried to a high degree, which explains the frequency of diseases of the digestive passage and of

the pulmonary apparatus. When I speak of the etiology of the diseases of infancy and of the temperature of children, I will point out to you the importance of cold as a very frequent cause of disease at this age. I will here only remind you that the foetus in the uterine cavity lives in an uniformly elevated temperature; but scarcely has it come to the light when its delicate organs are under the influence of cold, and of all the other external agents, and hence the readiness with which conjunctivitis, bronchitis, etc. occur. A little later, when the first smile and the first tears begin to appear (at two or three months), and when the brain begins to perform its functions, as indicated by the few connected words (at two years) or entire phrases (at three years) which the child learns to pronounce, the very delicate structure of the nervous centres will explain to us the frequency of convulsive diseases. It is only from the fifth or seventh year that memory and attention are manifested, and the child learns to read. I will speak to you at the proper time of dentition and the disturbances of health which it produces; but there is another still more potent cause of disease, that is to say, weaning. A sudden change in the kind of food is the habitual origin of those enteric affections which decimate children, especially among the poor classes.

I will now examine the physiological modifications a little more in detail.

1. *Circulation.*—I will not describe the foetal circulation; you know that the placenta acts as lung, intestine, and kidney. The umbilical cord having been tied, the placenta ceases to perform its functions, and the blood is carried to the lungs, abandoning the course through the ductus arteriosus. From the lungs, the blood arrives at the left auricle, distends it, and increases the internal pressure, the effect of which is to render the foramen ovale imperious. It is to the dilatation of the chest and to the increase of blood-pressure in the left auricle that the physiological changes in the circulation must be attributed.

2. *Lacrymal Secretion.*—The function of the lacrymal gland, according to Darwin, remains in abeyance until the third month, up to which time the cries of children are not accompanied by tears. Hence, in the early months, we cannot recognise the prognostic value attributed by Coën to the cry, viz., that when accompanied by tears, it indicates a slight malady; but if there be a cry without tears, the disease is a severe one.

3. *The nasal secretion* is scanty but thick and glutinous, adhering easily to the parts with which it comes into contact; hence the frequent occurrence of irritation, and the formation of crusts on the upper lip in the neighbourhood of the nostrils.

4. *The sweat* is scanty. It appears in children affected with fever, but may, perhaps, be regarded as a moisture of the skin rather than true sweat. Sometimes, however, true drops of sweat are found on the face and neck; I have sometimes seen this.

5. On the *hairy scalp* scurf collects easily, combined with dust, epidermic scales, etc., whence arise incrustations through neglect. Attention to cleanliness, oilyunctions, and washing with soap, are sufficient in the greatest number of cases.

6. *The salivary secretion* begins to appear very soon after birth (Korowin), but in small quantity; it increases after the first month, and at the fourth it escapes at the commissures of the lips. In the aphorism, *Prima digestio fit in ore*, the ancients cer-

* Concluding lecture of the Course of Obstetric Operations. (*Gazzetta delle Cliniche*, July 13, 20, and 27, 1875.)

tainly desired to point out the importance of the saliva in digestion, without, however, knowing its chemical and physiological properties. For this knowledge we are indebted to Mialhe and to Bernard. According to Korowin, the diastatic properties of saliva already exist at birth, and increase up to the eleventh month, when it is as powerful as in the adult; while Bidder, on the contrary, maintains that the diastatic properties are not manifested until the time of the first dentition. Korowin's opinion is probably the more correct one.

7. The *gastric and intestinal secretion* exists and performs its function in foetal life, as has been recently proved by Professor Moriggia. The meconium found at birth in the lowest part of the intestine seems to be composed of epithelial cells, of a small quantity of pancreatic juice, of mucus, of amniotic fluid, of cutaneous *vernix caseosa*, of epidermoid cells, and of bile, which gives the whole a green-brown colour. In the infant, digestion consists in the saccharification of starchy matters, in the transformation of the albuminoids into peptones, and in the emulsionising of fats by means of the special principles of the digestive juices (diastase, pepsin, pancreatic juice, bile). The residuum of digestion, the fæces, are capable of affording us useful information in children's diseases; in the normal state they have a yellow brown colour, and a characteristic odour which they begin to acquire in the neighbourhood of the ileo-cæcal valve. If the bile be wanting, the excrements acquire an intolerable putrid odour, and remain uncoloured as in the dog. Thus it seems that the bile acts on the fæces as an antiputrescent and colouring substance. The following materials enter into the composition of the fæces of the infant: the remains of food not acted on by the digestive juices, or which is not absorbed although digested; the intestinal mucus; the products of secretion by the digestive glands; and gases, among which, according to Ruge, hydrogen predominates if the diet be exclusively of milk; in the opposite case, carbonic acid.

8. The *urinary secretion* is abundant in the unweaned infant, and becomes more scanty when lactation has ceased. It is of rather low specific gravity, and not much coloured; but it is rich in urates, and, according to some, in consequence of the renal circulation not being as yet slow, the urine of a newly born infant contains urates. I do not think this opinion absolutely correct, since, in about fifteen cases in which I drew off the urine by the catheter very soon after birth, in two only did I find traces of albumen. In order to guard against error, I employed not only the test with heat and nitric acid, but also Millon's reagent. Nocturnal incontinence of urine is frequent in infants, and in some cases resists all treatment; in meningitis, on the contrary, there is retention. It is rare to find foreign substances (such as blood and sugar); albumen, however, generally appears in scarlatina. It is unnecessary to say that in febrile diseases the urine becomes high-coloured and scanty, assuming the characters of febrile urine in the adult.

9. The diseases of infancy generally arrest development. The organism of the infant has a marked tendency to increase in weight and in length; and this increase occurs in a sufficiently regular manner to allow us to establish an average; forty-eight centimètres of length and 3,000 grammes of weight appear to be the numbers which indicate the average dimensions of children at birth in our country. In

order to estimate exactly the growth of infants, we ought to take into account race, sex, hereditary influence, and hygienic conditions; but this would require us to enter too much into detail. The increase in length appears to be eighteen centimètres in the first year; nine centimètres in the second; eight centimètres in the third; sixty-five millimètres in the fourth; fifty-five millimètres in the fifth; and so on up to the age of fifteen. In the first days of extra-uterine life the weight diminishes, and at the end of the second day there is a loss of about 100 grammes. This loss is very soon compensated; at the end of the first week the weight has reached the original figure; it goes on increasing by twenty to twenty-five grammes a-day during the first five months, and by ten to fifteen grammes a-day from the sixth to the twelfth month. The weight is tripled in the first year; according to Tourdes, the child seven years old is five times as heavy, and according to Quetelet seven times as heavy, as at birth.

10. *Closure of the Anterior Fontanelle*.—This fontanelle presents a space which remains constant during the first three months of life, increases during the next six months, decreases from the ninth to the twelfth month, and is closed in the next three months. The mechanism of the early increase and subsequent closure of the anterior fontanelle has been studied with precision. Three bones with four edges enter into its formation. For every millimètre of deposit of osseous substance on the edges which tends to cause the closure of the fontanelle, there is a millimètre of increase in the length of the edges; and, the bones being three in number and the edges four, the fontanelle will not close until the cranial sutures have become united. The anterior fontanelle allows the increase of the cranial cavity, and thus acts as a safety-valve, avoiding compression of the cerebral mass, which, from a weight of 500 grammes at birth, increases to 750 grammes at the end of the first year.

The anterior fontanelle projects in cerebral hyperæmia and in hydrocephalus, is depressed in atrophy, is closed later in rickets, etc.

In spite of the endeavour of Dr. Fischer, of Boston, cerebral auscultation (which is practised by placing the ear or the stethoscope over the great fontanelle) has not come into favour, because the results obtained by it are almost *nil*. Besides the sound produced by the entrance of air into the nasal fossæ, and that of deglutition, there is heard a systolic soufflé, generally mild in character, which has been called the cephalic soufflé, and is said to be peculiar to chronic hydrocephalus, but is not constant. Another cephalic soufflé is perceived in anæmia, coincident with the soufflé produced in the vessels of the neck, and is probably nothing but a murmur propagated from that region.

11. The last of the physiological modifications which we have to examine is *Dentition*. [The dental formulæ of man, and the periods of eruption of the teeth, are here given.] The eruption of the teeth does not always follow the order laid down; it is not rare to see one of the groups of teeth slow in appearing, and in certain cases we see various accidents arise which it is well to know, because they sometimes assume a peculiar gravity. These accidents are in the first dentition, general and local; in the second, purely local.

Local Accidents of the First and Second Dentition. The gums may become inflamed during the first eruption of teeth; and this may be accompanied by

the series of symptoms to which is given the name of dentition-fever; it is continuous or intermittent, sometimes with sleeplessness, crying, and restlessness; sometimes with depression and somnolence. The gingival inflammation may be the starting-point of phlegmonous periostitis. In the second dentition the local accidents (neuralgia, periostitis) almost always appear during the eruption of the third large molar, especially the lower one.

General Accidents of the First Dentition.—These accidents are due to the reflex action of the nerves, and also to the state of weakness in which infants generally are at this time of life, which renders their nervous system more susceptible. The most dangerous of these accidents (convulsions, ophthalmia, inflammations of the digestive or respiratory apparatus) are convulsions, which in certain cases of great severity may prove fatal by asphyxia, by syncope, by cerebral congestion, etc., or be followed by paralysis of one of the senses or of a limb. I believe, however, that the cases which present so great severity are rare.

Infantile Semeiotics.—The clinical examination of an infant is attended very often with serious difficulties, through its want of reason, through its defective intelligence, through its crying, and through its agitation when it sees the physician. Hence a rigorous examination of the persons surrounding the little patient ought never to be passed over, in order to complete the description of the symptoms, which are often defective and incomplete. It is to the mother that we should in preference direct our inquiries, since in her maternal love develops the spirit of observation; otherwise, an attentive and intelligent nurse will be able to furnish the information which we require.

If the sick infant be not more than three months old it easily allows itself to be examined, and does not offer any resistance; but at the same time it cannot furnish indications of any kind, and the physician then finds himself in the condition of the veterinarian; if, on the other hand, the infant be more than three months old, we may certainly be able to gain from it some information regarding the previous or present state of its disease; but in the greatest number of cases it resists examination and is frightened at our presence. Hence it is necessary for us to win its confidence, a task all the more difficult when the child lives a family life, retired from society, so as not to be accustomed to the sight of strangers. On this point authors give us special rules as to the *modus faciendi*, rules which, as they are sufficiently well laid down in the additions which Sonsino has made to Galligo's treatise, it is unnecessary for me to describe in detail.

On first entering the chamber, if the child be awake, the physician should appear to take no notice of it, and should at first interrogate the persons surrounding the little patient. He should always direct his questions so as to obtain information on the following particulars.

1. The state of health of the parents, the age at which conception occurred, and whether the marriage was consanguineous (Mantegazza), and the strength of the child at the time of birth. All these inquiries should be made with great prudence; it is unnecessary to state the motive.

2. Whether the child has already suffered from those infantile diseases which leave a certain immunity (scarlatina, measles, etc.); whether it has been vaccinated and with what result.

3. Cold being one of the most potent causes of diseases of infants (of which we shall see the reason when we speak of temperature), the physician will endeavour to ascertain if this cause has acted in the case in question.

4. He must learn where, how, and when the illness was first manifested, what remedies have been used, and with what result.

5. He must bear in mind the liability of infants to complications and successions of disease (as where laryngitis passes by continuity of tissue into bronchitis, and this into pneumonia, etc.), and must also notice the prevailing type of disease.

These particulars having been collected, we come to the examination of the present condition. We will examine the infant in the state of rest, or while sleeping, and in the state of activity; passing in review the various functions in place of following the method of examining *a capite ad calcem*, because it is too long, and the infant easily becomes tired. We will commence with the external aspect, passing then to the study of the pulse, the temperature, the respiratory organs, the digestive apparatus, and the nervous system.

External Aspect.—This may be divided under three heads: the attitude, the physiognomy, and the external surface of the body.

a. The *attitude* of an infant is best examined during sleep. During the first days of life, it tends to assume an attitude analogous to that which it had in the uterine cavity; later, it assumes indifferently almost any position, so that the articular ligaments are relaxed. The infant should be lightly covered, so that it may not be awakened when we wish to examine it. Certain diseases oblige it to assume a certain position. 1. If it be threatened with asphyxia (from pulmonary disease, etc.) the trunk is raised, and the infant endeavours to sit in the bed in order to allow the respiratory muscles better action. 2. If it be affected with febrile disease, the infant is agitated, as if it wished by its movement to disperse the superabundant heat which is generated in its organism. 3. If the disease be painful, there is immobility. 4. In typhoid affections, a lateral or pendulum motion of the head is sometimes observed, the fixed point being at the occiput, which rests on the pillow. 5. In spinal meningitis, the head is buried in the pillows by the contraction of the spinal muscles. 6. In hydrocephalus, and in meningo-encephalitis, the infant carries its hand to the head, the seat of its suffering, as if it wished to pull at its hair. 7. During the eruption of the teeth, it puts the fingers, or any object it has in its hands, into its mouth. 8. In rachitis, the infant cannot sleep with its occiput resting on the pillow (in consequence of the softening of this bone, which is the first to be attacked in this disease); in the nurse's arm, on the other hand, it rests the head on her breast, and sleeps; it has a repugnance to movement and to the upright position, and walking is painful and even impossible. 9. We must also remember prostration, which is a state of apathy; the infant is motionless, and indifferent to whatever is about it: but it follows its nurse with its eyes. 10. In stupor, there is hebetude of the physiognomy; the patient seems strange to whatever surrounds it; if it be grown a little, it answers only with some incoherent words; it does not follow the nurse with its looks, and the eyes close involuntarily, as if the patient were contending against sleep (Rigal). If to the state of agitation proper to febrile diseases

be added that of stupor, we should give a guarded prognosis, since in an acute disease this condition always indicates a profound disturbance of the cerebral functions, and leads us to fear coma. Stupor is specially observed in cerebral congestion and in adynamic fevers.

b. The *physiognomy* of infants up to the third month is without expression: the eye of the mother only can trace in her child's plump face the expression of intelligence or of imperfect perception. But the physiognomy is greatly modified by pathological conditions. 1. In diseases of the intestines; which, by consuming the fat, render the face pinched, and furrowed with wrinkles, the true image of a decrepit old man; and in certain conditions this may occur within a few days (as in infantile cholera, etc.). 2. In pulmonary diseases, the physiognomy expresses anxiety; the *alæ* of the nose are dilated, and the face becomes cyanotic. 3. In cerebral diseases, the face has an expression of stupor; it is habitually pallid, but from time to time becomes suffused with a lively redness which rapidly disappears. 4. The natural expression of the face may also be changed by a disturbance of the muscular equilibrium, as when there are convulsive movements of all or of any group of muscles (if the eye, especially of the internal rectus) which give the physiognomy a very disagreeable wrinkled appearance.

c. The examination of the *external surface of the body* should never be passed over, and must be made in every new case. The coloration of the skin in jaundice, in eruptive fevers, in cyanosis; the loss of colour in intestinal diseases, in disturbance of nutrition, and especially in diphtheritic angina, in which it indicates the approach of death; the *oedema* of the eyelids and the *anasarca* in scarlatina; the pathognomonic grimaces and convulsions of eclampsia, of chorea, and of spasmodic tic, are all data, the observation of which is of great value. The proportional development between the skull and face in hydrocephalus, microcephalia, and idiocy; the asymmetry of the cranium in epilepsy, which Müller (cited by Bouchut) saw thirty-nine times in forty-three epileptics; the condition of the anterior fontanelle, of the dentition, and of the chest in ricketty children, are also valuable indications. The temperament, the development of the body in proportion to the age, the state of nutrition, etc., will give you a physiological idea of the patient. It is scarcely necessary to mention the importance of this examination in skin-diseases. Thus *crusta lactea*, *eczema*, and *impetigo capitis*, *intertrigo* in the axilla and groins, *erythema* on the nates and heel, the cutaneous manifestations of syphilis in the vicinity of the anus, scabies, etc., have signs which are discovered by this examination. The atrophy of a limb consequent on essential or symptomatic paralysis, or on affections of the joints; the manifestations of *scrofula*; and the club-shaped fingers with enlarged nails known by the name of Hippocratic fingers, the state of the joints in rheumatism, the impress left by rickets—all these will be revealed by external inspection. This brief enumeration will be enough, I hope, to prove to you the necessity of habitually examining the external surface of the body.

Pulse.—The pulse becomes slower as the age of the child increases. It should be examined during sleep; and if this cannot be done, remember that when the infant is awake there is an increase of ten to twenty beats. To feel the pulse in an infant, special rules must be attended to; the radial artery

is found with the index finger; if the infant be asleep and move, its movement is accompanied with the hand, and if there be danger of awakening it, the examination is suspended. When the position of the infant does not allow us to examine the radial artery, we may choose the temporal, carotid, etc.

The physiological average of the pulse varies much with different authors. Thus, according to Trousseau, the average during the first weeks is 137; according to Valleix, 87; we will regard 111 as the average for the first period of infancy, and 80 to 90 for the second. The pulse of the infant, when it has fever, rises to a comparatively higher number than in the adult; thus it may exceed 200, without indicating immediate danger. In order to be able to count the pulse in these cases, it is necessary to follow Bouchut's advice, who recommends it to be counted in series of five pulsations. The febrile state, from whatever cause arising, accelerates the pulse; on the other hand, if the pulse be slow, especially after it has been accelerated, and become irregular, we may almost certainly make the diagnosis of tubercular meningitis.

Temperature.—In ordinary cases, it is best to use the hand in ascertaining the temperature; in this way certain special characters can be recognised, such as *calor mordax*, dry or moist skin, etc. If we use instruments, we can employ two kinds of thermometers; one with a cylindrical bulb for the axilla, mouth, and rectum; the other with a flattened bulb for the various points of the cutaneous surface. For the purpose of taking the temperature, Roger has divided infants into three categories: (1) newly born infants; (2) infants from one to seven days old; (3) infants above one week old.

The temperature of newly born infants is about 1 degree Cent. (1.8° Fahr.) higher than that of the mother; after three or four minutes, it falls about 1½ degree Cent. (2.7° Fahr.); twenty-four hours after birth, it has risen to the normal figure. We must take account of this fall of temperature, as explaining to us the low calorific power of infants, which renders it necessary to keep them in a warm temperature.

In infants from one to seven days old, the medium temperature in health is 37.08° Cent. (98.76° Fahr.); the minimum 36° Cent. (96.8° Fahr.); the maximum 39° Cent. (102.2° Fahr.). Inconstancy and variation of intensity in the course of the day, without disease, are, according to Litzmann, special characters of the temperature of infants at this age. There are daily and nightly oscillations, with two maxima of elevation at 9 A.M. and 5 P.M., and a minimum at 4 A.M. The differences between the day and night temperatures are but slightly marked (Litzmann).

The average temperature of children above seven days old is 37.21° Cent. (about 99° Fahr.). *Ceteris paribus*, the temperature is higher in strong and well-made children, in whom the circulation is more active. Respiration, sex, temperament, and sleep, have little or no influence in raising the thermometer.

Diseases of infants, under a thermometric point of view, may be divided into three categories:

1. Diseases in which the temperature is raised.
2. Diseases in which it is normal.
3. Diseases in which it is diminished.

The temperature is raised in ephemeral, synochal, and intermittent fevers; but especially in pneu-

monia, in scarlatina, and in typhoid fever, in which the thermometric tracing is analogous to what is seen in the typhoid of adults. The temperature remains normal in chronic diseases of the brain, lungs, and intestines. It is diminished in sclerema (in which it may fall to 22° Cent. = 71.6° Fahr.), and in cholera.

When you take the temperature by the thermometer, use the axilla in preference to the mouth or rectum. Remember that a quick pulse and hot skin always indicate an acute and febrile disease.

(To be continued.)

THE MEDICAL PARADOXES OF M. LORRAIN.

Our lively contemporary, the French *Lancet*, or *Gazette des Hôpitaux*, for July 10 and 31 last (nos. 80 and 89, 1875) devotes four pages to the views of M. Lorrain on the subjects which we have italicised below. With questionable taste, but quite in accordance with the fashion long prevalent in America, and becoming perhaps too common in England, we are treated to a description of M. Lorrain himself, which amounts, indeed, almost to a dissection, when it comes to delineate the mental qualities of its hero. A brief extract will show the kind of portraiture thus given.

‘A strange and most original creature, whose nature is essentially sympathetic, he is at one and the same time a most careful and exact observer, and a most adventurous theoriser. A mystic dreamer and a sceptic both combined, losing himself in the thinnest regions of ether, or plunging into the most earthly of positivisms. A soul which has in its recesses the freshest feelings of poesy, with the virginal purity of a young maiden, but in its outward aspect “bearded like the pard,” or rather like some ancient Zouave, and broad-shouldered as that warrior, he discusses every question as men were wont to do in the Academic groves of old Greece!’

This exordium must not be allowed to prejudice our views of M. Lorrain’s theories.

His theory of *genital rheumatism* was promulgated publicly in a recent discussion at the Société Médicale des Hôpitaux, and is briefly as follows.

In common with many other observers, he cannot help admitting that joints become inflamed in the course of blennorrhagia (the so-called gonorrheal rheumatism). These attacks of arthritis have a peculiar, and one may say, a specific character. M. Lorrain, however, does not believe that this depends upon any virus or materies morbida, but attributes the peculiar character of the rheumatism to the organs which are affected at its outset. According to him, any irritation of the genito-urinary passages, whatever its cause or nature, may produce inflammation of any of the joints of the so-called gonorrheal or blennorrhagic type, e.g. the introduction of a sound or catheter, in an old man of sixty-two, in M. Lorrain’s wards, appeared to be the cause of rheumatism. The attacks which supervene on childbirth may perhaps admit of other explanations, such as pyæmia or septicæmia. M. Lorrain states that in healthy pregnant females, a pus-like liquid can commonly be squeezed from the urethra after micturition. Thus, a pregnant woman is, according to him, always ripe for rheumatic joint-affections. Although this seems to us somewhat rash, we must admit that gouty and rheumatic attacks are exceedingly

common in some patients just after marriage, or after sexual excitement.

As regards the treatment of *lead-colic* by opium, there seems to us to be but little originality in either the views or practice of M. Lorrain, except, perhaps, in the idea that the constipation is in exact relation to the pain, and that purgatives alone fail, because they set up fresh pain. His mode of administering opium is in clysters containing eight to ten drops of laudanum, and repeated four times in the twenty-four hours.

As regards phthisis, and what M. Lorrain calls *infantilism* and *feminism*, his theory is perhaps entirely original, though Dr. Laycock has promulgated some views which closely approximate to these under other names. A carpenter in no. 3 bed, ward S. Michel, in La Pitié Hospital, aged sixty-eight, was admitted for fistula in ano, with signs of tubercular deposit at both apices. He was still muscular, and said that he had been exceedingly strong, and that when twenty-five years of age he could easily support a weight of forty pounds on his hand, with the arm extended. Yet he was then without any hair except on the head, and looked so young that people would hardly trust him to take orders or to do work. He never had much beard; the chest, arms and legs were quite smooth and hairless, his skin was like that of a young man, or rather young woman; it was soft, supple, elastic, and of almost transparent rosininess. His tall stature and large chest made these peculiarities more striking. The hair of the head was fine, silky, and of a light chestnut; another characteristic of feminism according to M. Lorrain. Both fistula and chest-symptoms were quite recent. Must we consider him as an old man who has become phthisical by accident? Not at all, according to M. Lorrain. In his eyes this man was phthisical from birth; potentially so, to follow the phraseology of the schoolmen of the middle ages, who distinguished between entities *in potentia* and those *in actu*. In other words, phthisis, like gout, is a diathesis. The germs of it may be born with us, and form an inseparable part of the constitution, although the disease may never be developed. Phthisical individuals of this kind may even reach extreme old age, exempt from active disease, and die centenarians. Or they may be attacked with phthisis in old age like this man, who must be regarded as an aged consumptive. The importance of recognising the characters of this diathesis must at once appear, if we admit the hypothesis to be demonstrated. These characters M. Lorrain sums up in these words:—*Infantilism* and *feminism*. The fineness of his hair, the length of his eyelashes, his delicate skin, and delicate outlines, the habitual slenderness of his limbs, the want of muscularity, and an excess of cellular tissue, each and all remind us of a female although we meet them in a young man. The tardy development of puberty, or an air of extreme youth in one who has already attained puberty; in men a scanty development of hair, with fineness of such hairs as exist, and a general want of virile aspect; in women, the long persistence of delicate features, a want of roundness in their outlines (‘la peu de saillie des formes, etc.’), such characters seem to prolong the period of youth far beyond the normal. There are many phthisical patients whose age, says M. Lorrain, we underestimate by six, eight, or even ten years. These are slow in becoming decrepit, and so far, their diathesis is good for them. Even after tubercles and cavities

too have formed, life is often much prolonged. One case is known to M. Lorrain, in which a phthisical patient lingered so long that he killed himself from ennui at the age of eighty-five! Patients with this diathesis are, therefore, no more all doomed to a swift death, than all the sons of gouty parents are to be covered with chalk-stones! Careful hygiene and careful treatment will often 'obviate the tendency to death.'

The last of M. Lorrain's hypotheses, to which he himself has given the name of medical paradoxes, is on the *relations of dropsy to diuresis*. Although he calls them paradoxes, he has long conducted a series of the most careful researches with the chemical balance and other instruments of precision. But he knows too well how fallacious mathematical formulæ often are when applied to medical uses. These formulæ were enunciated *à propos* of a patient in no. 20 bed, ward Notre Dame. M. Lorrain says that every individual ought to secrete a definite quantity of urine every day. This represents his 'Normal of health.' If this weight be exceeded, he at once grows thinner. If it be diminished, he becomes dropsical. When he is dropsical, if we succeed, with diuretics, in again raising the quantity of urine above the 'Normal of health,' his body-weight will diminish in exact proportion to that excess.

As an illustration, he adduced the patient referred to, a patient who had dropsy following heart-disease. The use of digitalis, in doses of one-and-a-half grains in the form of infusion, soon produced copious diuresis. Before the medicine she passed only 600 to 700 grammes [about twenty-two and a half ounces] of urine in twenty-four hours, instead of 1,500 grammes [about thirty ounces], which was estimated to be her 'Normal of health.' She then gained weight daily, though the dropsy lessened. But the moment the urine exceeded this quantity she lost weight every day. At the end of a week she had lost nearly twenty pounds. The figures which represented the daily excess of urine over the norm of 1,500 grammes were then added up, and found to amount to the same weight as she had lost, *plus* twelve grammes (or about three drachms). This seems almost a demonstration, but M. Lorrain admits that this 'Normal of health' for her, fixed at 1,500 grammes, was arbitrary, from twelve to fifteen hundred grammes being average amounts. Hence an element of doubt, which is fatal to the scientific character of the formula. M. Lorrain affirms, however (from careful weighings), that in all dropsies, no matter what the cause, the quantity of urine is diminished. He regards digitalis as a mere diuretic, a conclusion in which his reviewers cannot support him. His description of the xanthous or rheumatic diathesis has been anticipated long since, and although Dr. Laycock has given us one of the best descriptions of its external characters, we believe it was recognised long before.

SAYRE ON SPINAL CURVATURE.

In the *New York Medical Journal* for September will be found a clinical lecture by Dr. Lewis A. Sayre on spinal curvature, with an account of some novel treatment used by that eminent surgeon. He commences by detailing the difference betwixt true spinal curvature (Pott's disease) and the lateral rotary curvature which depends entirely upon irregular muscular contraction. He does not think Pott's

disease is essentially of strumous origin, but that it much more frequently depends upon some injury than upon any constitutional condition. Children, in their play, often jump from some height, and come down straight without bending their knees or hips, thereby giving a sudden and severe concussion to the bodies of the vertebræ and the intervertebral discs of cartilage; and in this manner disturbing some centre of ossification to such an extent that inflammatory action follows, and the case terminates in inflammatory softening and disintegration of the bone itself. After such disturbance or separation of one or more ossific centres of the vertebræ, several months may elapse before attention is drawn to the case, and perhaps by that time the bones have been partially destroyed, and the distortion developed. Then it is said at once that the exhausted condition which may be present is evidence of constitutional cachexia, whereas it is simply the result of long-continued suffering from a local disease dependent upon some direct injury to the parts involved. The symptoms vary according to the part affected, and if the disease be low down, the leading symptoms are referable to the bladder and rectum. The chief symptom may be a frequent desire to pass urine. Early in the progress of the disease reflex contractions are excited among the muscles, which result in a change in the appearance and action of the child. Every joint of the lower extremity is bent for the purpose of preventing any concussion from affecting the bodies of the vertebræ. The chin is made to project; the shoulders become elevated; and it is impossible for the child to stand upright, and receive any concussion whatever which may be communicated to the bodies of the bones, without suffering pain. The muscles of the back are held rigid in order to prevent any movement of the bodies of the vertebræ upon each other. The child is unable to stoop down and pick up any object upon the floor; but, if asked to do so, begins by bending the hips, and then the knees, and, finally, reaches the object by squatting down to it. These patients never bend the back, for bending presses the bodies of the vertebræ together, and gives rise to pain; consequently all the movements of the child are directed in such a manner as to prevent any motion in the spinal column. When walking about the room, the child will reach with the hands from one article of furniture to another, making careful calculation that it shall not be deprived of the support derived from one article until it is sure of another. If it cannot obtain any support from catching hold of various articles within reach, it will rest the hands upon the thighs, in order to transmit the weight of the head and shoulders through the legs to the ground, thereby giving them support without bearing on the diseased vertebræ. In the diagnosis, it is often desirable to place some object on the floor and ask the child to lift it, carefully noting the position assumed in the act. If the vertebræ be diseased, the child will squat down and pick up the object, rising again in such manner as shall keep the spine straight, allowing no movements in the spinal column which it can prevent. It never bends over like a healthy child. Then the child should be stripped, and laid, face down, with the arms over one thigh, and the legs over the other thigh, of the surgeon; the legs should then be gradually separated, so as to extend the child's body. A long drawn sigh of relief follows the traction on the vertebral column; there is a full

inspiration and complete expiration instead of the grunting respiration which obtains. On closing the thighs again, the child recommences the short catching respiration. There is usually some spasmodic action on the removal of the extension, but if not present it will at once be induced by placing one hand on the head and the other on the sacrum, and pressing the vertebræ against each other. The instant that is done spasm is produced, accompanied with a cry, and the moment extension is made the child is easy again. The other means of making out a diagnosis are then given, after which the treatment follows. Rest in bed, of course, is the first thing; with the local application of cold, and good nutritious food. All blisters, setons, etc., are worse than useless. The plans of treatment of the disease itself are those which will afford relief to the diseased parts and are very ingenious. If the cervical vertebræ be those affected, an apparatus is fixed to the shoulders, and a steel rod passes over the head from one shoulder to the other; from the top of this the head is slung, so that the weight of the head hangs upon this frame, and does not rest on the diseased cervical vertebræ. When the disease is lower down, the wheeled crutch enables the child to move about, the weight of its body being supported by the crutch. By sustaining the body of the patient in a pendent position without fatigue, the diseased parts are relieved of pressure, while the patient can have all the benefits of exercise without injury. The chief point of novelty is the application of a plaster of Paris cuirass to the patient. The child is held up by the arms (the weight of the body acting as an extending force), the shirt is stretched smoothly over the body, then, commencing at the pelvis, rollers saturated with plaster of Paris are carried over the whole trunk, just as in dressing a fracture of the thigh. Being held in this position for thirty minutes, the plaster becomes set. The cuirass is then divided from the sternum to the pubes, when, of course, the respiration becomes perfectly easy. The lower portion is then firmly secured by a roller, while the upper portion is tied at various points with elastic bandages, so as to allow free respiration. Great comfort is thus secured. The advantages of this plan are these: Its simplicity, its economy, the material for its construction being attainable anywhere; its ease of application; the readiness with which it can be adjusted to the growth of the child; and the accuracy of fit secured, more comfort being given than could be procured by any other appliance, unless made over a plaster model which would be very expensive. The objection is, that it is not very clean, but this can be obviated by using starch, flour and eggs, silicate of sodium, etc. The interference with respiration is much less than might be anticipated. Several illustrative cases showing the beneficial effects of this method are given.

J. MILNER FOTHERGILL, M.D.

MOSSO ON SOME NEW PROPERTIES OF THE WALLS OF THE BLOOD-VESSELS.

A. Mosso (*Arbeiten aus dem Phys. Anstalt zu Leipzig*, 1874), working under Ludwig's direction, has continued and extended the researches upon the artificial circulation of blood in excised organs, begun by Professor Heger, of Brussels, in the same laboratory (LONDON MEDICAL RECORD, March 17, 1875). The complicated apparatus, carefully figured

in all its details, consists of several parts. An arrangement constructed on the principle of a Mariott's flask, so as to give a constant pressure in the principal artery of the organ upon which the experimenter is working, the pressure remaining constant throughout the entire duration of the experiment. A second part of the apparatus is employed for measuring the changes which take place in the volume of the organ experimented on itself, a most essential point, and one which till now has not been taken into consideration. To this part of his apparatus Mosso gives the name of *pléthysograph*. Lastly, there is an exceedingly ingenious arrangement for measuring the velocity with which the blood flows out of the vein. We must refer to the original for the details of the apparatus.

Almost all the experiments were made with the kidneys and livers excised from large dogs, which had been previously bled from the carotids. Of course the blood employed was defibrinated.

Several series of experiments were performed. In the first series Mosso observed the phenomena of the artificial circulation of blood defibrinated in contact with air; in the second, he studied the effects of electric currents on the irritability of the vessels; in the third, the influence of interruption of the current of blood on the velocity of the blood; fourthly, the influence of different gases on the walls of the vessels; fifthly, the action of certain poisons; sixthly, the production of oedema; and lastly, the phenomena of artificial circulation in the liver.

1. After having excised the kidney and completed the necessary arrangements, the artificial circulation is begun. The velocity of the blood from the vein and the increase in size of the organ reach their maximum, and become afterwards successively smaller until their tonus is re-established. Sometimes even with the highest pressure it is impossible to cause defibrinated blood to circulate in the kidneys. This is not due to clots interrupting the circulation, but this arrest is rather to be ascribed to a tetanus of the vessels; in fact, the circulation becomes re-established after a few minutes, to be again arrested. There are other mere movements of contraction and dilatation (rapid), which modify the velocity of the current without interrupting it. These phenomena in their rhythm resemble very closely those which Schiff observed in the ear of the living rabbit. These spontaneous movements which modify the rapidity of outflow are not shown by all kidneys. When they exist, they are very pronounced a short time after death, and even are not completely absent two days after death.

2. To ascertain whether the cause of the preceding phenomena was to be ascribed to a contraction of the vessels, Mosso stimulated the kidneys with an electric current during the artificial circulation. The kidneys were enclosed in the electrodes of tin-foil. The effect of stimulation of fresh kidneys is a pronounced fall in the rapidity of outflow of the blood. It is very remarkable, however, that the induced current has no influence, whilst the constant current interrupted every second always produces a very obvious contraction.

3. After having interrupted the artificial current for a certain time, on again recommencing the current with the same pressure, it was found that the blood flowed out with a velocity much greater than before, and the muscular tonus was soon re-established. The paralysis of the vessels which was produced during these interruptions is for intervals

which are not too large, proportional to the length of the interruptions. These phenomena can be observed even on the third day after death.

The rapidity with which the vascular tonus is re-established is in inverse proportion to the length of the interruptions; a short time after death the tonus is re-established in a very few minutes, whilst two days after death it requires three-quarters of an hour of artificial circulation to cause the paralysis of the vessels slowly to disappear, and even in this latter case small oscillations are to be perceived in the rapidity of outflow.

4. In this series, Mosso studied the influence of the gases of the blood on the circulation in the kidneys. He employed four sorts of defibrinated blood: arterial blood defibrinated without contact with air; venous or asphyxiated blood defibrinated in the same manner under mercury, so as not to lose any of its gases; blood defibrinated in contact with air, which he calls apnoëic; and lastly blood treated with iron filings, which he calls reduced blood, *i.e.*, deprived of its oxygen.

In all these researches nitrogen and non-compressed air was employed. The result obtained was, that asphyxiated blood circulates with a smaller velocity than the apnoëic. The result of this series of researches is that, in artificial circulation, every time that a species of blood is made to follow another which is poorer in carbonic acid, the velocity of outflow increases, in such a way that the vessels, even though independent of the nerve-centres, can regulate the velocity of the blood which passes through them.

5. The researches made on the circulation in the kidneys of poisoned blood, show that many of the phenomena, which up to this time have been ascribed to the vaso-motor centre or the heart, are really due to a special action on the walls of the vessels. Nicotine and atropine, in small doses, produce a contraction which is of short duration; whilst in larger doses there is considerable dilatation, with increase in the velocity of outflow. Hydrate of chloral produces also, at the commencement, a slight contraction of the vessels, which is soon followed by a very considerable dilatation. Quite as constant a phenomenon is tetanus of the vessels, when blood which has been poisoned with chloral is followed by normal blood. In order to demonstrate that all these phenomena were not due to a modification of the blood-corpuscles, the experiments were repeated with poisoned serum, which gave the same results.

6. In passing from these facts to others which have a direct bearing upon pathology, we have another series of experiments on oedema of the kidneys, where the disposition to the production of oedema increases after death. On employing non-poisoned blood for the fresh organs, there is a production of oedema or exudation for a certain time; but several hours after death there are all the characters of a well-pronounced oedema.

7. Lastly, the author studied the artificial circulation in the liver. The same phenomena are reproduced in this organ, although the portal system and the hepatic vein are very poor in muscular fibres. The variations in the velocity, and its increase after each stoppage, show that in the liver, in spite of the absence of muscular fibres in the small vessels, there occur phenomena similar to those in the kidney.

The author also demonstrated these results with

poisons (nicotine, atropine, chloral, prussic acid, etc.), which yielded the same results with the liver as have already been cited for the kidney. One difference between the vessels of the liver and those of the kidney—a difference of great interest—is that stimulation with a galvanic current, interrupted every second, is followed in the liver by a very pronounced augmentation in the velocity during the irritation; whilst the induced current has no obvious action. We have here the singular case of a stimulant which dilates the vessels without first causing them to contract.

WM. STIRLING, D.Sc., M.D.

KNAPP ON ARSENIC-EATERS IN STYRIA.

At the meeting of the German Association of German Naturalists and Physicians at Gratz in September last, Dr. Knapp presented two arsenic-eaters, and made the following remarks on the subject (*Medicisch-Chirurgisches Centralblatt*, October 22).

That there are persons who eat arsenic, that is, take it in doses which in other cases are deadly, was asserted many years ago by Professor Schallgruber (*Medizinische Jahrbuch des Oesterr. Staates*, Gratz, 1822). They also formed the subject of an article by Tschudi in the *Wiener Medizinische Wochenschrift* for October, 1851, on arsenic-eaters in Styria and Lower Austria; and the communications were much commented on in English scientific literature.

In 1857, Dr. Schäfer, then professor in the Medico-Chirurgical School in Gratz, communicated to the Academy of Sciences in Vienna a case of poisoning with Scheele's green, with a number of chemical researches on the absorption and elimination of the preparations of arsenic and antimony; he also gave an account of the examination of the urine, containing arsenic, of a man who took half a drachm of arsenious acid every second day.

At the request of the royal and imperial councillor Dr. von Vest, I took the trouble to institute some new observations on arsenic-eaters, and was able to subject one to experiment.

Johann Wölfler, aged thirty, small, but strongly built, a woodman, had, he said, taken arsenic, for twelve years. On February 21 he came under my observation. He said that he had already eaten some arsenic on that day. On the 22nd, he took, in my presence, a piece of arsenious acid, weighing just four and a-half grains. On the 23rd, he ate a piece weighing five and a-half grains. While he was under observation, the man had a very good appetite, drank a large amount of alcoholic liquors, and went away on the 24th quite well. He is still alive, an Alpine shepherd, quite well and strong, and continues the use of arsenic. Unfortunately, he could not be prevailed on to come here.

I carefully collected his urine in clean vessels, and sent it to Dr. Schäfer, who found arsenic in it.

Professor Schäfer has related these facts in a communication on 'Arsenic-eaters in Styria,' published in vol. xli. of the 'Reports of the Imperial Academy of Sciences.'

This case is also given in Hasselt-Henkel's *Giftlehre* (Brunswick, 1862) with several other cases; such as one of a director of arsenic-works at Salzburg, who at the age of seventeen began with three grains, and increased the quantity to seventeen grains daily, but in what time it is not stated.

These facts, and the above-mentioned work of Dr.

Schäfer, were made known in England through a communication of Dr. Roscoe to the Philosophical Society in Manchester. Two young English physicians, Dr. Craig MacLagan of Edinburgh, and Dr. Rutter of London, became interested in the subject; and, while travelling on the continent in 1864, they came to Styria, and desired to convince themselves of the fact by personal observation. They went to medical councillor Dr. Vest, who introduced them to Dr. Macher of Stainz, and to myself, then residing in Ligest. I had often heard that there were arsenic-eaters in Ligest, but had not yet convinced myself of the fact. I was, however, able to find two arsenic-eaters, who consented to eat arsenic in the presence of the English doctors. On March 25, M. Schober ate nearly five grains of white arsenic. Flecker, whom I have the pleasure of presenting to you to-day, took, on March 26, a piece of arsenious acid weighing six grains, having on the previous day taken arsenic in the presence of several inhabitants of Ligest. The mouths of the arsenic-eaters were examined by the English doctors, to see whether they kept back the arsenic; they took away small pieces of the substance used, in order to ascertain that it really was arsenic. Some of the urine passed by the men was carefully packed, and analysed in Edinburgh, where arsenic was distinctly found. I have the honour of laying before you some copies of Craig MacLagan's *brochure*.

It is difficult to say definitely how far the practice of arsenic-eating extends. I have convinced myself that there are many arsenic-eaters in Upper and even in Middle Styria; a number of grooms, woodmen, and hunters are known to me as arsenic-eaters, and women even follow the practice. Many begin to use arsenic at the age of seventeen or eighteen, and continue the practice to a very advanced age. Most arsenic-eaters conceal the fact, so that it is impossible to obtain certain statistics. The principal reason alleged for eating arsenic is that it protects from disease, as in the case of the man Flecker; it is also regarded as a means of producing a ruddy appearance, as a remedy against difficulty of breathing, and as an aid to the digestion of food that is digestible with difficulty. A poacher in Upper Styria told me that he gained courage through the use of arsenic. It is effectual also as an abortive; and in 1865, while in Ligest, I had the opportunity of making the *post mortem* examination of a peasant girl, Maria Payer, who had taken arsenic for this purpose; the foetus was expelled, but she herself died of arsenical poisoning ten days afterwards.

The appearance of the arsenic-eaters in the cases known to me is strong and healthy; and the sexual impulse is strongly developed in all of them. I believe that it is only strong persons who can accustom themselves to the habit. They sometimes reach a great age. I have seen in Zeiring a still very strong charcoal-burner, seventy years of age, who was said to have used arsenic for forty years. In the *Giftlehre* above quoted, is related the case of a vigorous chamois-hunter, eighty-one years old, who had long been accustomed to use arsenic. I have never observed arsenical cachexia in habitual arsenic-eaters. A case, however, occurred in Ligest in 1865 in the person of a leather-dresser, who, when intoxicated, took too much, and had symptoms of acute poisoning. According to his account, he took a piece as large as a bean; he perfectly recovered, and later again used arsenic, but with more care.

According to my observation, both white arsenic

(arsenic acid or *Hüttenrauch*), and yellow arsenic or orpiment, are used in the dry state, either alone or strewed on bread. The dose is, of course, at first very small, and is gradually increased. The greatest quantity that I have seen taken is fourteen grains. The man Schober, above mentioned, took seven and a-half grains in my presence, on April 17, 1865. The intervals at which the arsenic is taken vary much; fourteen days, eight days, twice or thrice a week.

All doubt as to the correctness of the statement that there are arsenic-eaters, ought to be for ever removed by the existing proofs.

J. F., aged fifty-five, a tailor, has taken arsenic, generally orpiment, since 1849. He was led to the practice by being obliged to go into a house where fourteen persons had died of typhus, and which no one would venture to enter; he wished to protect himself against the disease by the use of arsenic. He began by taking a grain daily for three days. Although at first he did not feel quite well, he had no vomiting, nor irritation of the stomach. He now takes about six grains of orpiment once a week; more when he has to undergo greater exertion, or when his digestion is impaired. He says that the arsenic expels gastric flatus. According to his statement, his father also took considerable quantities of arsenic. He also knows many people in the neighbourhood of Ligest, who take arsenic, many in larger doses than he uses; and he says that they all enjoy very good health.

P. H., aged twenty-five, a servant residing in Schwanberg, while serving as a herdsman, noticed that the other herdsmen gave arsenic to the cattle, and took it themselves. He also tried it, and became accustomed to it. He takes every eighth day a piece on bread or bacon, and has always been fresh and healthy; when he endeavoured to leave off arsenic-eating, he felt uncomfortable.

In both these cases orpiment was generally used.

After the reading of the paper, the man J. F. took four and a half grains of yellow sulphide of arsenic, and P. H. six grains of arsenious acid, in the presence of the meeting.

After Professor Leube, of Erlangen, had, in the name of the meeting, thanked Dr. Knapp for his communication, Dr. Barthel asked what influence the continued use of arsenic had on the sexual impulse, and whether it was the fact that arsenic-eaters became impotent. Dr. Knapp replied that he had observed the contrary in the cases that had come under his notice. Professor Gerhardt inquired whether paralysis or diminution of electric irritability had been observed in arsenic-eaters. Dr. Knapp had not noticed anything of the kind. Professor Kaposi made some remarks on the use of large doses of arsenic for a long time in chronic skin-diseases. In one case the quantity of arsenic taken in a year amounted to 225 grammes (about 340 grains). The result was very favourable; there were no symptoms of poisoning at any time.

A. HENRY, M.D.

ANATOMY AND PHYSIOLOGY.

MATTHIEU and URBAIN ON THE CAUSES AND MECHANISM OF THE COAGULATION OF THE BLOOD. MM. E. Matthieu and Urbain, according to the *Bulletin Général de Thérapeutique* of September 5, have made an important series of experiments on

the mechanism of the coagulation of the blood and albuminoid substances, which allow them to assimilate the phenomena of coagulation to a chemical precipitation. Their pamphlet on the subject (*Causes and Mechanism of the Coagulation of the Blood*, Masson, 1875) states that the transformation of the soluble substance into an insoluble compound is produced by the intervention of an acid usually masked by the alkalinity of the liquor. This acid, indispensable to the formation of the coagulum, does not pre-exist either in the milk, the muscles, nor even in the normal liquids of the organism; the blood excepted. On the contrary, the acid which coagulates the fibrine and the so-called albuminous liquids is pre-existent in the blood, in white of egg, and in the secreted or pathological fluids of the animal economy.

Carbonic acid is the agent in the coagulation of albumen and serum. Its effects are produced at a high temperature only, because the ammoniacal salts which are normally found in albuminous solutions form an obstacle to its action. Albumen deprived of volatile salts is precipitated in the cold way by carbonic acid, and transformed into a powerful embodiment of the principal properties of globuline. Carbonic acid is likewise the cause of the coagulation of the fibrine. The removal of this gas, obtained by exosmosis or any other proceeding, renders the blood incoagulable. Amongst living creatures, carbonic acid is not in a condition to coagulate fibrine dissolved in plasma, because it is combined with red corpuscles which are endowed with a great affinity for this gas. Hæmatin removes it from the tissues, and eliminates it by the medium of the lungs and the glandular or cutaneous secretions.

The obliteration of the passages by which carbonic acid is excreted cause it to pass into the plasma and bring on accidents of intravascular coagulation, induced by direct retention (pulmonary asphyxia) or by change in the corpuscles (suppression of cutaneous transpiration). The displacement of the acid gas of the blood by the oxygen of the air determines the spontaneous coagulation of the fibrine when an animal membrane does not permit its rapid diffusion into the atmosphere. The fibrine coagulates in the interior of the vessels after ligature, an extreme slackening of the circulation or inflammation, because carbonic acid, a product of direct or neighbouring oxydation, accumulates in the blood beyond the limits of saturation of blood-corpuscles. Venous or capillary thromboses develop themselves spontaneously in cachectic affections, because there supervenes an alteration of the red corpuscles, characterised by the diminution of their power of absorbing oxygen, or the acid gas of the blood.

Cadaveric rigidity is the consequence of the accumulation in the muscles of the same acid gas, developed under the influence of slow oxidations which are produced by exposure to the air. During life, venous hæmatosis, by removing the carbonic acid from the tissues, prevents the muscular coagulation in the same way as pulmonary or arterial hæmatosis, by eliminating the carbonic acid from the blood-corpuscles, puts an obstacle to the coagulation of the fibrine of the blood. The coagulation of milk is preceded by oxydation, like the muscular coagulation; and this oxydation accompanies the transformation of lactose into lactic acid. Caseine is coagulated by this acid at the ordinary temperature, or by alkaline lactates at a temperature of from 112° to 146° Fahr.

STRELZOW AND OTHERS ON THE FORMATION OF BONE.—The current series of the *Archiv für Mikroskopische Anatomie* contains three papers on this subject. They are analysed as follows in *Nature* for September 25. Two of these, those by Strelzow and by Stieda, speak of the ossification of cartilage and of bone-growth, and arrive at quite contradictory results. The older view on bone-growth starts from the supposition that the bones once formed undergo no further plastic change, that their single parts cannot displace each other, that, therefore, an interstitial growth cannot be imagined. If the growing bone, as usual, does not merely show a uniform increase in size, but little by little changes its shape too (the bent bones for instance, the bends of which change during growth), this naturally leads to the supposition that besides the deposit of fresh material, a solution or absorption of those older materials took place, which did not fit the new shape. In opposition to this view, which Stieda also defends, Strelzow tries to prove that the bone grows interstitially, that, therefore, it can change its shape in an outward direction without reabsorption of any of its parts, that it is useless, therefore, to suppose the latter to take place, and that there is no reason for such a supposition. Now, with regard to the change from cartilage to bone, it has certainly been proved, for most cases, that the cartilage is first destroyed before in its place a bone grows from fresh materials. But while Stieda thinks this the case everywhere, Strelzow observes that the lower jaw and the shoulder-blade form exceptions to the general rule, the cartilage there passing immediately from its softer state to bone. Hertwig's observations, which he makes with regard to his investigations of the teeth of Reptilia, have a much more extensive range. In Hemibatrachia the teeth form earlier than any other bones of the head, and starting from this basis those bones in the oral cavity are destroyed, which only cover the exterior of the original cartilage-skeleton, and are therefore called covering bones. In frogs these bones certainly form without the help of the teeth, which only appear at a later stage; but as frogs (Batrachia) and salamanders (Hemibatrachia) are of the same order, and particularly as the former are the more recent family, Hertwig thinks that in their ancestors the formation of teeth took place in the same way as in the salamanders now, but that in course of time they lost the primitive bone-forming teeth and retained only the bones resulting from them. The formation of teeth now observed in frogs is therefore a secondary phenomenon. Just as the bones of the oral cavity have their origin in the teeth, Hertwig supposes the covering bones on the exterior of the head to result from scales, and states that this is still very evident with certain fishes. What is a rule for lower vertebrata may also be applied to the higher orders, so that all covering bones may be derived from scales or teeth, which in sharks and rays are still equivalent and homologous formations. Therefore sharks and rays must be looked upon as the oldest forms of Vertebrata provided with bones; they are succeeded first by salamanders, then by frogs, and finally by the remaining reptiles, birds, and Mammalia.

GRAY ON CONVERSION OF NERVE-FORCE INTO HEAT.—Dr. H. A. Chatham Gray argues (*Indian Medical Journal*, September, 1875) that the direct cause of animal heat is the conversion of nerve-force into thermal energy, while chemical changes only

affect the temperature of the body indirectly by originating nerve-force. The reasons which seem to him to warrant such an idea he divides into physical, physiological, and pathological. The physical proofs consist of a very rudimentary attempt to enunciate the doctrine of the correlation of forces. The physiological facts may be thus briefly summed up. 1. 'During action, the temperature of muscle rises, not indeed from more vigorous chemical changes in the muscle,' 'for there is a considerable increase in temperature in the muscle of a frog' (*sic*). 2. 'The temperature is higher when a muscle is prevented from shortening than when it is allowed to do so,' 'the nerve-force which should have produced muscular motion being converted into heat.' 3. 'The temperature of the body falls rapidly when the brain is severed from the spinal cord.' 4. 'Division of the cerebrospinal nerves causes a fall of temperature in the parts supplied by them.' 5. 'Division of the cervical sympathetic of one side causes a very great rise of temperature on the same side of the face,' 'the superabundant nerve-force being converted into heat.' The pathological facts are:—1. 'All acute inflammations of the brain and spinal cord are accompanied with a high temperature;' 2. in tetanus the temperature is high, and this because a large amount of nervous force is liberated; 3. hysterical patients may be able to generate heat at a spot to which their attention is directed. The author thinks 'that anyone with time and opportunity at his disposal can soon settle the matter,' and he 'is very sanguine that the theory will stand the ordeal of demonstration.'

[The author appears unacquainted with the recent literature on the subject. Most of the arguments he uses, that have any connection with the question, seem rather suited to refute than support his views. As may be seen, his *data* do not partake of the singular originality displayed in his mode of reasoning.—*Rep.*]

MASIUS AND VANLAIR ON VASO-MOTOR CENTRES AND THEIR MODE OF ACTION. — M.M. Masius and Vanlair, in a paper read at the International Congress in Brussels (*Gazette Hebdomadaire*, no. 41, 1875), described researches which they had instituted with the object of checking Goltz's conclusions respecting the existence of peripheral tonic centres and vaso-dilator nerves. Their investigations led them for the most part to share his views.

Their experiments, which were performed on dogs, gave the following results, the variations of temperature of the part being taken as a measure of the amount of dilatation of the vessels. Electric excitation of the sciatic nerve or the spinal cord always caused immediate dilatation of the vessels of the parts supplied, the retraction of the vessels following the cessation of the irritation. Irritation of either end of the sciatic nerve or of the cord after section, was followed by the same result, which was very striking when the central extremity of the cut sciatic was irritated, the cord having been previously cut in the lumbar region.

More section of the sciatic nerve or of the cord was always immediately followed by dilatation of the vessels, which fact the authors consider to confirm Goltz's view that section acts as an exciting agent; however, they did not find, as he did, that the anterior limbs were similarly affected. The section of the nerves or cord was invariably followed by a progressively increasing fall in temperature of the

parts supplied; this commenced towards the end of the first week, and that remained as the ultimate result of the operation. Its gradual occurrence is explained by the slow degeneration of the vaso-dilator fibres of the cut sciatic, allowing a free field of action to the peripheral tonic centres.

The authors conclude that in the normal condition 'the vaso-dilator apparatus of the spinal centre is constantly solicited by peripheral excitations and at once reacts upon the sciatics. When part of these excitations is annihilated by severing the nerves from the cord, the latter necessarily loses part of its vaso-dilator power.'

The vaso-motor apparatus then consists of two principal centres and intermediate nerve-fibres. The centres are (1) the cerebro-spinal axis, and (2) the aggregate of the nervous cells distributed at the periphery along the vascular system. The fibres are vaso-constrictor (centripetal) and vaso-dilator (centrifugal).

GERALD F. YEO, M.D.

WARLONT ON THE FUNCTION OF THE CILIARY MUSCLE.—In conjunction with Dr. Nuel, of Luxembourg, Dr. Warlont has contributed an elaborate account of the ciliary muscle to the *Dictionnaire Encyclopédique des Sciences Médicales*; and the entire article is to be found in the *Annales d'Oculistique* (May and June, 1875). The anatomical relations of the muscle, as a whole, and the arrangement of its two principal sets of fibres, are elaborately illustrated in the first portion of the article. Before stating his views on the function to be assigned to these different sets of muscular fibres, Dr. Warlont quotes the opinion of Dr. Giraud-Teulon upon this very point, which is to the effect that no hypothesis has as yet served to explain the exact rôle played by the ciliary muscle in producing the convexity of the crystalline lens; and he himself was unable to aid in clearing the obscurity. Since Giraud-Teulon wrote as above, ten years have elapsed, and still the problem is unsolved; and while Warlont agrees with Giraud-Teulon in considering the theory propounded by Helmholtz, and now generally received, as the most probable, yet he is of the opinion that it only partly explains the facts as they occur; and he thinks it highly probable that the relaxation of the suspensory ligament, and the consequent increase in the convexity of the crystalline lens, are due to the action of the circular fibres alone; and that it is the function of the radiating fibres to antagonise the circular fibres, by again putting the suspensory ligament on the stretch, and by restoring the somewhat flattened condition of the lens. Although he admits this to be a hypothesis, Dr. Warlont thinks that the functions of the ciliary muscle are analogous to, if not identical with, those of the iris; and that, although the power of accommodation is compatible with absence of the lens, as a rule the two structures perform their functions in the same manner. The probability of this being the case is due to the fact that the innervation of the two structures is through the same nerves; so that in a state of health the accommodation takes place *pari passu* with the movements of the iris. As exceptions to this, there are some diseases of the spinal cord in which there is persistent action of the iris, although the power of accommodation is completely abolished.

Very remarkable differences have been shown to exist between the ciliary muscles of eyes which were myopic and those which were hypermetropic

during life, and they are relied upon by Dr. Warlomont as supporting his theory; and while he adopts the general opinion that there is no such power as that of negative accommodation—adaptation of the eye for distant objects—he yet holds it impossible that the accommodation can under these circumstances be absolutely relaxed, inasmuch as the muscular tonicity still remains, and must be taken into consideration.

‘It has been objected,’ says Dr. Warlomont, ‘that, as the radiating fibres of the muscle, when in action, form an arc with the convexity inwards, a separation of the muscle from the sclerotic must take place after each contraction, and that, unless the space so formed be filled by some fluid or other, the pressure of the atmosphere would prevent any action of the muscle whatever.’ And, in answer to this objection, he asks whether it is clearly proved that there is any such separation between the muscle and the sclerotic? or whether it is quite clear that the sclerotic does not follow and adapt itself to all the movements of the muscle, which must, in any case, be of very limited extent?

In concluding this part of his subject, Dr. Warlomont admits that he also, like Dr. Giraud-Teulon before him, can throw but little light upon this confessedly obscure problem in physiological optics.

BOWATER J. VERNON.

DE SINÉTY ON THE DEVELOPMENT OF GRAAFIAN FOLLICLES IN THE OVARIES OF NEWLY BORN INFANTS.—The observations of M. de Sinéty on the ovaries of infants at birth (*Société de Biologie*, June 5, 1875) tend to confirm the views of Waldeyer and of Slavjanski as opposed to those of older authors. The author found in all the specimens examined Graafian follicles so developed as to be quite evident to the naked eye, and especially so in the neighbourhood of the hilum. At birth the vascular portion of the ovary, which at a later period becomes the medullary layer, was observed to be situated almost entirely outside the organ, forming a pedicle of support like a mushroom-stalk. This pedicle contains large vessels which nearly reach the ovary proper, and this last has distributed through it ovules in various stages of development. The author observed further that, during the few days succeeding birth, many of the follicles had increased so much in size as to form true cysts, and that in all cases the cysts contained ovules, a fact which left no doubt as to their origin. Beneath the cysts were several cicatrices, more or less folded upon each other, a circumstance which showed that hypertrophied cysts may become retracted.

The author is inclined to associate this activity of the ovary at birth with what occurs in the mammary gland at the same period, but thinks his observations scarcely numerous enough to justify the assumption of its constancy. (See LONDON MEDICAL RECORD, August 16, page 480.)

Moreover, just as the congestion which accompanies the secretion of milk in infants may overstep the physiological limits, and give rise to inflammation or mammary abscess, so the process of development of Graafian follicles may pass on to the production of ovarian cysts.

The author suggests that it would be interesting to learn whether any corresponding activity of the testes occurs in the male infant, which, equally with the female, has the milk-secreting function of the mamma at this early period of life. The well-known

inflammation of the mammary gland in both sexes at puberty may be placed in comparison with the above facts.

The cicatrices which result from the occlusion (*atrésie*) of the follicles cause the connective tissue and vessels to pass more deeply into the ovary, and to force the ovule-containing layer towards the surface. The Graafian follicles of this layer are found deeply situated, and therefore near to the vascular supply, a fact which may account for their active growth at this early age.

BUSHELL ANNINGSON, Cambridge.

SCHULTZE ON PRICKLE-CELLS IN THE WALL OF THE STOMACH OF VARIOUS ANIMALS.—In 1864 M. Schultze discovered the so-called ‘prickle-cells’ in the mucous membrane of the mouth and conjunctiva, and in the rete Malpighi. A few years later these peculiar cells were found by F. E. Schultze, in the epithelial covering of the lip, of the tongue of the sturgeon in the skin of *Triton niger*, *Rana esculenta*, etc. Joh. Brümmer (*Centralblatt*, no. 28, 1875) has found these cells in the first or muscle-stomach and in the œsophagus of the dolphin, in the stomach of the ox, in the left part of the stomach of the horse, in the stomach of the common rat, house-mouse, water-rat, and field-mouse. The author is of opinion that these cells occur wherever the epithelium of the stomach is hard and like horn, and their formation is proportional to the extent of the corneous process. They seem by their firm attachment to form a firm tough epithelium which serves in one place for protection—e.g. in the skin; in another for breaking up the food—e.g. in the wall of the stomach.

PICARD ON GLYCOGEN IN MARINE ANIMALS.—P. Picard (*Gazette Médicale*, 1874, no. 49), in estimating the amount of glycogen in the liver, converted this substance into sugar, the amount of which was estimated by titration with Fehling’s solution. In different species of osseous fishes, the quantity of glycogen in the liver varied from 1.1 to 6.4 per cent.; in cartilaginous fishes from 0.3 to 1.6. The difference is explained by the liver of the latter being more voluminous. In relation to body-weight, on the contrary, the quantity of glycogen nearly coincides. In the liver of lobsters there was 0.4 to 0.5 per cent.; of crabs, 0.3 per cent. of glycogen. The presence of glycogen was also proved in echinoderms, polyps, and sponges. Sugar was regularly found; still the change of glycogen into sugar proceeds in general slowly in fishes. No sugar was found in crustacea, mollusca, etc.

VULPIAN ON THE VASO-DILATOR ACTION OF THE GLOSSO-PHARYNGEAL NERVE ON THE VESSELS OF THE MUCOUS MEMBRANE AT THE BASE OF THE TONGUE.—A. Vulpian (*Comptes Rendus*, lxxx. 330) shows that the glossopharyngeal is the vaso-dilator nerve for the posterior parts of the lingual mucous membrane, just as the chorda tympani is for the anterior part of the tongue. Electrical stimulation of the glossopharyngeal produces intense redness of the part of the tongue supplied by that nerve. Further, the author has convinced himself that, after destruction of all anastomoses, this action of the glossopharyngeal nerve remains the same.

BERNHARDT ON THE QUANTITY OF WATER IN THE HUMAN CENTRAL NERVOUS SYSTEM.—M. Bernhardt (*Virchow’s Archiv*, lxiv. 297) finds from his analyses that the mean value of the quantity of

water in the spinal cord of patients who died from various diseases is, for the cervical part, 73·05 per cent. water; of the lumbar regions, 76·04; results which correspond pretty closely with those of Bischoff, but are higher than those of von Bibra. The cortical portion of the brain gave a mean value of 85·86 per cent., while the white matter only gave 70·08 per cent.; that of the sympathetic, 64·30 per cent.

WM. STIRLING, D.Sc., M.D.

PATHOLOGY.

RIEGEL ON PARALYSIS OF THE VAGUS NERVE. Dr. F. Riegel (*Berliner Klinische Wochenschrift*, August 2, 1875) says that the pathology of the vagus is still deficient. The following case is recorded as a contribution thereto.

The patient was a locksmith, fifty-three years of age. In the last spring he was in hospital for several weeks suffering from bronchitis, after which, for some time, he returned to his work, but was again disabled by difficulty of breathing on exertion, with slight cough and palpitation. Hæmoptysis occurred on one occasion. On his admission under Dr. Riegel's care, in March last, he was greatly emaciated, his aspect withered and shrunken. He had occasional convulsive twitchings of single muscles of the forearm and hands. He had suffered from these twitchings at the age of twenty-three; these, after a time, had subsided, but had gradually returned within the last two years. The lungs, with the exception of slight bronchitis, were in a normal condition. The number and character of respirations were also normal. The heart's impulse was feeble, and indistinct; its sounds were clear. The radial pulse, small and sometimes scarcely perceptible, was 164 in number. The extent of the heart's dullness on percussion was more extensive than usual. There was nothing abnormal observable in the abdominal viscera. His temperature was normal. Both lungs became dull behind under percussion, the sputa became of a dark red colour, the heart's action continued much the same, and the temperature slightly fell; in the course of a few days the patient died.

With reference to diagnosis in this case, the congestion of the lungs contributed but little. More or less bronchitis had existed throughout. The one prominent and more distinct symptom was the persistently accelerated pulse, with which, moreover, the diminished temperature contrasted. The absence of derangement of any other organs left only to be inferred that there existed a paralytic affection of the vagus nerve. It was noted, as a clinical observation, that beyond a trifling hoarseness there was no affection of the voice.

When the results of the experimental division of the vagus in animals are borne in mind, there could be little doubt that here was a paralytic affection of that nerve. The cause of this paralysis it was not easy to determine. With the exception of the slight amount of bronchitis and the secondary congestion of the lungs, there were no symptoms which could be referred thereto. The nearest solution of this question lay in the possible existence of an intrathoracic tumour of some kind, but there was no other indication of the existence of anything of the sort. The death of the patient afforded an opportunity of investigating the lesions of these parts. The lungs presented patches of congestion.

The heart, beyond slight hypertrophy, exhibited nothing particularly abnormal. The bronchial glands were slightly enlarged and firm, and were of a deep black colour. The vagus nerves were carefully examined throughout their course. The left nerve, directly below the giving off of the recurrent nerve, was imbedded in and incorporated with the tissues of a lymphatic gland. The nerve was, at this point, atrophied and soft, and, examined microscopically, was found to have become degenerated into fat-cells. The right vagus was healthy in structure. The brain and other parts were also in a normal condition. Thus, the results of anatomical examination confirmed the diagnosis formed during life.

It is to be observed as remarkable in reference to this case, that the dyspnœa, which is produced by the division of both vagi in animals, was not present; while at the same time the acceleration of the heart's action that has been observed under such conditions, was here noticeable. From experiments which the author has made on animals, he has observed that these symptoms are not always present when only one nerve is divided. Tumours, such as aneurisms and tumour of the anterior mediastinum, generally affect the recurrent branch, and thus exhibit symptoms affecting the larynx, but seldom or never affect the respiration. If they do occur, they may be referred to the condition of the larynx. The respiration in these cases may be affected when the cardiac action is interfered with in consequence of the pressure on the vagus. When this is the case, the pulsations of the heart are considerably accelerated. A case of this kind, related by Hayem, only differs from that related above in the fact that, although only one side was affected, the acceleration of the heart's action was much greater. In conclusion, the author remarks that the case above recorded shows the facility with which the diagnosis of paralysis of the vagus may be made, and the ease with which the locality of the lesion may be designated.

COSSY AND DÉJÉRINE ON THE DEGENERATION OF NERVES SEPARATED FROM THEIR TROPHIC CENTRE.—MM. A. Cossy and J. Déjérine (*Archives de Physiologie*, August and September, 1875), give the results of certain original observations on the divided nerves of young guinea-pigs. These observations were made on nerves at every stage of degeneration, from twenty-four hours to nineteen days.

The following are the conclusions which are arrived at from these observations.

1. The loss of power of exciting movement, which is observed in the peripheric end of a divided nerve at the end of the third day, is caused by an alteration in the molecular constitution of the axis cylinder, an alteration which renders it fragile, perhaps even causing a solution of continuities. This alteration, whether the solution takes place or not, renders the nerve incapable of transmitting impressions of any kind.
2. This alteration is primary; the lesions of the nuclei and of the protoplasm are secondary.
3. There is an analogy between the loss of the excito-motor property of the nerve, and the diminution of contractility in the muscles thereby supplied. The muscular fibres, however, do not present any appreciable difference in appearance.
4. The central nervous system may be considered as exercising an exciting influence on the nutrition of the nerve-tubes, which lose their physiological properties, on separation therefrom.

5. All the myeline tubes are subject to this influence, but the fibres of Remak are not so distinctly subject thereto. W. HENRY KESTEVEN.

BAILEY ON ARREST OF GROWTH.—In the *Boston Medical and Surgical Journal* for August 26, is an article on arrest of growth, by Dr. F. K. Bailey. The patient was a negro girl, aged eighteen, with perhaps a slight admixture of Anglo-Saxon blood. She was a little lame, and there was inequality in the length of the lower extremities, and also of the upper. At the age of twelve an eruption made its appearance upon the left elbow, which extended above and below for some distance. To some extent the same appeared upon the shoulder and the scapular region. This had continued to appear at times, and from what was discoverable upon the arm it appeared to be eczematous.

From the time above stated, both extremities ceased to grow. Menstruation appeared at fourteen, and development appears to have been rapid and normal upon the right side. On measurement, the left upper extremity was twelve inches from the acromion to the olecranon, and fifteen from that point to the end of the middle finger. On the right side a comparative measurement gave thirteen and seventeen inches respectively, a difference of three inches. The circumference of the left wrist was five inches, and of the right six inches. The left hand was small and tapering, like that of a delicate little girl. The right was plump and rather 'stubby.'

There was a difference of from two to three inches between the lower extremities. The left foot was at least two sizes smaller than the right. On measurement about the chest, there was but little if any difference in size, although the girl stated that she had her dresses made smaller upon the left side, especially across the shoulder, where a perceptible difference could be seen. Her health was not good, as she had suffered from dysmenorrhœa and scanty menstruation from the commencement of the flow; she had also been much annoyed by palpitation, and, till within two years, wholly unable to lie upon the left side. She had sick head-ache very often, and indigestion. There were a heavy forcible beat of the heart, and physical signs of hypertrophy of the left ventricle; no valvular derangement, but the first sound was unusually loud. She said that walking up a hill, climbing stairs, or running had always caused her to be short-breathed, with some pain in the side.

Owing to the unequal size of the limbs there had been a corresponding impairment of strength and of ability to labour; still she managed to use the right arm in many kinds of work, but had never been able to find employment as a house-servant.

Her mother had cicatrices upon the face from scrofulous sores, and, although the mother of twelve or more children, was not very strong. The father died lately of consumption.

J. MILNER FOTHERGILL, M.D.

BODDAERT ON THE COMBINATION OF ARTERIAL HYPEREMIA AND VENOUS CONGESTION, WITH AN APPLICATION TO THE PATHOGENY OF EXOPHTHALMIC GOITRE.—Dr. Richard Boddaert (*Gazette Hebdomadaire*, no. 41) described at the meeting of the Brussels Congress some experiments on the above subject, which lead him to support the view formerly expressed by Trousseau, namely, that the exophthalmos in the disease of Graves depended upon a kind

of pathological erection, *i.e.*, arterial hyperæmia with venous congestion. He ligatured the jugular veins in a rabbit, and found that but slight exophthalmos resulted. After section of the sympathetics in the neck, he found the eye rather retracted. By means of a combination of both experiments, however, *i.e.*, tying the four jugulars at the root of the neck, and section of both sympathetics at the same level, he found very notable exophthalmos, which only subsided very gradually after several hours, and which could be reproduced at will by impeding the flow of blood to the heart by allowing the animal's head to hang down. A considerable rise in pressure occurred in the ligatured veins, but no hæmorrhage resulted, and very rarely œdema. The temperature of the head was not sensibly altered by the double operation, as it fell after ligature of the veins, and rose after section of the nerves. He believes that in all cases of the disease in question both factors of the experiment are found to exert a certain amount of influence. 1. The paralysis of the sympathetic, as is shown by the exaggerated pulsations in the carotids and their branches and by the remedial efficacy of electrification of the nerves. 2. Impediment to the return of blood to the heart, as evidenced by the venous congestion, the tendency to hæmorrhage and œdema, and by the fact that the goitre and protrusion of the eyes are both augmented by the spasmodic cough which frequently accompanies the disease (Dusch). The venous congestion the author believes to be the consequence of some anatomical or physiological change in the centre of the circulation, the exophthalmos and goitre being diminished when the heart is quieted.

GERALD F. YEO, M.D.

DUMONT-PALLIER ON CANCER OF THE STOMACH, INTESTINES, GREAT OMENTUM, AND LUNG.—In *La France Médicale* of July 14, 1875, no. 56, M. Dumontpallier reports a case of extensive cancerous growths in a married woman, aged fifty-eight, who made pasteboard. There was no history of previous illness till four months before her death. The enlargement of the abdomen had only been noticed three or four weeks. There were great nausea, constipation, fæcal vomiting, and retention of urine. She was admitted moribund to the Hôpital Saint-Antoine, and died seven days after. Nearly the whole abdomen was filled with an irregular mass, in which it was difficult to distinguish the left lobe of the liver and the omentum from each other. At the necropsy, some ascitic fluid escaped on opening the abdomen. The abdominal wall on its inner surface was covered with a large number of knobs (*maimelons*) of some size. The great omentum was one large thick hard mass of cancer. No intestines were in the pelvis, which was full of serous fluid, with fibrinous strings, resembling coarse muslin. The walls of the stomach and intestines were much thickened, and the cavity of the intestines almost obliterated. The mesenteric glands were all infiltrated and enlarged. The brain, liver, spleen, kidneys, heart, and uterus, had all escaped the cancerous growth. Both surfaces of the diaphragm, especially the left pleural, had little cancerous patches. Both lungs at their bases had nodules of cancer. M. Cadiat found large cells, of epithelial type, granular, and containing numerous large nuclei.

W. BATHURST WOODMAN.

MEDICINE.

BERTRAND AND BUCQUOY ON THE DIAGNOSIS AND TREATMENT OF HYDATID CYSTS OF THE LIVER. The *Gazette des Hôpitaux* of August 10, 1875, contains a report by Dr. Bussard of a case of hydatids at the Hôpital Militaire du Gros Caillou under the care of M. Bertrand, and *La France Médicale* for August 18 and August 21 (nos. 66 and 67 for 1875) contains a clinical lecture by M. Bucquoy on two cases in the Hôpital Cochin, reported by M. Boulet. Dr. Bertrand's case was a soldier, aged twenty-nine, who was admitted an in-patient on March 14, 1873. Originally robust, he had suffered from dysentery in Algeria in 1865; in 1871, whilst a prisoner in Germany, he had acute rheumatism, and two months later jaundice, lasting three weeks. Again in August, 1871, being in Algeria, he had intermittent fever, which forced him to return to France in November. Then for the first time he began to feel pain in the hepatic region, and noticed that his belly increased in size and became hard. From November, 1871, to March, 1873, he suffered occasional pains in the same region, and the abdomen increased in size. On admission, there were no acute symptoms. A bilobed tumour of the size of a fist on the right, of a nut on the left side of the linea alba, was attached to the liver, which extended about two fingers' breadth below the costal cartilages. It followed the movements of the liver. The tumour was most evident in the epigastric region when the man stood upright. Its outline was smooth. There was no pain produced by handling it. Percussion gave to the finger a perfect example of 'hydatid fluctuation.' Dr. Dieulafoy confirmed the diagnosis of hydatid cyst, and aspirated the tumour with number two trocar. Seven hundred and fifty grammes (about 24 ounces) of perfectly limpid fluid, not coagulable by either heat or nitric acid, in which microscopic examination showed numerous hooklets, were withdrawn. Towards the end of the operation the patient was attacked with acute dyspnoea, which lasted about a quarter of an hour, after which he was quite free from pain. Collodion, cotton-wool, and a firm bandage were applied. Twenty-five hours afterwards he had slight rigors, and his temperature rose to 102.1°. In five hours more, he had urticaria on the abdomen and thighs, which disappeared next day. There was no return of the tumour. In Dr. Dieulafoy's *Traité de l'Aspiration*, two similar cases are recorded. M. Jaccoud, in his clinical at the Lariboisière Hospital, mentions a large number of cases of hydatid cysts cured by a single puncture. On July 10, 1874, M. Lanceraux related two similar cases to the Medical Society of the Hospitals. A male patient, aged fifty-five, had about three pints of hydatid fluid removed from a cyst. A little vomiting and slight peritonitis followed: but he was quite well in nineteen days. Another man had four litres (about seven pints) of fluid removed from a hydatid cyst. He was quite cured in less than a month. See also M. Desnos (*Bulletin de Thérapeutique*, July 15 and 30). The presence of hooklets in the fluid is noticeable, since it is sometimes said that the cysts cured by a single puncture are only simple cysts, not truly hydatid. In reality, simple serous cysts of the liver are very rare. M. Bucquoy's case was a young man, aged twenty-five years, a shoemaker, who was admitted an in-patient on December 12, 1874. For two months he had felt weight and oppression in the

right hypochondrium; but it appeared, on closer questioning, that his abdomen had been somewhat swelled for some five years or more. However, he had been passed for military service, and had been two years in Algeria without being invalidated for a day. Liver-dulness in the mammary line reached from the nipple to the navel. There was a large rounded tumour in this mass. Hydatid fremitus was not audible on auscultation. The absence of acute pain, the absence of jaundice or ascites, all pointed to hydatids. On December 19, Dieulafoy's aspirator was used, and 2,400 grammes (nearly four pints) of perfectly limpid non-albuminous fluid, which contained hooklets of echinococcus, were drawn off. The cyst soon refilled, and on December 25 was again tapped, when about a pint of clear bile-stained fluid was removed. After this he went out and went to work. On February 8, 1875, he was re-admitted. A week before, after dancing at a ball, he had been seized with violent pain; from this time to March 3 he was tapped three times; one pint, three pints, and about fifty ounces of fluid, which was each time more turbid, being withdrawn. M. Prunier, pharmacien of the Hôpital du Midi, found 3 per cent. of coagulable albumen, and about 1 per cent. of non-coagulable albumen (paralbumin), with salts, bile-colouring, and a few leucocytes in this fluid. On March 15, after about seventy-five ounces of fluid had been withdrawn, an injection containing one-third of rectified spirit was introduced and left. Only slight momentary burning was produced at the time. Four days afterwards there were rigors, local tenderness and pain, general fever, and vomiting. On March 24 and 31 purulent fluid was evacuated, amounting to fifty-five and thirty-eight ounces. It was then decided to open the tumour by means of Vienna paste. This was done; and on April 8 a fresh puncture through the eschar gave exit to about twenty-two ounces of very nasty-looking purulent fluid. Very few seconds elapsed before the patient was seized with acute pain, first in the right hypochondrium, afterwards radiating over the whole right side of his abdomen. Subacute peritonitis, with a temperature of only 98.4°, ended in death on April 15. The necropsy showed peritoneal injection, and false but easily separable membranes, gluing together the intestines, without any ascites. The whole of the right lobe of the liver was converted into a great fluctuating pouch, weighing, with its contents, nearly ten pounds. The eschar had not penetrated the cyst, though firm adhesions had been formed round it. The dimensions of the cyst were 25½ inches circumference in one direction by 23½ in another. All liver-tissue had disappeared; the wall of the cyst was about one-sixth of an inch thick. It contained about five pints of whitish purulent fluid. Through the opening a large opaline bladder of some stoutness protruded, which was, in fact, a large hydatid. Some striated membrane escaped from it. There were some doubtful secondary cysts of very small size, and two small hydatids, the rupture of which gave exit to a little clear typical hydatid fluid. No more hooklets could be discovered. The gall-bladder, though imbedded in the cyst, was not diseased. Not a drop of the fluid could have escaped into the peritoneum at the last puncture. The fatal issue was, doubtless, due to the suppuration of so large a cyst, with extension of the inflammation to the peritoneal covering. There may also have been purulent infection. M. Bucquoy had another case in the same hospital, in a woman aged

thirty-six years, who had suffered from gastralgia after food as far back as 1872. At the end of 1873 she noticed a swelling in the epigastric and right hypochondriac regions. When admitted she had feelings of weight and pain in the epigastrium, bilious vomiting, and occasionally very sharp pains. A smooth, rounded, and elastic tumour was discovered just below the right costal cartilages, near the false ribs. Dieulafoy's aspirator gave exit to about twenty-two ounces of limpid, non-albuminous fluid, in which no hooklets were discoverable. She recovered without a bad symptom, and at the end of two months was quite free from any tumour and from any symptoms of its return. The hydatid was in all probability a sterile one, as no hooklets were discoverable in the fluid. [These cases show that hydatid cysts may sometimes be very painful, even apart from suppuration. The reporter has seen two cases in the London Hospital, one under Dr. Andrew Clark's care, in which the pain was so severe as to make the diagnosis of cancer not improbable. An exploratory puncture rendered the diagnosis of hydatid a certainty. The safety of puncture, with proper precautions, and the danger of injecting very large cysts with irritant fluids, is also shown in the cases given above.—*Rep.*]

BOUCHARDAT ON THE HYGIENIC TREATMENT OF GLYCOSURIA. — In the *Montpellier Médicale*, tom. lxxxix. 3^e Livr. pp. 97-107, Professor Bouchardat gives an extract from his forthcoming volume on Glycosuria, which will be published by Germer Baillière. He complains that many of his researches have been attributed to others by the medical press, partly, perhaps, because never collected into one volume. The key-note or, rather, dominant characteristic of his researches has been the use of scientific methods to determine the rôle of different alimentary substances, and the best methods of utilising them in the diet of diabetics, and to apply these researches in practice, by indicating what ought to be ordered or forbidden to such patients. He classifies the chief results thus obtained as follows :

1. Experiments showing the origin of sugar in the urine diabetics ;
2. Choice and varieties of food suitable to such ;
3. The principle of substitution of fatty foods for those farinaceous materials which cannot be utilised ;
4. Principles guiding the use of farinaceous food ;
5. On the choice of clothing, and on attention to the skin in glycosuria ;
6. On the effects of exercise on the progress of this disease ;
7. On the nature of glycosuria.

1. As regards the first point, the origin of the sugar, Bouchardat, by weighing accurately each kind of food supplied to diabetics and then estimating the sugar in their urine for a given time, has discovered the relation between the quantity of farinaceous food ingested and the sugar excreted. These researches include cane-sugar, lactine, milk, inuline, and inosite. The results were given in his first publication. After this, M. Claude Bernard made the remarkable discovery that many other kinds of food, notably animal food and gelatine, could produce glucose when digested. Whilst fully recognising the value of M. Bernard's researches, he contends that essentially they support his own—explaining anomalies which puzzled us before.

2. As regards food which produces little or no sugar, he claims to have done great service in showing that the apparent cures thus wrought in hospital or private practice, were seldom really such ;

and that although the sugar disappeared, the general health often suffered by the privation ; that the 'diabetic diet' soon disgusted, and ceased to nourish. He insists most strongly on the necessity of a sufficiently varied diet for the preservation of health. It is, therefore, not true that he ever pretended to cure diabetics with gluten bread.

3. In conjunction with M. Sandras, Bouchardat has made many researches on the substitution of fats and alcohol for farinaceous food. He has shown that farinaceous food is of more staying character than alcohol, and less so than fatty food. Therefore, the effects of alcohol being too transitory, it cannot replace farinaceous food with advantage by itself. On the other hand, chyliferous animals digest oils so slowly that they cannot take enough to replace farinacæ. Hence, it seems only reasonable to combine the use of alcohol and fatty foods, in the case of diabetics. His researches have shown the proper proportions. The use of good wine in moderation is a powerful means of supplying the mental and moral energy of which these patients stand in so much need. This is the experience of many years' observation of such cases. But excessive use of alcohol is so highly dangerous in such cases that it should never be rashly prescribed.

4. As to the use of farinaceous foods ; we cannot hope ever to cure diabetics who have tubercles in their lungs, or albumen in their urine, or other renal symptoms. We can, however, often relieve them. In ordinary cases, even treating the symptom of glycosuria by withholding farinaceous food leads to a more or less permanent cure. Diabetics dissolve and digest these foods in the stomach rather than in the intestines, as in health. This sort of fermentation may sometimes be stopped. The gastric juice of diabetics secretes diastase. To restore the gastric juice to its healthy character may be difficult, but should be our aim. M. Bouchardat (in the text and in a note) lays great stress on the frequent examination of the urine. Every patient has, so to speak, a personal equation in this matter, which should be recognised and regulated. Starchy food must be allowed, but only with extreme care. For if the sugar in the urine and blood be in great excess, pneumonia may destroy the patient.

5. As regards the skin and the choice of dress, M. Bouchardat insists strongly on the advantages of flannel. The temperature of diabetics being 1° or 2° Centigrade (1·8° to 3·4° Fahrenheit) below the average, indicates the propriety of this : exercise, baths, frictions, douches, shampooing, may all be useful in their place.

6. As regards the utility of exercise, of course with due care to prevent over-fatigue, our author is eloquent, and adduces, as we think, good reasons for his opinions.

7. The essential characteristic of glycosuria, at least in severe cases, is, according to M. Bouchardat, the production of a glycogenic ferment, a ferment of the second order, diastase, which produces the excess of glucose found even in the vomit of a fasting diabetic. An excess of sugar in the blood has been over and over again demonstrated by him. As his observations on the disease and its treatment have been made by instruments of precision, he does not agree with M. Bernard that our treatment of diabetes is necessarily empirical [Claude Bernard, *Revue Scientifique*, April 5, 1873]. [The reporter, whilst fully recognising the justice of many of these views, cannot help thinking that their author is far more

sanguine than most English physicians dare be, as to the success of treatment in diabetes mellitus.—*Rep.*]

LASÈGUE ON RHEUMATIC PLEURISY.—The *Gazette des Hôpitaux*, of July 17 last, no. 83, contains a clinical lecture delivered by Professor Lasègue, on a case of pleurisy at La Pitié. The patient was a tall, stout-built, almost plethoric Alsatian, aged thirty years—a policeman, exposed to cold and wet in his vocation. On March 6 he had a rigor, followed by feverishness and copious perspirations. Almost simultaneously he felt acute pains all over the right side of the chest, intensified by movement and respiration. Decubitus on the left side and cough were almost impossible. Even deglutition was painful. After some days, the pains persisting, though over a more limited area, he entered the hospital, still suffering considerable pyrexia; and pleurisy was diagnosed, over a very limited space, near the base of the right lung, behind. The stabbing pain was most intense just below the nipple, and was very severe. Wet cupping over the affected spot gave great relief; the next day, the ninth of the attack, there was but little pain, the effusion was less, the feverishness gone. The diagnosis was *rheumatic pleurisy*. M. Lasègue thinks that pleurisy of a rheumatic nature may be distinguished by its site, its severity, its extent, and its duration. The inflammation is limited to the parietal pleura, the subcostal and intercostal *fibrous tissues*. The pain is localised, and is extremely severe, and increased by movement, like the pains of a rheumatic joint. It may, indeed, alternate with, or be metastatic with, a joint-affection. The attack is seldom prolonged very greatly, and the prognosis is favourable. The fever runs high in these attacks. On the other hand, in pleurisies which commence with the lungs or bronchial tubes, which one may therefore call visceral pleurisies, broncho- or pneumo-pleuritis, the fever is less, the stabbing pain is less; there is more difficulty in localising them, and though the pain does not last so long, the disease lasts longer, and is of less favourable prognosis. It is not, however, denied that a rheumatic pleurisy may involve the lungs, and perhaps bronchial tubes also, after it has existed for some time. Hence it is important to distinguish the two forms early. In the later stages of both, thoracentesis may be necessary. M. Méhu, chief *pharmacien* at the Hospital Necker, has shown that *when a pleuritic effusion is found to be rich in chlorides, and other mineral salts, it seldom recurs after tapping; whilst those which leave little saline residue when evaporated to dryness, are not only reproduced, but commonly end fatally.*

It is rare, however, for a pleurisy of rheumatic origin to need paracentesis. M. Lasègue says that once, when in doubt as to the nature of a paraplegia with acute spinal pains, and pains round the loins, the supervention of a pleurisy of this sort enabled him to diagnose rheumatic meningitis of the cord, and to give a hopeful prognosis which was fully justified by the event.

LASÈGUE ON A NEW FORM OF ANGINA.—A midwife, aged sixty years, was admitted an in-patient of La Pitié, under the care of MM. Gombaud and Rigal. The case is reported in the *Gazette des Hôpitaux*, July 17. She stated that her health had always been good, except that twenty years ago, having burnt her finger, she delivered a young woman whom she be-

lieved to be free from venereal disease, but who was not so. Some days afterwards, her finger developed a sore with indurated edges, and she learnt from the young woman's doctor that he was attending her for syphilis. The glands in the axilla swelled, and some of the lymphatics were reddened. She took a little medicine, which she believed to be mercury. She never had any rash, nor any other venereal symptoms. Indeed, her health was quite good, until six months ago, when she fell several times on the frozen pavements. From this time she was never well, her legs became feeble, and she was feverish every night. She lost flesh and appetite also. About two months ago, in an omnibus, whilst perspiring, she was exposed to a draught of cold air. After this she began to sneeze and cough, and supposed she had caught a common cold. When, after some months, the cough ceased, the nose was not cured, and nasal breathing was still difficult. At the same time the throat became worse—and she had pain in swallowing. This was eight days before her admission to hospital. On inspecting the throat, the tonsils and back of the pharynx were covered thickly with small ulcers, varying in size from a lentil to a large pea, with greyish floor, and between them the mucous membrane was red and glistening. The mucous membrane between the ulcers was indurated, and the edges of the sores were raised, and the ulcers themselves looked as if punched out. The rapid healing of the finger twenty years before, and the reddened lymphatics, with the absence of specific symptoms, led M. Lasègue to believe that the sore on the finger was a soft chancre only, and that the present affection was not venereal—and that the angina in question was a new form of pustular sore-throat which had ended in ulceration. [The reporter knows of several cases in which there was an interval of twenty years between the primary sore and the occurrence of any well-marked specific affection. The nocturnal fever and the nasal affection in the case mentioned, also point to syphilis. Further, Dr. Revillout, who reports this case, mentions another of a policeman, under the care of Dr. Jobert de Lamballe, who, twenty years after a primary sore not followed by rash, had acute periostitis of the clavicle, which was perfectly cured by iodide of potassium in fifteen days; though so severe as to have been mistaken for necrosis by a surgeon, who could not believe that syphilis could lie dormant twenty years.—*Rep.*]

W. BATHURST WOODMAN.

CHARCOT AND GOMBAULT ON A CASE OF PROTOPATHIC MUSCULAR ATROPHY.—A case related by MM. Charcot and Gombault in the *Archives de Physiologie* (August and September, 1875), forms a nucleus, or rather is taken as the text, for a number of valuable remarks on the symptomatic differences between two forms of chronic muscular atrophy. Muscular atrophy, when of spinal origin, is caused by destruction of the nerve-cells in the anterior cornua of the spinal cord. In one of the forms of this disease which is brought under our notice, this pathological change is a deuteropathic or secondary phenomenon. That is to say, the original lesion takes place in some other portion of the cord, and, by certain steps now partially traced, finally affects the grey matter of the anterior cornua. In the other form of the complaint, the primitive lesion occurs in the grey matter itself. It may from that point spread to other portions of the cord, but this state of things is rare. In the

latter case the amyotrophic condition is the sole symptom ; in the former it is superadded to the pre-existent symptoms, but is of independent evolution, and clearly marked among the other symptoms. Such diseases as locomotor ataxy, *sclérose en plaques*, and unilateral sclerosis dependent on a cerebral lesion, afford instances in which the amyotrophic condition is deuteropathic.

Protopathic muscular atrophy presents certain negative symptoms which are nevertheless important. These are, that the cutaneous sensibility is never much altered, the nutrition of the skin, and the functions of the bladder and rectum are never affected. These symptoms are, however, not conclusive, and it is sometimes very difficult to distinguish this form of muscular atrophy from that which occurs when a primary and symmetrical sclerosis of the lateral columns of the cord gives rise to a lesion of the anterior horns. Among the symptoms of a non-negative character the first to be noticed is the individual atrophy, that the affected muscles undergo, 'neighbouring muscles preserving their normal contour, and standing out in marked relief, distinct from the affected muscles. This symptom, to use an expression of Duchenne de Boulogne, is the 'facies' of the disease. There is no downright paralysis, but the muscles lose their liberty of movement. There is, of course, consequent on this atrophy a certain amount of deviation from the normal position in the limb, owing to the action of the antagonistic muscles. Stiffening of the joints is, however, not produced in this disease, except when there has been prolonged immobility. The muscular fibre also preserves its faradic contractility.

In a case of lateral sclerosis the muscular atrophy is modified by its co-existence with the proper symptoms of that disease ; instead of individual muscles being attacked, a whole group is affected or an entire limb ; in consequence also of the spasmodic rigidity which becomes more and more marked as the disease goes on, the joints become fixed in an abnormal position.

In both forms of disease the upper limbs are generally attacked first, but the condition of the lower limbs is very different in the two forms. In the protopathic forms they maintain their integrity till quite at the close of the patients' life ; in the deuteropathic form they are weakened and atrophied, in from two to nine months after the commencement of the disease.

The course of the two diseases is also different ; that of true muscular atrophy being sometimes prolonged to eight, ten, and even twenty years, while in the atrophy dependent on lateral sclerosis the course of the disease is rapid, and death soon occurs from the lesion spreading to the medulla oblongata. The lesion of the medulla, as shown by labio-glossolaryngeal paralysis, is very rare in the protopathic form of the disease, but is almost a necessary condition of the evolution of the deuteropathic form.

The case related in the paper is that of a woman aged thirty-seven years, who was admitted to the Salpêtrière in March, 1869. She died in 1875. The symptoms of protopathic progressive spinal muscular atrophy were in her case all well marked. The necropsy and a very careful microscopical examination of the cord proved the diagnosis made during life to be correct. There were certain symptoms which came on in the later stages of the disease, which showed that the disease had communicated itself to other parts of the cord, though

only to a trivial degree. This was also established by the *post mortem* examination. The paper is illustrated by two plates, which show very clearly the morbid appearances presented in the cord, the nerves, and the muscular fibres, of the patient who was under observation.

W. HENRY KESTEVEN.

PIORRY ON VERTIGO.—In the *Bulletin de l'Académie de Médecine* there is printed a paper by M. Piorry on vertigo, with some remarks on megrim, and other vibratory nervous affections spreading from a centre of irritation (*névropathies prosasiques*), such as epilepsy, hysteria, etc.

The *Dictionary of the Academy*, M. Piorry observes, has defined vertigo as 'an indisposition in which the person affected fancies that he is turning round, or else that everything is turning round him.' It would have been better, in the first place, if it had said that it consisted not in fancying this turning, but in seeing it ; and, in the second place, if it had realised that vertigo includes not only turning, but displacement of objects up and down or to either side, and also a hesitation in the movements of the lower limbs. The chief point, it may be gathered, which M. Piorry is anxious to bring out is, that the sensation of the movement of external objects which is felt in vertigo is not a hallucination or subjective impression, but the result of an actual displacement of the images of the objects on the retina, due to an involuntary contraction of the muscles of the eyeball. The oscillation of the eyeball, which is the cause of this, has been completely passed over by the writers on the subject ; and the first actual observation of it in a case of vertigo, is to be credited to a doctor's wife, who found it in her husband coincident with the vertigo, both in beginning and end. That this is the origin of the feeling of vertigo is confirmed to M. Piorry, by finding that a skilful pressure on the eye in health will produce a similar displacement of near objects ; and he believes the oscillation to occur in many, if not all, cases of vertigo.

M. Piorry goes on to a detailed comparison of vertigo with the irisaigia which often accompanies megrim. He confirms the picture which Dr. Living has given of the fortification pattern or teichopsia (*On Megrim, etc.*, pp. 84, 514), which appears in ophthalmic megrim as being an exact representation of what he has himself been subject to for more than forty years. It begins as a vague phosphorescence, which hinders any clearness of sight, and then shapes itself into a bright and sparkling toothed circle, which vibrates and grows until it fills the field of vision. Then it becomes pale, and sometimes smaller, and disappears after a few minutes, or at most a quarter of an hour. So long as it lasts there is no pain ; but as soon as it is gone acute pain or throbbings follow above the eye, and spread to the temporal or frontal nerves, from them by the anastomoses of the spheno-palatine ganglion to the eighth pair of nerves, whence arise nausea and sickness. In vertigo, on the other hand, the first symptom is the displacement of near objects in the field of vision ; after this no pain follows beyond a feeling of throbbing and heaviness in the same nerves. After irisaigia a pain sometimes runs through the suboccipital nerve, and there results a tingling and quivering in the fingers which passes up the fore-arm. After vertigo there is the same feeling of discomfort in the suboccipital region ; but it spreads thence not to the arms, but legs, producing an unsteadiness of gait. After both affections, nausea and sickness often

follow; both tend to recur at regular intervals, the irisaigia especially in cases where it is associated with disease of the spleen; in both the mind is unaffected, and there is no permanent paralysis, and M. Piorry has never known a case where cerebral hæmorrhage or softening supervened. The conclusion is that both must be considered members of the same family of diseases, of which the characteristic is a vibratory movement spreading from a single centre through various nerves. These morbid vibrations M. Piorry calls 'névropallies prosasiques,' and is anxious to distinguish them from nevropallisme, the normal vibration which constitutes the vital action of the nerve. In the case of irisaigia the point of origin is in the iris and its sensory nerves; in the case of vertigo it is in the muscles of the eye.

It seems very possible that many movements which are now called sympathetic, may be similarly produced; and of nervous diseases, epilepsy, hysteria, and hydrophobia may be put in this class. In epilepsy the irritation may start from the eye, pass along the optic nerve to the brain, and affect first the mind and then the muscles. In hysteria it may start from the ovary, pass through the pneumogastric nerve to the nerves of the cesophagus and larynx, and reach finally that part of the brain which controls the genital organs. Lastly, in hydrophobia it seems to originate in the bite of the animal, and pass thence by the nerves to the salivary glands, pharynx, and larynx.

J. B. BRADBURY, M.D.
(Cambridge).

ISHAM ON SMELL IN THE DIAGNOSIS OF DISEASE.—In the *Cincinnati Clinic* for October 9, is an article by Dr. A. B. Isham, on the above subject. It formed a communication read before the Cincinnati Academy of Medicine, October 4. Dr. Isham says:

An enumeration of the affections which were supposed to emit a characteristic odour, from the time of the father of medicine, would include very nearly the whole catalogue of diseases. The advance of medicine as a science has eliminated smell as a special entity pertaining to individual disease until now its application is comparatively limited.

Heat is admitted by the best authority to be the quality principally concerned in the evolution of odour. To this source we may attribute the unpleasant odour arising from the arm-pits and feet, of very strong and annoying character in some persons, despite frequent ablutions. In these situations the nice adaptation of the free surfaces one to another maintains a temperature corresponding to that of the internal body. Such a heat operating externally upon the skin would engender activity of the cutaneous secretory apparatus. Here the matters volatilised would be dispersed so rapidly by the media of the atmosphere as not to be appreciable to the ordinary sense of olfaction. In the axilla, however, where the sudoriferous glands and sebaceous follicles are more numerous and aggregated, and free evaporation hindered, there would be a concentration of odour, rapid and powerful in exceptional individual cases. The oil poured out by the sebaceous ducts is probably assimilated by the hairs, but where it is furnished in excess it would add to the offensiveness of the smell.

The rank and butyric odour of the feet we would account for by the decomposition of the fatty principles of the secretions. It is familiar to all how

soon butter confined in a close receptacle and exposed to summer temperature will become rancid. The two products do not differ materially in composition and it seems a reasonable deduction that, under the same circumstances, they would develop the same odour. This would apply also to the glandulæ odoriferæ of the genitals. In the latter case the continual washing of the urine would prevent an augmentation of smell.

This seeming digression has been made because, in health, no odours other than the above mentioned are appreciable; but put diseased processes in force, temperature is elevated, secretions and excretions are changed, new products are formed and a variety of odours are evolved. We will attempt to set forth how much they may profit us in the diagnosis of disease.

Diabetes mellitus is a disease insidious in its approach. A more general appreciation of the saccharine aroma, which has been described as similar to new mown hay or crushed apples, might often induce its recognition long before other symptoms would be sufficiently pronounced to elicit inquiry. The frequent association of phthisis with diabetes, either as the primary affection, or secondary, is a matter of general note. A like connection with pneumonia has been observed by Beale, Flint and others. Andral has found asthma in five instances preceding diabetes. It is not unlikely that saccharine urine would be much more often discovered in the above diseases, as also in bronchitis and emphysema, if thoroughly sought for. Good quotes Dr. Bardsley as affirming that he could not recollect a case of diabetes uncomplicated with pulmonary disease. A significant fact is also stated by Andral in a recent contribution on diabetes, that in nearly all the necropsies conducted by him there was an appearance of commencing tubercular granulations in the pulmonary parenchyma. But in these states of lung trouble only a portion of the structure is rendered incompetent to allow of the natural interchange between the blood and the inspiratory current, and the uncomplicated balance of the respiratory tract is sufficient for the metamorphosis of the sugar, particularly also, as in diseases of the pulmonary organs there is anorexia, and in the decrease likewise of the saccharine formative material. On the other hand, the cerebral irritation and the chloroform administration impresses the whole muscular tissue of the lung and no portion is left solely free for exercise in the purposes of aerification. Besides the pathological condition governing diabetes gives rise generally to bulimia, with increase of matter introduced into the stomach and corresponding increase, of course, of saccharine principles to be separated from the blood.

It is notable that in phthisis the sputum not uncommonly has a sweetish smell. It is in such cases not improbable that the urine, where interrogated, has returned evidence of sugar, produced, may we not say, by the extension of the phthisical lesion over an extent of lung texture sufficient to impair its uses in the depuration of the blood?

In carbuncles and boils, too, temporary glycosuria, with the sweet odour, is often observed. May not the accumulation of sugar in the blood and its excretion by cutaneous channels enter into the etiology of furunculi, rather than the reverse?

Smell is an aid, often the only and certain element in the detection of the alcohol habit, alcoholic coma, as distinguishable from narcotic poisoning, apoplexy

or epilepsy; of poisoning by phosphorus, prussic acid, the alkalies, chloroform, camphor, carbolic acid, laudanum, chloral and the oils of savin, tansy and turpentine.

In chronic discharges from the nasal and aural cavities an extremely offensive odour is indicative of implication of the bony structures. A fetid exhalation of the breath occurring in the course of pneumonia would be presumptive of gangrene of the lungs; supervening on phthisis—gangrene of the lung or destructive ulceration in the bronchi, trachea or larynx would be a rational inference.

Foreign substances, as of brass, tin or copper, lodged in the air-passages might be determined by the metallic flavour of the breath. A case has been brought to my notice where a small brass charm was drawn through the larynx of a child and carried down into the bronchial tubes, giving rise to ulceration, which, while the origin was not suspected until the body was expelled, diffused through the breath a strong and marked metallic odour.

Diphtheria not unfrequently fixes itself without any general manifestations pointing to its presence. In such an event the fetor of the breath incident to this affection may strike the olfactory organ, and it is an invaluable sign which may often give us early warning of the disease.

Among the insane, the idiotic, the imbecile, the excessively modest, the aged and the infantile, disease may commit secret ravages from inability or fear on the part of the sufferers to make suitable expression. Smell might here be an agent of invaluable purport in the disclosure.

In cases of obstruction of the bowels, preventing the descent of feces, the expulsion of feculent matter by emesis would be first revealed by the smell; and it affords the most important clue to the nature and seat of the trouble.

Worms in the intestinal canal usually produce a most nauseous breath. Either alone or in connection with other symptoms it is an indication of value.

In affections of the female generative organs smell is a useful adjunct to diagnosis. A very foul condition of the discharges from the vagina in a female with any claims to cleanliness would point to ulcerations of the os uteri or vaginal walls, to cervicitis or endometritis with loss of tissue and to cancerous growths seated in these parts. In some females menstruation may be determined by the odour.

In puerperal fever, where the discharge is not altogether suppressed the abominable stench of the decomposing lochia will not infrequently first arrest the attention and exhibit the nature of the affection almost beyond possibility of error.

Peculiar to lying-in women is a pungent, unpleasant smell. Where there might be a design on the part of the patient and attendants to cover up a miscarriage, this smell would be of service in revealing it.

Odour would determine a disease of the urinary organs of the male, as gonorrhœa, cystitis, nephritis or cancer. These affections are common to the female as well; but in either sex where smell would lead directly to diagnosis, the subjects would be either lunatics, idiots, bashful to a sense of imbecility, or suffering from other maladies serving as a mask.

In wounds of the abdomen with or without penetration of the intestine or stomach the presence or

absence of the fecal odour of the former and the acid smell of the latter, may mark the extent and gravity of the injury.

Incontinence of urine can be discovered by the smell, and in persons of secretive or remarkably diffident nature it might be a sign of great significance.

It is universally conceded that the perspiration and breath of acute rheumatism exhale a markedly acid smell. It has no diagnostic consequence, and is probably due to a surcharging of the blood with lactic acid and its escape by the cutaneous and pulmonary excretory channels.

Small-pox has been described as dispensing a singular odour during the sweating and also pustular stages. The first, in my estimation, possesses exactly the same features pertaining to the general class of fevers, and the smell does not differ therefore, except perhaps in the quality of strength, from freer sudorification. To the fever group, particularly the exanthemata, does suppression of the internal secretions belong, the sweat glands and lungs performing vicarious functions of elimination, and the sebaceous follicles also taking part in the abnormal activity. When these emunctories are thus crowded with excrementitious principles; increased smell is a natural accompaniment of the concentration. To my mind, at least, it is evident that the odour bears a relation to the grade of febrile action and the state of the internal glandular apparatus, and not to any special disease. In regard to the pustular stage of variola, the scent, so far as I am able to discriminate, does not depart from that generated during suppuration following burns of the cutaneous envelope, nor of suppurative skin-diseases.

The excreta of dysentery and cholera have attributed to them exclusive odorous impressions. The evacuations of typhoid fever with ulceration and exfoliation of the internal coat of the intestine, the disintegration and discharge of cancerous growths implanted in the bowel, have an odour so similar to dysentery that the most delicate olfactory sense must go astray in an attempt at isolation. So likewise, by the same token, advanced phthisis with colliquative diarrhœa and emesis, and chronic diarrhœa with profuse perspirations, I opine, would be indistinguishable from cholera.

That disordered state of the stomach commonly known as dyspepsia gives rise to two distinct odours according to variety—the sour or acid, and the sulphuretted hydrogen smell. The affection occurs as a complication of many others, but when this odour exists without lesions of other parts, as may by careful examination be determined, it is of value as diagnostic of the malady.

The ulcerations commonly called bed-sores, occurring in the course of any affection necessitating long confinement to the bed in one position of recumbency, may first attract notice by the smell diffused.

In a few cases of habitual masturbation I have fancied a rare perfume, a very much mitigated liquor amii sort of odour. Individuals who may contaminate the atmosphere with such a flavour are, in police parlance, 'entitled to suspicion.'

Porrigo favosa is said to disengage an odour. It is described by some as having a smell similar to the urine of mice, and by others to be more like that of a cat. It has no diagnostic use, as the affection is well declared before the smell is developed. Of

prognostic value, if true, is the assertion of some observers that the urinary secretion of the patient acquires the smell of cat's urine when the disease is about to terminate.

Hyperhidrosis of the feet and axillæ may be predicted upon the powerful logic of smell with absolute certainty.

In conclusion, the insane are supposed by some authors to generate a characteristic smell. At this time, this idea is confined principally to lawyers. This professional class can, with unerring certainty, discover an odour of insanity to emanate from all individuals confined under charge of capital offence.

GRANCHER ON TONIC MEDICATION.—An analysis of M. Grancher's thesis on this subject, published in the *Archives Générales de Médecine* for June, 1875, remarks that the limits of tonic medication are difficult to define; and that anyone going through many treatises on therapeutics is struck with the difference of opinion existing between their writers respecting drugs which should be so classed. Medicines of the most opposite kinds may at any given moment exercise the most decided tonic action. For instance, what can be more restorative than the action of mercury on syphilitic patients, of the alkalies on the gouty, and of the potash-salts on scorbutics? The limit is specially hard to find between tonics and stimulants. As a rule, those medicines which address themselves to the vital powers *in posse*, so as to increase them, are considered as tonics; and those which act on those powers *in actu* to excite them, as stimulants; but a great number of drugs are both tonic and stimulant at the same time. The tonics really worthy of the name are those which slowly and permanently increase the strength of the patient. With these may be ranked the neurosthenics or dynamophorous medicines, such as coffee, which by acting on the nervous system rapidly induce the slackening of the progress of denutrition and combustion. A large part of the thesis is consecrated to the special study of the action of, and the indications for, sulphate of quinine, alcohol, coffee, arsenic, iron, the bitters in general, etc. Tonics act by moderating organic combustion, but to induce this result it is a question whether they act primarily on the blood, the nervous system, or on the cardio-vascular system. Their principal action seems to influence the nervous system, but it is very probable that a certain number of them, alcohol for instance, also have a rapid and powerful action on the blood-corpuscles, but it would be unwise to wish to decide this question in an absolute manner. The various tonics are not given indifferently to all patients whose strength requires sustentation or reparation; febricitant adynamics call for the use of alcohol and quinine; convalescents require analeptic reparatory elements, and quinine and feeding may be combined with advantage in their cases. Almost a specific for chlorosis may be found in the chalybeate preparations, whilst nothing can stay the progress of cancerous cachectic conditions. Iron augments the activity of the nutritive phenomena; after its administration the temperature rises, the appetite is larger, therefore the administration of this drug becomes dangerous when digestive difficulties forbid the hyperactivity of nutrition from being compensated by a proportionate increase of food, and it is thus that the noxious action of iron in the course of febrile affections and consumptive diseases is explained.

TILLOT ON THE TREATMENT OF CHRONIC RHINITIS BY PULVERISATION.—Dr. Émile Tillot, after having studied the different forms of chronic rhinitis, shows in *Annales des Maladies de l'Oreille et du Larynx*, 1875, that the treatment of this disease should fulfil three indications: 1. To combat the diathesis under the influence of which the disease of the nasal fossæ has shown itself; 2. To completely cleanse the mucous membrane from its secreted products, muco-pus and crusts; 3. To combat the lesions of the mucous membrane. The first result is attained by a constitutional treatment in sulphurous or sodaic chloridised waters, if the rhinitis depend on scrofula; antisyphilitic, if it be due to syphilis; arsenical or alkaline, according as there is need to fight against an herpetic or an arthritic diathesis. The second indication is drawn from the large nasal douches justly extolled by Dr. Duplay; and if these injections cannot be borne—for instance, when there is a great tendency to epistaxis—they must be replaced by injections with cold water or some appropriate mineral water. The third indication is fulfilled by means of absorbent and slightly cathartic powders, such as calomel, tannin, etc., or by the administration of these substances suspended in liquids, and used in spray-producers. M. Tillot has modified the end of the spray-producers so as to allow them to produce this pulverisation in the nasal fossæ, and the liquid he uses in preference is the Eau de Saint-Christau.

SURGERY.

REULING ON A CASE OF MYOSIS AFTER A GUN-SHOT WOUND.—In the *Virginia Medical Monthly* for September, is a report by Dr. George Reuling of a case of myosis, caused by paralysis of the left side of the cervical portion of the sympathetic, in consequence of a gun-shot wound.

In 1866, an officer in the army, Captain McC., was shot through the left side of his neck. The bullet entered about two inches above the clavicle, immediately behind the belly of the sterno-cleido-mastoid, and passed out about half an inch higher up at the anterior edge of the platysma myoides. During the two following years, the gentleman sank rapidly in consequence of small purulent formations along the course of the sheath of the sterno-mastoid, as well as because of a pharyngeal soreness, which, greatly increased by every attempt at deglutition, amounting at times to a spasmodic seizure. The patient had been pronounced a hopeless consumptive by his medical attendants, when one day a little piece of cloth belonging to the coat-collar, which had formerly been penetrated by the bullet, appeared through the open wound, which very soon after became scarred over, and the patient grew visibly stronger. Being put on a liberal diet, and having had the benefit of a voyage by sea to Key West, he completely recovered; so much so, indeed, that he undertook the management of a farm.

In the year 1868, while cicatrization was going on, he for the first time noticed shooting pains in the arm of the affected side, radiating especially from the little finger. At first, these pains appeared only after great exertions, or in consequence of a 'cold,' but in the fall of 1869, the neuralgia became of daily recurrence and great severity. At the same time the patient was aware of a myotic condition of the left eye (of sudden occurrence), and accompanied with lancing pain. He then came to Dr. Reuling for advice.

The patient was a wiry, though muscular man, thirty-six years old. At the left side of his neck the characteristic scar was seen running in the before-mentioned direction. Immediately above and below the clavicle, and partly in contact with it, there were three separate distinct scars of the formerly fistulous openings. The neck was somewhat constrained in its movements; the head could not be turned very readily to the right, and was a little directed towards the left side because of a slight shortening of the skin and its muscles. The affected arm differed in nothing from the healthy arm in development, structure, or temperature. In following the course of the nerves of the arm, however, and pressing tightly with the thumb, a well-marked painful point was met with over the ulnar nerve at the elbow, as well as near the insertion of the pectoralis major into the humerus; these symptoms pointed to neuralgia consequent upon pressure by cicatricial formations on branches of the brachial plexus.

The left eye differed materially from the right, the pupil being contracted to the size of a pin's head. The pupil was also turned somewhat awry in its direction from below and inward, to above and outward; light had no influence whatever upon it. Neither its size nor its form was affected by the direct light transmitted by the sun, nor when that light was intercepted by the hand being placed before the eyes. That the pupil was contracted to its

maximum extent, was shown by the fact that Calabar bean could cause it to contract no further. At a distance of three inches the finest writing could be read, although the patient declared that he could read only a few words at a time. When he held the eye steady and looked at large objects, he could discern only portions of them, the field of vision showing a considerable concentric limitation.

After a one-grain solution of atropia had been instilled, and the pupil of the affected eye had, after the lapse of half an hour, enlarged to the diameter of the normal pupil on the right side, a healthy state of the internal structures, with the exception of a slight hyperæmia of the choroid and retina, was discernible.

The diagnosis was paralysis of the cervical portion of the sympathetic, caused by the gradual contraction of the cicatrix left after a gun-shot wound.

The treatment consisted in instilling a solution of atropia twice a day for several weeks, as well as in the application of the continued current to the sterno-mastoid and along the course of the ulnar nerve. The neuralgic pain abated in frequency and violence after two days. The effect of the atropia, which during the first few days was dissipated after six or eight hours, became of the usual duration after the sixth day. As soon as this was accomplished, Dr. Reuling prescribed unguentum cinereum, to be made into an ununction with extract of hyoscyamus, and had it rubbed into the scar. Every fifth day he applied one of Heurteloup's artificial leeches, to remove the hyperæmic state of the choroid. After he had been three weeks under treatment, the patient was discharged. The pupil was of nearly the normal size, and the visual power but very slightly impaired.

EVANS ON DISEASE OF THE RECTUM.—In the *Canada Lancet* for September 1 is a communication by Mr. H.B. Evans, on an uncommon and painful disease of the rectum not described in books. He writes: During a long practice I have met with but two cases, whilst two others have been indirectly communicated to me. Summing them all up, the symptoms may be described as follows. There is great difficulty always attending defæcation, which is immediately followed by intense agony in the lower part of the rectum. This pain generally continues from a quarter to half an hour, and then subsides entirely until the next movement of the bowels. When the stools are examined they will be found very small in their diameter, flattened on their surface, and somewhat resembling a ribbon. During the effort to relieve the bowels, the spasm of the external sphincter is so intense that the patient would often give up in despair, a little fluid fæces only passing. Sometimes the sphincter seems more disposed to relax itself and the stools assume a more natural appearance; but on no occasion have they been of a perfectly cylindrical form. A digital examination of the rectum or by bougie causes the most excruciating pain, with violent contraction of the sphincter, so that the finger is removed with difficulty. This contraction extends to the upper limit of the internal sphincter, above which the cavity of the bowel is of the natural size. The mucous membrane of the rectum in the contracted part is perfectly healthy, soft, and not thicker than usual, and moves very readily on the inner surface of the contracted muscle.

This disease is very different in its nature and

consequences from the ordinary stricture of the rectum, and it is of considerable importance it should be distinguished from the latter. In the former the affection is functional, and the prognosis favourable; in the latter, the disease is organic and the termination generally very much the contrary. On a slight examination we should generally confound the two diseases, but when carefully considered they may be distinguished from each other. In both cases the fæces will be found flattened in shape, small in size, and somewhat twisted; but other symptoms present a marked difference. In organic stricture of the rectum, its situation is generally two or three inches above the external sphincter, and there is a sound natural portion of the bowel between the stricture and this muscle. At the seat of the stricture, the coats of the rectum are felt to be more or less thickened and ulcerated, and generally secrete a thin ichorous offensive discharge. This disease has impressed its mark on the constitution, as the sallow countenance, morbid appetite, and wasting of the muscular system imply. In the patient there may be generally traced some cancerous, scrofulous, or venereal taint. On introducing the finger, the agony does not commence until the actual stricture is reached. In the functional disease, the pain commences at the real opening of the anus, surrounded by the sphincter muscle, whilst no alteration of structure in the mucous membrane can be detected. There is no trace of constitutional taint to be observed, and the general health is not immediately affected.

The following is a representative case of this painful disease. Mrs. B., aged forty, had had seven children. About twelve years since she became affected as above described. There was intense pain on relieving the bowels, so much so that the act was avoided frequently when it should have been encouraged; when effected, the motions were either liquid, or thin and flattened. Of late, the general health began to suffer, marked by a train of dyspeptic symptoms, accompanied by neuralgia of the facial nerve. The countenance was pale and bloodless, the bowels costive, and there was great mental depression. In the words of the patient, 'life had become a burden almost too hard to be borne.' On making an examination with the speculum ani, so great was the agony occasioned that syncope took place. This patient had been treated for piles, stricture and fissure, none of which really existed. A slight amelioration of the symptoms took place under the use of belladonna suppositories and laxatives, but no permanent improvement. In conversation with Mrs. B. I found that a sister of hers had been similarly affected, and that she obtained relief by applying to Dr. McLean, then of Kingston, who performed an operation that resulted in a perfect cure. I wrote to Dr. McLean, Professor of Surgery at Ann Arbor, and received from him a courteous reply. 'He recollected the case perfectly; it was one of contraction of the sphincter muscles, and the operation for its cure consisted in a subcutaneous division of the fibres of that muscle.' The operation was performed on Mrs. B. two or three months since. A tenotomy-knife was inserted on each side of the anus parallel with the rectum, and moved backwards and forwards so as to divide all the fibres within the sweep of the half circle. Very little blood was lost. The operation was by no means painful, and the patient declared herself quite relieved, and has been well ever since. J. MILNER FOTHERGILL, M.D.

PUKY ON A CASE OF COMPOUND LUXATION AT THE METACARPO-PHALANGEAL JOINT OF THE INDEX-FINGER.—The following case, which occurred in the hospital practice of Professor Dumreicher of Vienna, is reported by Dr. A. Puky in the *Wiener Medicinische Wochenschrift*, no. 27, 1875. A man, aged forty-one, fell from the top of a ladder which was seven feet in height, and as he reached the ground the whole weight of his body was thrown upon the projected left hand. When the patient was first seen, about a quarter of an hour after the accident, there was found a luxation of the index-finger backwards, with protrusion of the head of the metacarpal bone through a wound on the front of the hand. Frequent attempts were made to reduce the first phalanx by extension and sudden flexion, but without success. Reposition was finally effected by hyperextension and rotation, and then by sudden flexion. To the back of the hand and fore-arm was applied a splint, bent at the position corresponding to the wrist at an angle of 45°. The hand was firmly fixed to this splint, and kept at perfect rest, and an ice-bag was applied constantly over the small wound in front of the metacarpophalangeal joint. This wound healed by first intention, and on the sixteenth day the patient was discharged as cured, and with a freely movable joint. In some remarks on this case, Dr. Puky states that compound luxation of a finger, although not necessitating primary amputation or excision, must be regarded as a serious injury. Reduction is often impossible and always difficult, and the lesion may result in acute articular inflammation with suppuration, in gangrene, or even in tetanus. Indeed, tetanus has frequently been observed after this form of luxation, and fatal cases have been recorded by Dupuytren, Wanderbach, and Cramer. Dr. Puky asserts that laceration of the soft parts in compound luxation of a finger occurs only at the articular furrow on the palmar surface, the wound corresponding usually to the transverse wrinkle; and the portion of bone which protrudes is always the head of the metacarpal bone. Dr. Puky endeavours to prove by reference to the views and clinical reports of modern surgeons, and by the results of experiments, that the obstruction to the return of the dislocated phalanx in cases of this kind is due to interposition of the flexor tendon, and that this interposition of a tendon occurs more frequently than is generally supposed. In cases where reduction cannot be effected by extension and flexion, rotation of the finger will usually be found successful.

RINALDI ON LUXATION OF THE SUPERIOR EXTREMITY OF THE FOURTH METACARPAL BONE.—Dr. Rinaldi, of Algiers, relates (*Le Bordeaux Médical*, August 15, 1875) a case of a police agent whose right ring-finger had been bitten and violently twisted by an Arab prisoner. Two small teeth-wounds were observed on the finger, one in front of, the other behind, the second phalanx. Flexion and extension of the finger were hindered and attended with much pain. There was acute pain on the dorsum of the hand, especially over the upper extremity of the fourth metacarpal bone, which was prominent and very movable. The neighbouring parts were in their normal position, and no other lesion was observed. The dislocated extremity of the metacarpal bone could be readily replaced on slight pressure. At the end of eight days, during which period the hand was kept at rest on a splint, the cure was complete there being no longer any osseous projection on the

dorsum. The author, in commenting on this case, states that difficult as it may seem at first to account for simple luxation at so strong and well-protected a joint as that formed by the fourth metacarpal and its opposed bones, one may, on anatomical examination, be clearly convinced of the possibility of such a lesion. In observing a preparation of a hand deprived of all its soft parts save tendons and ligaments, Dr. Rinaldi found that, on forcibly compressing the member at a part corresponding to the metacarpophalangeal line, so as to exaggerate very much its anterior curvature, the upper extremities of the second and third metacarpal bones remained in position, and that of the fifth metacarpal bone was rotated inwards. As the pressure was increased, the upper extremity of the fourth metacarpal bone gradually slipped backwards from between the opposed facets of the third and fourth metacarpal bones. The superior dorsal ligaments were then much stretched, and finally gave way. This observation, Dr. Rinaldi states, shows that simple and isolated luxation of the upper extremity of the fourth metacarpal bone in a backward direction is possible. The injury may be recognised through the following signs: Dorsal projection and abnormal mobility of the bone, especially at its upper extremity; pain over this extremity increased by movements of the ring-finger, which movements are not free; slight swelling on the back of the hand, most marked over the upper extremity of the fourth metacarpal bone. This prominent portion of bone may be readily replaced on slight pressure; on the removal of which pressure, however, when the lesion is recent, the luxation is immediately reproduced.

W. JOHNSON SMITH.

TAYLOR ON SOME OF THE ELEMENTS OF DIAGNOSIS IN THE DIFFERENT STAGES OF DISEASES OF THE HIP-JOINT.—In a paper read before the New York Medical Library and Journal Association, April 16, 1875, Dr. C. Fayette Taylor thinks 'the symptoms generally relied upon as diagnostic of disease of the hip-joint are worthless for all practical purposes of either anticipating the graver stages of the disease, or of affording indications for treatment.' He has 'no confidence in pain as a symptom from or through which we may justly draw conclusions of any definite value whatever, at any period of disease pertaining to the hip-joint.'

'It is the condition of the muscles which is the most constant and delicate diagnostic indication of disease in the joint.' 'This condition of the muscles may result from various causes, but must not be confounded with nor mistaken for the constant, excessive, unrelaxing, tonic contraction, in greater or less degree, varied or not with spasm, but always present when there is any disease whatever in the joint. The latter may exist so slightly as not to prevent the extremest flexion and extension, or it may exist to such a degree as to arrest all motion as completely as true ankylosis; but it can always be detected when we have a clear conception of its distinguishing characteristics. In the earliest stages of any injury to the joint there may be a mere stiffening of the muscles, not enough perhaps to prevent motion, but always enough for the educated touch to detect what I have named, a reluctance to relax. It is quite independent of the patient's volition, though it often requires careful management to prevent the voluntary efforts from mingling with and obscuring this condition. In the beginning, this symptom, being

less pronounced, may be overlooked; and later, when it has increased to its greatest degree, it may be mistaken for contracture or permanent shortening; and it is also often mistaken for ankylosis when it is sufficient to arrest motion.'

One is a physiological act, the other is a physical effect. Now this physiological condition does, and necessarily must, exist during the continuance of any exciting cause, and it therefore becomes symptomatic of the cause which excites it. And it is of itself an important element in perpetuating and increasing the very condition which produces it.

NEPVEU ON OSTEOCLASIS AND OSTEOTOMY FROM AN ORTHOPÆDIC POINT OF VIEW.—Dr. Nepveu (*Archives Générales de Médecine*, September, 1875), after briefly noticing the history of osteoclasia, proposes especially to pass in review the practice of Billroth and Volkmann.

Manual and mechanical osteoclasia have been employed up to the present time in cases of four different classes, viz., (1) badly united fractures; (2) articular deformities resulting from ankylosis; (3) bent bones in rickety subjects; (4) deformities resulting from old dislocations.

Of the various methods of producing osteoclasia, the author deduces that, first, that of manual force, and next, that of Rizzoli, have been most frequently employed.

In his summary he states, under the head of 'Dangers of the Operation,' (1) the rupture may not take place at the desired spot, the operation then becoming useless; and (2) the operation may be dangerous if the pressure on the part to be broken have been great enough to cause accidents, such as sloughs and so on.

Taking into account all circumstances, osteoclasia, when performed with judgment, is generally a beneficial operation. In the majority of cases the artificially fractured limb is in the same state as a limb accidentally fractured subcutaneously. In the 108 unselected cases of osteoclasia referred to in this work there was not a single accident.

The therapeutic results seem satisfactory in the treatment of deformities produced by ill-formed callus (De la Motte, 1699, Dupuytren, Gurlt) and in rickety deformities (Volkmann, Billroth). In old dislocations, the operation only corrects a part of the deformity, the angular deviation (Volkmann). The rupture of bony ankylosis is sometimes sufficient to re-establish the normal position of the limb, but not always to restore mobility. Any attempt of the sort should be avoided, when the ankylosis is of very long standing, when the arteries are atheromatous, when the periarticular tissues are matted together, or when the bones themselves are much atrophied.

JOHN CROFT.

LEFFERTS ON INTRALARYNGEAL SURGERY.—In the *New York Medical Record*, June 25, Dr. Geo. M. Lefferts reports two cases of intralaryngeal growth successfully removed by incision. In speaking of the various instruments, he says: The instrument which was devised some time ago by Professor Stoerk will fulfil many of the indications desired, and in a very simple manner—the principle involved being that the wire should be protected from contact and disarrangement, and this is accomplished by covering it with a double oval, rigid, metallic guard, through which the loop, fully protected, runs; and finally, traction being made upon it by means of

the handle to which the extremities of the wire are fastened, compresses the growth between itself and the upper edge of the guard. These metal guards are provided of different sizes, so that one principal objection to the instrument, viz., that the loop cannot be made to assume the diverse forms suited to the shape of the variously formed neoplasms to be extirpated, is partly overcome. A second objection which has been urged against *écraseurs* in general, that the use of the fine wire causes the instrument to act practically as a guillotine, and to rather cut than crush off the growth, can hardly be urged against this instrument, which, carrying as it does, a large wire, can hardly cut, but must crush its way; and, furthermore, the pressure being applied gradually, the growth will be removed in strict accordance with the true principle of the *écraseur*.

The process, of course, requires time, and on this account this form of instrument can only be used in tolerant cases and on growths of some size, which, on account of their location, are readily seized and comparatively quickly removed. Very large growths, or those of a vascular nature, for the removal of which the *écraseur* is thought necessary, will probably demand the preliminary performance of tracheotomy, as a necessary precaution against disastrous results.

A still further improvement in the instrument—suggested, I believe, by Gibb, but elaborated by Stoerk—and a very desirable one when operating for the removal of small growths, consists in the substitution of a small metal tip, perforated in four directions, for the oval protecting guard. The apertures in this tip are threaded with the wire, the direction of the loop being either in an antero-posterior or a transverse line, according to the location of the neoplasm; and the wire, being thus held by the holes, is effectually prevented from turning from the given direction—a very common occurrence with the old tube-form of instrument. The wire used with this form of apparatus also assists in attaining this desirable result; that formerly used, thin iron or silver wire, very easily losing its shape if pressed upon while entering the larynx, and usually requiring many readaptations to the form of the growth. The steel wire, as used for musical instruments, will be found preferable, having the necessary elasticity and firmness, and therefore fulfilling the indications required.

In the first case, the size of the growth rendered the employment of a large guard necessary in order to pass successfully over it, and the difficulty of easy introduction into the larynx was thereby increased, the size of the guard rendering contact with the laryngeal walls almost impossible of avoidance, and the immediate contraction of the parts which followed obstructed somewhat a view of the entire process of extirpation. By introducing the instrument carefully, however, guided by the reflection in the laryngeal mirror, and causing it to enter the larynx far posteriorly between the arytenoid cartilages, where the greatest amount of free space presented itself, it was possible to then pass forwards and see the apex and part of the neoplasm within the loop, before firm pressure forwards and subsequent constriction of the growth were performed. The first attempt failed, owing to the barrier which the hypertrophied false cords presented anteriorly, and the requisite force necessary to press between them and over the growth being under-estimated; and resulted in carrying the whole larynx more or less forwards

before the instrument, and consequently altered so materially the relative positions of the growth and the wire-loop, that complete extirpation failed, and only the apex of the neoplasm was removed. On a second attempt, a few moments later, external manipulation of the larynx was called into requisition, and it was found not only practicable, but also easy, while an assistant first elevated the organ and then pressed it slightly backwards and held it steadily, to carry the oval guard, with its contained wire-loop, directly forwards, nearly into the anterior commissure, and upon drawing up the wire to crush through the pedicle of the neoplasm.

Some embarrassment in the respiration attended the procedure, but the amount of dyspnoea was not excessive and caused no anxiety. Immediate improvement followed the extirpation of the growth, the patient drawing deep, full inspirations, unattended by stridor, and expressing herself in marked terms as to the amount of relief that had been afforded; and a subsequent examination with the mirror showed that, the obstruction being removed, the approximation of the vocal cords was nearly perfect. The stump of the pedicle was seen to be located just above their anterior insertion, reaching well down towards their superior surfaces.

The subsequent treatment of the case presenting no unusual or interesting points, may be summed up in a few words. The patient remained under observation and treatment for several weeks, during which time applications directed against the catarrhal condition of the parts were regularly made to the larynx. The progress towards complete cure, though slow, was sure, being delayed only by the chronic form of the disease and the general hypertrophy of the tissues, and resulting finally in the patient's discharge, the voice being clear and forcible, the respiration unembarrassed and easy.

In the second case, one of papillomatous growths upon both vocal cords, attempts were at once made to remove the various growths by means of the laryngeal tube-forceps; but owing to their soft and friable nature, the instrument was found to be unsuited for complete extirpation, and Stoerk's guillotine was substituted. With this it was designed to cut the growths cleanly away from the cords at their bases, or even a line below that point, and to remove them entire, leaving no scattered portions behind to serve as a nucleus for the development of new outgrowths, and the result proved its applicability and thoroughness for all the growths, with the exception of those at the anterior commissure. Three sittings were necessary to effect complete clearance of the vocal cords, followed by one during which the 'ball-shaped' cutting forceps of Winternich were used to remove the small growths at the anterior commissure of the cords.

No untoward incident occurred during these steps of the operation; the patient, being well trained to bear the introduction of instruments into his larynx, bore the various stages of the procedure well; the latter being of short duration and conducted at frequent intervals.

The hæmorrhage following the excision of the masses was but slight, and readily checked by cold and astringent gargles, and the application of ice externally over the larynx.

The growths having been removed, approximation of the cords was rendered possible, and the good result of the operation was demonstrated a few days later to the eye, in the nearly perfect closure of the

glottis, and to the ear by the full, almost clear, voice of the patient, especially in the higher notes. This clearness of voice was subject to partial relapses, due either to an accidental access of the catarrhal inflammation of the cords, or to an overuse of the voice, exhausting the impaired nerve-force of the larynx; both of these conditions improved, however, as time elapsed, and some few weeks later the verdict of cure could be pronounced, with a guarded prognosis regarding recurrence of the growths.

BOECKEL ON RESECTION OF THE SCAPULA.—

Dr. Boeckel, in a communication made to a general meeting of the medical men of the Lower Rhine, and reported in the *Gazette Médicale de Strasbourg* for 1874, related two cases of resection of the scapula. One was a case of resection of the acromion and of the external third of the spine of the scapula. The cure was completed in two months, and the movements of the arm were perfectly re-established at the end of six months. In the second case there was caries of the scapula; subperiosteal resection of the scapula was performed, leaving the articular portion, and the inferior angle. Cure was effected in between two and three months. At the end of between three and four months there was complete bony regeneration, and at the end of six months use of the limb was restored. Dr. Boeckel thus describes the method of operation employed.

1. Tegumentary incisions. A first transversal incision was performed, starting from the extremity of the acromion to the level of the fistula, that is to say, almost as far as the external third of the spine; then instead of following the spine throughout its length, like the majority of surgeons, we got near to the upper edge of the bone, hoping in this way to thoroughly lay bare the upper part of the scapula and to protect ourselves against the objection made to the transverse incision of Langenbeck, Syme, etc., which but imperfectly uncovers the infraspinous fossa. It did not occur to us at the time that the caries could be so extensive, and we proceeded to rasp the acromion and the commencement of the spine by detaching the subscapular muscle and the periosteum from their attachments to the bone. This process was very easily performed, favoured by the slightness of the periosteal adhesions. When I came near the spinal edge I found this portion diseased. An incision, in the first instance perpendicular, keeping along the spinal edge, and reaching to the bone, was made over a space of a few centimètres; but it soon became necessary to prolong it on account of the caries, which extended further than had at first been supposed, so that finally there was a vertical incision nine centimètres long.

2. Denudation of the bone was then proceeded with rapidly. I separated the muscle on the side of the infraspinous fossa, as far as above the coracoid notch, that is to say, until close to the base of the coracoid apophysis, without finding the subscapular nerve; on the side of the infraspinous fossa the muscles were detached as far as two finger-breadths of the inferior angle, which was healthy; the lower fibres of the infraspinatus were bisected; the insertions of the teres major were left completely intact. I afterwards tried to raise the scapula and to roughen a portion of the subscapular fossa, in order to pass a chain-saw and leave the lower angle of the bone in the wound. A certain number of the fibres of the subscapularis were divided, and section of the bone

was then performed. I was then enabled to lay hold of the scapula, draw it out of the wound, and lay it entirely bare. This process was easily performed, and was continued on the two surfaces almost as far as the glenoid cavity. As the vicinity of the cavity appeared relatively healthy, the chain-saw was passed through the coracoid notch, and the neck of the scapula was divided. At this moment, the subscapular artery gave out a strong jet of blood, and was taken up with much difficulty, but after some time was successfully tied. The amputation was terminated by the division of the acromio-clavicular ligaments.

MATERIA MEDICA AND THERAPEUTICS.

CLARKE ON THE CONTINUED AND THE FREQUENT DOSE.—In the *New York Medical Journal* for September, is an article of much interest on the continued and the frequent dose, by Dr. Edward H. Clarke. He says:

The systematic treatises on materia medica with which American and foreign medical literature abounds usually give, near the close of their description of the various drugs whose virtues they rehearse, the appropriate dose for therapeutical use, and also the toxicological dose, if the article is capable of exerting any poisonous action on the human economy.

Thus Waring, after describing the salts of morphia, adds, 'Dose of the morphia salts, gr. $\frac{1}{8}$ - $\frac{1}{4}$ up to gr. 1.' Stillé concludes his account of the carbonate of lithium with the statement that it 'may be administered in doses of from one to five grains three times a day, dissolved in not less than four ounces of water.' The United States Dispensatory, speaking of the sulphate of quinia, says, 'The dose varies exceedingly, according to the circumstances of the patient, and the object to be accomplished;' and then adds that, as a simple tonic, a grain may be given three times a day, or more frequently; that in intermittents, from twelve to twenty-four grains may be given between the paroxysms, in divided quantities, according to the condition of the patient and other circumstances. These and similar statements with regard to the doses of medicines, that may be found in all works on materia medica and therapeutics, are essential. They are true as far as they go, but they do not represent the whole truth. They fail to give to the student and practitioner an accurate notion of what an important factor in therapeutics the dose is; and especially do they fail to convey an accurate notion of the therapeutical importance of variation of dose and method of administration.

In saying this, I do not forget that we are told by all works on materia medica that doses should vary with age, sex, temperament, idiosyncrasy, disease, habit, and the like. This is all true. It has been confirmed by the experience and observation of centuries, but it is not the whole truth. It does not give an adequate notion of the therapeutical power which can be exerted by appropriate physiological doses.

It is the object of this paper to call attention, as briefly as possible, to this therapeutical power, and especially to the action of what, for want of a better designation, may be called the therapeutical action of continued and frequent doses.

Doses of medicines may be appropriately considered under four distinct heads or classes, namely: 1. Single doses; 2. Continued doses; 3. Frequent doses; 4. Toxicological doses. The first and last of these, or the single and the toxic dose, are the doses given in treatises on materia medica, and are recognised as representing the therapeutic and poisonous action of any given drug. It is unnecessary to dwell upon them, for they are universally understood. But the bare statement of what is the legitimate single or average toxicological dose of an article like opium, for instance, gives no adequate or intelligent notion of what the continued or frequent dose of the same drug is; nor does it give any adequate or intelligent notion of the physiological action and consequent therapeutical power of its continued or its frequent dose.

Let us consider first the continued dose. By this is meant the administration of a drug in such a way that the elimination of one dose shall not be completed before the absorption of the following dose has commenced. By this method of administration the blood is kept constantly charged with the drug. . . . The difference between the single and the continued dose is the difference between keeping the blood constantly charged with the article administered and allowing the blood not only to free itself from one dose before a second dose is administered, but making the intervals between the doses so long that the blood shall be practically a longer period unchanged than charged with it.

The observance of this difference is important physiologically and therapeutically. The neglect

of it explains much of the confusion and discrepancy that may be found in the statements of different observers with regard to the action of drugs. Many of the phenomena, both physiological and toxicological, that follow the exhibition of the continued, do not follow that of the single dose. And, what is in fact a corollary from this, many therapeutical results may be obtained by the continued that cannot be got from the single dose. It is also to be remarked that, although few or no practitioners write as if they were aware of the important difference here referred to, yet the larger number of observations evidently are founded on the action of the continued dose. Physiologists, on the contrary, seem to have experimented oftenest with the single dose.

The continued dose means keeping the blood continuously charged with a medicine by a succession of single doses. The single dose is an appropriate quantity given once or oftener, without keeping it continuously in the blood. The therapeutical value of these doses and the physiological difference between them are of great importance.

Let us look at some illustrations of this difference and value.

Ammonia and its salts 'readily enter the blood, and must to some extent increase its alkaline reaction; but from their volatility and high diffusive power they are rapidly eliminated, and hence their action on the blood and the organs of the body is a very transient one.' The elimination of a single dose of carbonate of ammonia is practically completed in an hour or two after it is administered. Its physiological action is correctly stated by the *United States Dispensatory* to be 'stimulant, diaphoretic, antispasmodic, powerfully antacid, and in large dose emetic.' In consequence of this action, it is largely used in depressed conditions of the vital powers. This is the well-known action of a single dose or of a few doses given near together, after which the system is freed by elimination from the drug. No change is produced in the quality of the blood. If a continued dose of ammonia is given, that is, if it is given so often, say every hour for several days, that the blood is continuously charged with it, a very different set of phenomena from those just described appear. 'When ammonia or its carbonate is administered'—in this way—for some time to animals or man, the effect is to modify the blood-corpuscles; they become easily soluble, crenate at the edge, many-sided, colourless, transparent, collapsed, and loosely agglomerated, but not in rolls; and the blood when drawn, or after death, is absolutely fluid or loosely coagulated.' These phenomena were observed by Dr. B. W. Richardson, of London. They closely resemble the changes in the blood which occur in patients suffering from typhoid and typhus fevers. Hence it appears that the single dose of ammonia produces rapid and effectual stimulation of the heart, while the continued dose of the same article alters the quality of the blood, and notably of the blood-corpuscles. The single dose exerts a therapeutic, the continued dose a toxic action on the economy. It is unnecessary in this presence to dwell upon the obvious therapeutic inferences that follow from these data, at least so far as ammonia is concerned.

Gallic acid is another illustration of the difference between the single and the continued dose. This acid is rapidly eliminated. Physiologists tell us that, in a couple of hours after it has been swallowed,

it has practically left the system, by way of the kidneys, to such an extent that it exerts no appreciable action upon the blood after that length of time. Gallic acid has a well-deserved reputation for controlling certain forms of hæmorrhage. Suppose it is given in single doses of ten grains, more or less, three times a day, which I apprehend is the usual method of administration, the blood will be subjected to the restraining action of the acid only about six hours out of the twenty-four; not long enough to hold steadily in check a hæmorrhagic disposition. Suppose, now, that instead of the single, the continued dose is administered, by which the ratio of elimination to absorption is constantly regarded, and the blood kept continuously charged with gallic acid; the result will be a continuous action upon the blood, and not an intermittent one. It is needless to point out the fact that continuity of action is very sure to give rise to phenomena that will not follow intermittence.

No drug exhibits in a more striking light both the physiological and the therapeutical differences between single and continued doses than alcohol. The partial, confused, and incomplete recognition of these differences by various observers and experimenters, who have examined and described the physiological action of alcohol, goes a great way towards explaining the various and often discordant results at which they have arrived. We learn from the experiments of Messrs. Lallemand, Perrin, and Duroy, as well as from those of Drs. Anstie, Parkes, Smith, Binz, and others, that the disappearance of a single dose of alcohol from the system, either by elimination from it or combustion in it, or by both processes, practically takes place in about six or eight hours after its ingestion. Traces of alcohol may be found in the blood and in the excreta for a much longer period than this; but so much of it leaves the system within eight hours that what remains of any single dose beyond this length of time has no real physiological value. A person who takes a dose of alcohol, in the shape of wine or other alcoholic liquid, once in each twenty-four hours, subjects his organism to the action of alcohol about one-third of that time, and leaves it free from that action about two-thirds of the same period. A person who takes what is known in non-scientific language as an 'eye-opener' in the morning, wine with his dinner or lunch, a digester in the afternoon, and a 'night-cap' on retiring, takes the continued dose of alcohol. His blood is continuously charged with alcohol to a greater or less degree. There are phthisical patients who imitate this method of ingesting alcohol, and take a daily continued dose of it, keeping their blood charged with it more than two-thirds of the time.

Alcohol taken in a single daily dose, by which the blood is practically free from it more than two-thirds of the time, and alcohol taken in a daily continued dose, by which the blood is practically charged with it more than two-thirds of the time, are substantially different drugs, which produce different physiological phenomena and are or should be employed for different therapeutical ends. This is not the time, nor does it fall within the scope of this paper, to describe these differences in detail. It is sufficient for my purpose to indicate their existence as illustrations of the single and the continued dose.

The bromide of potassium affords another and most pertinent illustration of the different physiological and therapeutical action which the single and

the continued dose of an article may produce. I pointed out these differences in a comparatively recent monograph on the physiological and therapeutical action of the bromide of potassium, and will not repeat them here. Illustrations of single and continued doses, and of the therapeutical importance of recognising them as factors in the treatment of disease, might be multiplied indefinitely; but enough has been said to call your attention to them and to emphasise their importance. It was impossible to recognise and use them as separate therapeutical factors till physiological observation and experiment had discovered the time and method of the absorption and elimination of drugs, and the ratio of the former to the latter; nor can the practitioner apply them clinically till he knows, at least with approximate accuracy, the way every article he uses gets into and out of the system, the length of time it remains in the system, and its behaviour while there.

The administration of medicines to the sick, without regard to the different and often opposite results, physiological or therapeutical, that follow the single and the continued dose, is both unsatisfactory and unscientific. It is unsatisfactory because it fails to secure the legitimate action of medicinal agents. It is unscientific, because it ignores some of the most important physiological conditions upon which scientific therapeutics rest. The time has come for the clinician to recognise and use these and other phenomena of the *modus operandi* of drugs which the physiologist has discovered and whose accuracy he has demonstrated.

Secondly, the frequent dose is the giving of a medicine so as to impart to the organism some one or more of its actions, whether primary or secondary, with great rapidity. It is hitting blow after blow in quick succession, upon some organ which it is desirable to affect, in accordance with evident indications, with rapidity and power. It is usually, perhaps always, some action of a drug, manifested soon after its absorption, which it is desirable to obtain and which can be obtained by the frequent dose. Obviously the administration of the frequent dose is limited by the physiological behaviour of the system under its influence. After a certain period the frequent dose is equivalent to a full single dose or to a toxic one.

The action of opium almost immediately after absorption illustrates the frequent dose. One of the earliest physiological actions of opium after its ingestion, rarely after subcutaneous injection, is stimulation of the nervous system, and of the circulation. This is fully recognised by obstetricians, who advise its exhibition as one means of controlling *post partum* hæmorrhage. Stimulation is a primary effect of opium that soon passes over, the length of time varying with the quantity given and with the idiosyncrasies of patients, into an opposite condition. The administration of an appropriate quantity of opium every five, ten, or fifteen minutes, that is, the frequent dose of it, will prolong and enhance its primary stimulant action. How desirable it sometimes is to prolong the primary stimulating action of this invaluable agent, I need not remind those who hear me.

The physiological action of aconite upon the human economy illustrates the same principle. Fleming's admirable observations upon aconite have taught us the powerful sedative influence that five drops of the tincture of the root exert upon the system. If, instead of giving five drops in a single dose, half a drop is given every half-hour ten times,

or one drop every hour five times, a different physiological and consequently a different therapeutical result is attained from that of a single dose of five drops. In this case a less depressing sedative action is obtained by the frequent than by the single dose.

[In reference to what is said in the beginning of the article 'that doses should vary with age, sex, temperament, idiosyncrasy, disease, habit,' etc., it must be borne in mind that doses really are apportioned to the weight, and, as is found in experimentation, the dose must be apportioned to the size of the animal. The principle is seen in our practice of a less dose for women and for children, the less or younger the child the smaller the dose.—*Rep.*]

WOOD ON SUBCUTANEOUS INJECTION OF CHLOROFORM.—In the *Canada Medical and Surgical Journal* for July, is a communication by Dr. G. Wood on the subcutaneous injection of chloroform in the treatment of facial neuralgia. He says that he saw it recommended in some American medical journal, and availed himself of it in the treatment of one of the severest and most obstinate cases of facial neuralgia, that he ever met with.

D. C. H., aged about forty, with dark hair, eyes and complexion, very spare, weight 125 pounds, had suffered from facial neuralgia of the left side of the face since 1854. He had undergone all systems of treatment with little or no relief. In 1872 he had the lower jaw trephined and a portion of the nerve removed; this gave him relief for several months, but eventually the neuralgia returned, if possible more severely than ever. He first came under Dr. Wood's care in August 1873. He gave him different iron tonics, bark, hypodermic injections of morphia, croton-chloral-hydrate, and various neuralgic pills, with but temporary success. In August 1874, Dr. Wood injected fifteen minims of chloroform underneath the mucous membrane of the lower jaw, as near the exit of the mental branch of the fifth pair as he could. It gave him entire relief in an hour, but caused partial paralysis of the muscles of the left cheek. In a week he repeated the injection, and gave him drachm-doses of the elixir of guarana three times a day. In September and December, and also in April, he had a very slight return of the pain, each recurrence being less severe. At each of these times Dr. Wood repeated the chloroform, and he now seems to be entirely well.

Dr. Wood's partner, Dr. Rose, had a lady patient, unmarried, aged about forty-five, who had been a terrible sufferer from the same disease for seventeen years, had consulted the most eminent men in this and foreign countries, and had tried all the prescriptions recommended. The only thing that gave her any relief was hypodermic injections of morphia. She was obliged to use them, sometimes several times a day. Her mind and morals were very much disordered. Dr. Rose tried the hypodermic use of chloroform, and she is now entirely well. The injection of chloroform is extremely painful unless preceded by an injection of ten or fifteen minims of Magendie's solution of morphia,

J. MILNER FOTHERGILL, M.D.

BOUCHUT ON THE PHYSIOLOGICAL AND THERAPEUTIC EFFECTS OF ESERINE OR PHYSOSTIGMINE.—M. E. Ferrand writes to *La France Médicale* of August 18, an article on the action of eserine, embodying the experience of M. Bouchut, who has given it 437 times, either by the stomach or sub-

cutaneously, sometimes using the pure alkaloid, sometimes its sulphate. He has chiefly used it for chorea in children, and he declares that the results differ widely from those anticipated from experiments on animals. The tolerance or the excitability manifested by rats, dogs, rabbits, or guinea-pigs is no guide, he says, to the effects in human beings. Its use in medicine is still much restricted. It is used to contract the pupil, and has been tried a few times to calm the muscular irritability of tetanus. M. Bouchut has used it in the treatment of chorea, the patients being little girls of seven to twelve years of age, the medicine being given in 205 cases in pills containing two to five milligrammes ($\cdot 03$ to $\cdot 07$ of a grain), whilst in 232 cases the like dose has been given subcutaneously. In the case of the larger dose, given subcutaneously, the following effects are said to follow in about five minutes: Pain, distress, tears, loud outcries, due to pain of an agonising character at the epigastrium; pallor, slight chilliness, perspiring face, nausea, and expectoration of clear fluid or froth, cramps in the stomach, scanty glairy vomit, with much pain; and paralysis of the diaphragm, more or less marked in different children, rendering vomiting difficult. The scene in the ward resembles sea-sickness. Marked contraction of the pupils was only observed once, and slighter contraction twice. In all the rest the pupils were dilated, but contractile. The pulse, normal in some, has been diminished in volume and number in others, though never less than sixty-four. There has been no colic, no diarrhoea. Respiration has been painful and laboured by hyposthenia, or by diaphragmatic paralysis, not cyanotic. In all, the ribs were well raised, but the diaphragm, instead of descending, rose in the chest, dragging in the abdominal wall. There was no anæsthesia, and no sensorial or intellectual disorder. These phenomena last about three hours. During this time the choreaic movements are arrested. In ten out of twelve, when the effects of the eserine wear off, the movements recur, but less powerfully than before. With the smaller doses of two and a half milligrammes ($\cdot 04$ or $\frac{1}{25}$ grain) paralysis of the diaphragm, at least in any marked degree, was never produced; and with still smaller doses the distress and spitting were not present. The sulphate acts in a similar way, in the same doses. After two or three hours, the effects go off, and the children seem no worse. Hence from fifteen to twenty milligrammes, or one-fifth to one-third of a grain, can be given, in divided doses, in the twenty-four hours. The treatment of chorea in this way takes, on an average, about ten days.

HEDLER ON POISONING BY ATROPINE: MORPHIA-TREATMENT: RECOVERY.—Dr. Hedler, of Aschersleben, writes to the *Berliner Klinische Wochenschrift*, of August 23, 1875, and gives the details of the following case. He had given a lady, on whom he had previously operated for cataract, an atropine solution containing $0\cdot 06$ of sulphate of atropine in 80 grammes of water (about equal to two drachms of a four-grain solution). As these eyedrops had only been used twice at the furthest, more than half a grain of the atropine must have been contained in the bottle. A child aged fifteen months drank about half of this, but probably spat out a good deal of it. This happened about 6 P.M. At 8.45, except perhaps slight dilatation of pupils, there were no symptoms. Slight contractions of the limbs set in at 10 P.M. At 10.30 there were recurrent contractions,

at one time of the upper extremities, at another of the lower. These cramps were, however, slight. There was also frequent swallowing of saliva. Pulse 120, respiration quickened, face red and hot, pupils moderately dilated. One-sixth of a grain of morphia was ordered in four doses. The convulsions soon became more urgent—tonic and clonic spasms occurring rapidly. The pulse rose to 200, and then became uncountable. The head and chest became covered with a rash like scarlatina. The eyes rolled ceaselessly. The pupils were never very widely dilated. Soon the child began to smile and stretch out towards an imaginary bottle; then he stared at one corner of the room, and threw himself suddenly with a loud cry into his mother's arms. All this occurred between eleven and twelve at night. The four doses of morphia were given at intervals of a quarter of an hour. As no effects were produced, a subcutaneous injection of one-seventh of a grain of morphia was given (one-tenth of one gramme of a solution containing one in twenty) with some amelioration of the symptoms, but return of the delirium. A second hypodermic solution of the same strength was given. In five minutes all spasms ceased, and the child slept tranquilly till next day. The pulse was then 120, and, except for a little weakness and anorexia, the child was well. In two days there was no bad symptom. Dr. Hedler remarks that the long period of latency of symptoms (full four hours) is very interesting. Although Nothnagel (p. 38, 1874), will not allow that morphia is an antidote to atropine, it appears to have proved itself such in this case.

CARLOS ON THE TREATMENT OF WHOOPING COUGH BY CARBOLIC ACID.—*L'Union Médicale* (no. 91), for August 3, 1875, contains a letter from Dr. Domingos Carlos (of Bahia), stating that whooping cough is often frequent and severe in the West Indies. The epidemics are chiefly in autumn, and adults not seldom suffer. He has long suspected that the sporules of some fungus were the cause of the disease. On this theory he began in May, 1874, to make trials of carbolie acid. He chose an obstinate case, a child of two years old, whose cough had resisted all common means of treatment. The following formula was employed:

- R. Crystallised carbolie acid, 25 centigrammes.
Concentrated orange-flower water, 5 grammes.
Gum julep, 50 grammes.

To take four to six teaspoonfuls daily. [This is about equal to crystallised carbolie acid, four grains, concentrated orange-flower water ʒjss, mucilage to ʒij.] The improvement in three days' time was most marvellous, and Dr. Carlos's subsequent success has induced his colleagues to use the same remedy. [Without dogmatising on the cause of whooping-cough, the reporter thinks it noteworthy that in all the cases at the North-Eastern Children's Hospital, in which he has examined with the microscope the viscid mucus coughed or vomited up by children with this disease, and these amount to some dozens, he has found not only bacteria and bacteroids, but also sporules and mycelium, much resembling those of the *Oidium albicans*, with finer ones like the *Leptothrix buccalis*. The successful use of alum may also be explained on a similar theory.—*Rep.*]

W. BATHURST WOODMAN.

SISTACH ON THE TREATMENT OF PALUDAL FEVERS BY ARSENIC.—This paper (*Archives Générales de Médecine*, September, 1875) comprises the fruits of a large experience gathered at the military

hospital of Bona, in Algeria, one of the most malarious stations in that malarious colony. The author arranges his cases under four heads: intermittent fever, remittent fever, pernicious paludal fever, and paludal cachexia. The first group includes 229 cases, of which 136 were quotidian, seventy-four tertian, eleven quartan, five irregular, and three masked. Algerian intermittents are most frequent and severe during the summer months. The number of paroxysms is always greater in the first attack than in subsequent ones; and this difference is observed, whatever be the mode of treatment employed. Indeed, M. Laveran noticed it in his account of eighty-eight cases treated on the expectant method at Blidah. In comparing the results of treatment with those of simple expectation, it is indispensable that the cases should all have been subjected to the same telluric and climatic conditions. In a comparatively healthy locality, such as Blidah, recovery without specific treatment is not uncommon; whereas at Bona, where the patient continues to be exposed to miasmatic influences of a most intense kind, attempts at expectation may prove dangerous, if not fatal. Each of the 136 cases of quotidian ague furnished an average number of 1.7 paroxysms after the treatment by arsenious acid had been begun; this average only amounting to 0.75 in the seventy-four cases of tertian fever. Frémy, Fuster, and Girbal had previously noticed that the febrifuge action of arsenic manifested itself more promptly in the latter than in the former variety of the disease.

The following are the rules laid down by the author for the administration of the remedy. They are essentially the same as those originally promulgated by Boudin; and the failures which have been recorded since his time by various observers must be attributed to their neglect of those details on which the certainty and the safety of arsenical medication depend. 1. The arsenious acid must be given in solution. The previous administration of an emetic is only necessary when the stomach is overloaded. 2. The remedy must be freely diluted, and given in very small doses, frequently repeated. 3. The quantity taken in twenty-four hours must be proportionate to the severity of the fever, to the length of time it has lasted, and to the nature of the locality as regards malaria. 4. We must begin by giving from three to five centigrammes daily (.45 to .75 grain), to be continued as long as the paroxysms recur. 5. After the paroxysms have ceased to recur, the dose ought to be diminished by one centigramme every day; but the patient must continue to take about one centigramme daily for some ten days after he is apparently free from symptoms. When these directions are carefully attended to, the use of arsenious acid is wholly free from risk. A few cases of conjunctival irritation, sometimes associated with œdema of the eyelids and cheeks, occasional colicky pains with slight diarrhœa, and in very rare instances nausea and vomiting,—such are the only accidents which M. Sistach has ever observed. He concludes that for the treatment of intermittent fever arsenious acid is as effectual as quinine, and more effectual than cinchonine or quinium; though as regards quickness of operation, quinine must continue to hold the foremost place. The extreme cheapness of the mineral remedy is, of course, its chief recommendation; by substituting it, even partially, for quinine, many hundred thousand francs may be yearly saved on the war budget alone.

Under the second head, that of remittent fever, the author's results are by no means favourable. The remittent form of the disease is notoriously more obstinate than the intermittent variety, and demands much larger doses of whatever febrifuge remedy we may choose to employ. Now arsenious acid, if given in the necessary quantities, invariably aggravates the gastro-intestinal symptoms to a dangerous extent. Moreover, the comparative slowness of its operation renders it unsuitable for the treatment of a disease which does not bear delay. It is equally unsuitable, and for the same reasons, as a substitute for quinine in the treatment of the pernicious variety of paludal fever; of three cases treated by M. Sistach with arsenious acid, two died. As regards the divers forms of paludal cachexia, the author asserts that neither quinine, nor arsenic, nor any other drug, is of any avail; the patient's only hope of recovery lying in removal to a more healthy region, together with the diligent employment of hydro-therapeutic measures.

AUBERT ON THE COMBINED APPLICATION OF NITRATE OF SILVER AND METALLIC ZINC.—Professor Corradi having advocated the superiority of this method, especially for the cauterisation of fungating syphilitic excrescences, M. Aubert (*Lyon Medical*, October 17, 1875) endeavours to explain the way in which the zinc assists the action of the silver salt. The diseased surface is touched with the solid nitrate, or better still, with a concentrated aqueous solution of the salt, in the usual way; a pencil of metallic zinc is then rubbed lightly over the milk-white patch, which instantly assumes a black colour. The following are the chemical changes which take place. By contact with the tissues, the nitrate of silver is partly converted into an albuminate and chloride of the metal; a certain proportion, however, remaining undecomposed. The action of the metallic zinc is limited to this undecomposed residue; nitrate of zinc being formed, while metallic silver is set free. The nitrate of zinc itself is partially decomposed by the solid chloride contained in the juices of the part; zinc chloride and sodic nitrate being formed by double decomposition. The diseased surface is thus coated with a film consisting of (1) unaltered albuminate and chloride of silver, which may subsequently be decomposed by the action of light; (2) metallic silver; (3) nitrate of zinc; (4) chloride of zinc; (5) sodic nitrate and chloride. It is to the caustic properties of the nitrate and chloride of zinc that the efficacy of the method must be ascribed. The author goes on to suggest that nitrate of zinc in sticks, either pure or mitigated, may advantageously be substituted for nitrate of silver; for it is at once cheaper and more active as a caustic, while it does not soil the hands and linen.

E. BUCHANAN BAXTER, M.D.

CRÉQUY ON THE TREATMENT OF FISSURE OF THE ANUS BY CHLORAL.—In a letter to the editor of the *Bulletin Général de Thérapeutique* (September 30, 1875) Dr. Créquy calls attention to the advantages of this agent. He mentions two cases, one aged thirty-eight years, the other forty, where the fissure was well marked and the usual distressing symptoms present. Charpie soaked in a solution of chloral—one in fifty—was inserted just within the anus daily, attention being paid to the regular daily evacuation of the bowels. A complete cure resulted in each

case at the end of a fortnight, the pain on defecation disappearing after the first few applications.

ARTHUR W. EDIS, M.D.

EVERS ON INDIAN MEDICINAL PLANTS (*continued from page 495*).—Surgeon B. Evers continues, in the *Indian Medical Gazette* for October 1, his notes on Indian medicinal plants as follows.

Soymida febrifuga (N. O. Meliaceæ).—The plant is commonly known as 'Bastard Cedar' and 'Indian Red-wood' in English, and as 'Rohun' in the vernacular. It is common in Central India. The wood is of a red colour, strong, heavy, and durable, and well adapted for building purposes and for making articles of furniture; it is not readily attacked by white ants. The bark, according to Ainslie, is 'of a dingy red colour, and has a pleasant bitter taste, with a slight degree of austerity.' (A decoction of the bark dyes brown of various shades.) Both the decoction and the infusion of the bark are used in medicine; but the tincture, according to the authority named, is said to be the most valuable. The Baidis employ the bark in the treatment of malarial fevers, thus, six mashas (equivalent to a drachm and a half) of the bark are bruised and administered in combination with sugar or syrup, two or three times a day. It is considered by some as a good substitute for cinchona bark. Sir W. O'Shaughnessy, however, is of opinion that it is of little use 'in the treatment of obstinate or dangerous cases,' but that 'like all other astringent tonics,' it will often succeed in mild cases of ague. He recommends it to be given in the form of extract. Attempts have been made to obtain an alkaloid principle from the bark, but without success. The spicular crystals obtained when the bark was subjected to processes similar to those for obtaining sulphate of quinia, were found to be simply crystals of sulphate of lime. It is sometimes adulterated with *nux vomica* bark, but from this it is distinguished by the application of nitric acid; the acid when applied to the inner surface of *soymida* bark does not 'cause a bright red stain.' Waring recommends it as a good substitute for oak-bark when astringent gargles, injections, etc., are required. I have employed the bark in the treatment of ague, but cannot report favourably of it. Its action appears to me to be more that of a bitter tonic than a febrifuge. In overdose it is said to cause derangement of the nervous system, 'occasioning vertigo and stupor.' The bitter principle of the bark, according to Broughton, consists of an almost colourless resinous matter sparingly soluble in water, 'but more so in alcohol, ether or benzol.' It does not combine with acids or bases; it contains an abundance of tannic acid.

Anthocephalus cadamba (N. O. Rubiaceæ: vernacular, Kaddam).—The plant is common in Bengal and in the North-West Provinces, seldom seen in the Central Provinces. It is said to be indigenous to Assam. 'The flowers are offered in Hindu shrines; the fruit is eaten.' I have employed a decoction of the bark (prepared in the same way as decoction of cinchona) in the treatment of ague, but cannot certify to its efficacy as a febrifuge. In several trials I gave it, it appeared to me to act simply as a tonic.

Euphorbia antiquorum (N. O. Euphorbiaceæ).—According to Ainslie, 'the milky juice got by wounding the branches is extremely corrosive, but when boiled with a small quantity of gingilie oil (tin oil) the native practitioners use it as an external applica-

tion in rheumatic affections ; ' it is said also to deaden the pain of toothache. When administered internally it acts as a cathartic, and is considered to be specially useful ' in those cases of obstinate constipation which are often troublesome when there is an enlargement and induration of the spleen or liver.' The fresh juice is highly acrid. The Baidis and Hakeems seldom use it fresh. For ordinary blistering purposes it is combined with croton-oil; thus the juice is mixed with bruised croton-seeds, saffron, and butter; this mass is enveloped in three or more folds of calico, and fastened to the end of a long iron hook; the mass is then ignited and held over some vessel, when a dark oily liquid is obtained; this liquid is said to be powerfully caustic. As a purgative, the juice is administered thus. Two or three drops of the fresh juice are mixed with about half a drachm of roasted chenna (Bengal gram) powder, and a little ghee and sugar; this dose is considered sufficient to produce eight or ten copious evacuations. The inspissated juice was formerly held in great repute as an antisyphilitic, and indeed Dr. J. Shortt reports that he has found it an excellent alternative in these cases, in doses of five grains night and morning. For a long time it was supposed that this plant was the source of the euphorbium of the shops, but this has been disproved by Hamilton (*Linn. Trans.* vol. xiv.) and Royle (*Illust.* vol. i. p. 328). Fluckiger and Hanbury refer euphorbium to the *Euphorbia resinifera*. A plaster composed of the bruised roots and assafœtida is applied to the stomachs of children suffering from worms. The root-bark is said to be purgative. The resin in combination with cantharides forms gout-plaster. The *Euphorbium tirucalli* and *E. nivalis* also yield an acrid milky juice. All these plants are of a highly poisonous character, and great care therefore is necessary in employing them medicinally.

Zizyphus jujuba (N. O. Rhamnæ: vernacular, *Bair*).—A very common plant in the forests of Central and South India. The bark is used as a dye, and also for tanning; the root is considered a febrifuge by the natives, and oil is obtained from the kernels. O'Shaughnessy states that 'the bark is used in the Moluccas as a remedy for diarrhœa; the root with some warm seeds in infusion, in fever. The lozenges, and the thickened mucilage called *jujubes*, by the confectioners, are prepared from this, and the *Z. vulgaris*.' Pieces of the roots, threaded into a necklace, are worn by the natives during attacks of ague. I have tried the root as a febrifuge, but find it slow in its action. In seventeen cases treated with a decoction of the root, the drug did not check the paroxysms until about the seventh or eighth day; I believe it acts more as a tonic than an antiperiodic.

SMITH ON TINCTURE OF ARNICA.—Dr. Walter G. Smith points out (*Dublin Medical Journal*, September, 1875) that Dr. James C. White is convinced, from his own experience, that not only is arnica valueless as an actual remedy, but that it is often positively noxious. He relates (*Boston Medical and Surgical Journal*, January 21, 1875) three cases in which the application of an arnica lotion to excoriations occasioned severe outbreaks of acute inflammation, accompanied by development of papules, vesicles, excoriations, crusts, and scales in regular sequence. The local symptoms were intense itching and some degree of burning. The mischief-making powers of arnica are much more frequent

than is commonly supposed; and if its deleterious and toxic effects are seldom recognised, it is because all the disturbances really due to this so-called remedy are laid to the account of the injury. Dr. White coincides with Hebra and Tilbury Fox in ascribing the feeble therapeutic properties of tincture of arnica solely to the presence of the alcohol (see Garrod's *Materia Medica*, 3rd ed., p. 267). The dangerous qualities of arnica have also been appreciated in France (*Rev. de Thér. Méd.-Chir.*, no. 9, 1875).

The following remarks, taken from Dr. Charles Phillips' *Materia Medica and Therapeutics*, 1874, throw considerable light on the discrepant statements which have been made respecting the effects of arnica. The ingredient in arnica long supposed to be of most consequence was *arnicine*, an amorphous bitter substance, almost insoluble in water, but freely soluble in alcohol and ether; or else the ethereal oil, which is also insoluble in water. For a variety of reasons, it is now probable that neither arnicine nor the oil, but *trimethylamine*, an organic alkali, is the really useful constituent of arnica. Trimethylamine, C_3H_9N , is a clear, colourless fluid, very volatile, and freely soluble in water, alcohol, and ether.

'The external effect of arnica involves important questions; for, while it is known that many persons have found it an excellent application for bruises and for wounds, other observers have complained that it produces either an actual erysipelas, or a peculiar violet-coloured eruption, attended by great heat and pain. I venture to affirm that these are physiological consequences of the alcoholic, and not of the aqueous solution, which latter contains neither arnicine nor the oil. I have never seen inflammatory consequences follow the application of the purely aqueous lotion to wounds or bruises.'—(P. 306.)

'For external bruises and cuts arnica is, undoubtedly, very useful; and, as already observed, the mischances that have attended its use have probably resulted from the fact that the tincture, containing arnicine and the volatile oil, has been employed. The infusion or decoction alone should be used, and it would be better to give up employing all liniments and lotions in which the tincture is present.'—(P. 309.)

NEILL ON THE TREATMENT OF GONORRHOEA.—In the Report of the Pennsylvania Hospital (*Philadelphia Medical Times*, June 19), Dr. Neill says the common treatment of gonorrhea used to be, and to a certain extent still is, the administration of stimulating resinous diuretics, principally cubebs and copaiba. The abuse of these medicines is worse than the disease itself, and they have undoubtedly been the cause of much of the chronic urethritis and cystitis which now exist. They have also been productive of much dyspeptic trouble, especially since the introduction of capsules, admitting of large doses. It may therefore be laid down as a rule in the treatment of gonorrhœa, never to begin with cubebs or copaiba. In such a case as this, and indeed in nearly all cases, in the early and inflammatory stage Dr. Neill advises the following prescription:—

R. Potassii bitart., ʒiv ;
Potass. nitrat. (pulv.), ʒiij ;
Potass. et antimon. tart., gr. j.

This should be ground in a mortar and thoroughly

incorporated, and then divided into twelve powders, one of which is to be taken three times daily.

The result will be at once an increased action of the kidneys and the whole genito-urinary tract, which will diminish the vascularity and hyperæmia of the urethral mucous membrane. The discharge will, perhaps, at first be somewhat increased, and it is as well to mention the possibility of this to the patient, but it will then in its turn diminish, and in ten days will almost invariably be much less. In conjunction with this treatment urethral injections, may be ordered, consisting at first merely of cold water, and afterwards of some astringent, such as the sulphate or chloride of zinc or nitrate of silver, but never stronger than half a grain or a grain to the ounce. At the same time, the amount of solid food should be restricted, large quantities of water and alkaline drinks should be taken, and the use of spirituous liquors, violent exercise, and sexual excitement should be strictly avoided. The prejudice which exists against coffee, salt meat, etc., Dr. Neill believes to have no philosophical basis.

TREATMENT OF CHOREA BY ETHER-SPRAY AND ICE-WATER LOTIONS ALONG THE VERTEBRAL COLUMN.—Dr. Fabry has brought together in his *Thèse de Paris*, April 16, 1875, no. 107, the cases he saw whilst in Dr. Perroud's wards at Lyons of the treatment of chorea by ether-spray. This therapeutic means, employed for the first time in 1866 by M. Lubetski, a physician at Warsaw, has yielded very satisfactory results in M. Perroud's hands. The ether-spray is applied along the vertebral column by means of any spray-producers, especially those of Richardson and Marmier. Each application lasts from four to eight minutes; at the commencement of the treatment three applications *per diem* are made, and the number is then reduced to two. Ice produces the same effect as ether-spray; the effects being produced by moving a piece of ice along the vertebral column for five minutes. These two methods act on the excito-motor point of the nervous centres by their refrigerant revulsive action.

OBSTETRICS AND GYNÆCOLOGY.

PETER ON PUERPERAL MANIA.—In a lecture on this subject (*La France Médicale*, July 28, 1875), Dr. Peter stated that he considers puerperal mania to be due to a termination of the blood to the head; the blood, instead of going to the breasts to form milk,

goes to the head to produce a pathological cerebral hyperæmia. Why all suckling women do not have mania is purely a personal matter, depending upon the quality and condition of the brain, whether bad or labouring under mental distress. All functional work demands an afflux of blood, and this functional hyperæmia of an organ may at any time become a pathological hyperæmia. An immoderately active brain is immoderately hyperæmic, which predisposes to a pathological condition. Puerperal mania is, as a rule, in the hypochondriacal form, from the mental occupations of a pregnant woman being of a sad and melancholy turn.

He relates a case lately occurring in his clinic, as proof of this theory. The woman had had five children previously, without a bad symptom. The present pregnancy was an adulterous one. She was of an excitable temperament, and keenly felt her position. During the attack the temperature was normal; but the pulse was very irregular—every two, three, or four beats it intermitted unequally.

The irregularity he attributes to defective innervation of the heart. The nerves which supply this organ come from two sources—the pneumogastric and the cervical portion of the large sympathetic. The cardiac nerves spring from the bulb (medulla oblongata) and the cervical portion of the spinal cord; the cardiac disorder and the cerebral had, therefore, one and the same origin, viz., a cerebral and bulbous hyperæmia.

The treatment is to reduce the cerebral and spinal congestion by the application of leeches or cupping to the nape of the neck. The latter method was adopted in the case, with the effect at once of relieving the headache and the irregularity of the pulse. At the same time, eau de Sedlitz was given to purge the bowels. On the third day a dose of chloral (thirty grains) was given at bed-time, as the sleeplessness had not disappeared; its effect was immediate.

All attacks of puerperal mania come on at night; from the mind not being diverted from itself by the ordinary passing excitements of daily life, it dwells too much on its condition, which increases and intensifies the functional hyperæmia.

SCHRANK ON PERI-UTERINE HÆMATOCELE AFTER ABORTION.—A case of peri-uterine hæmatocele, a sequence of abortion, is related by Dr. S. Schrank, in the *Med.-Chirurg. Centralblatt* for July 23. The patient was not aware she was pregnant, although about three months had elapsed since she menstruated last. Three days previously to her observing a discharge of blood from the vagina, she had slipped down a couple of stairs. Homely measures failing to arrest the flow, she applied for medical relief. Vaginal examination showed the uterine cavity to be empty, the os readily admitting one finger. Vaginal injections of iced water were ordered, and 50 centigrammes ($7\frac{1}{2}$ grains) of ergot to be taken every hour, and cold compresses to be applied over the abdomen. The patient was somewhat overcome from her loss. During the night there were a few occasional gushes of blood, mixed with portions of the decidua. When seen next day she was extremely blanched, and any movement caused faintings. A digital examination discovered a few coagula in the vagina, and the uterus was full of them. External palpation revealed a swelling of considerable size, distended, and neither painful nor tender on pressure. No connection could be made out by examination

through the abdomen and vagina between it and the uterus. The suddenness of the appearance of the tumour, the collapsed condition of the patient, although there had been external hæmorrhage, and the non-connection of the tumour with the uterus, indicated the existence of a hæmatocele. The blood evidently, instead of escaping *per vaginam*, had, from some pathological or abnormal condition of the Fallopian tubes, passed backwards into the abdominal cavity, giving rise to a hæmatocele. It is a rare accident for any fluid to pass from the uterine cavity through the Fallopian tubes into the peritoneal cavity without some impediment to its exit; still there are several recorded cases of uterine injections doing so. Considering how frequently intra-uterine injections have been used, and how rare has been the accident, the author inclines to the belief that it only occurs under some pathological or abnormal condition of the Fallopian tubes and ovaries.

W. C. GRIGG, M.D.

RUGE ON INJURIES TO THE FŒTUS IN CASES OF BREECH-PRESENTATION.—Dr. Carl Ruge (in *Bulletin Général de Théraputique*, August 15, 1875), tabulates a series of cases of this nature.

In the first table are grouped forty-four instances of lesions produced in extraction after version. These include fractures of the humerus, femur, clavicle, parietal, occipital, and lower maxilla; rupture of the cervical and dorsal vertebræ; of various muscles—as the sterno-mastoid, pectoral, etc., and of the longitudinal sinus; effusion of blood into the abdomen, muscles of the chest, etc.; separation of epiphyses, as the clavicle, humerus, maxilla, tibia, etc.

In the second table of lesions produced in breech-presentations, twenty-nine instances are given, where fracture of the frontal bone, femur, clavicle, and other accidents similar to those observed in the former group, occurred.

The author insists upon the advantages of 'expression' of the aftercoming head over traction upon the trunk, as being far less dangerous, care being taken that the head is placed in the position best calculated for its delivery through the pelvis. The combination of the three methods, position, expression, and traction, should always be resorted to.

REPORTS OF FOREIGN SOCIETIES.

ACADEMY OF MEDICINE IN PARIS.

September 28. *The Will considered as a Moral Power and Therapeutic Agent.*—M. Jolly read a paper on this subject. After a rapid study of the faculty called will, the author, attacking the medical side of the question, asked if the will is not capable of imposing its law on physical deviations, and causing certain modifications in pathological conditions, which are more or less rebellious to therapeutic agents possessed by us. He cited cases where paralytic patients, treated ineffectually for years, suddenly recovered the use of their limbs under the stimulating influence of danger. Amongst the diseases in which the will can exercise a potent influence, M. Jolly cited tic, stammering, chorea, cough, whooping-cough, nystagmus, and hysteria. The empire of the will over sensibility may go to the extent of annihilating the latter; but it is especially in a time of epidemics that the will shows its power, and that the men most distinguished by courage and energy are seen to be spared by the disease.

The Classification of Mental Disorders, with reference to an alleged Religious Monomania.—M. Delasiauve passed in review the classifications given by Pinel, Esquirol, Morel, Renaudin, Falret, and Baillarger. They are all defective, since they are founded only on a single characteristic, the consideration of the cause in some, and in others the characteristic of excitation or lowering of the symptoms. These classifications are insufficient to explain certain forms of insanity arising from morbid impressions, vicious ideas, or modified sentiments. The variety, which he had named first pseudo-monomania, would have a special evolution and special characteristics. M. Delasiauve proposed to call it diffused partial delirium. The remarkable point in it is that the patients, dominated by an automatic impulsion and imaginary conceptions may, beyond the aberrative sphere, reason and act in a sane manner. In this class must be ranged those undecided forms called mania without delirium, reasoning mania or madness, reasoning monomania, etc. On this subject the author quoted three instances in which he endeavoured to show the difference between these cases and monomania; a difference characterised, according to him, 'by the logical faculty exercising itself simultaneously to the advantage of both normal and maniacal manifestations.'

October 5. *False Abscesses of the Bones, and the Neuralgic Form of Osteitis which accompanies them.*—M. Gosselin read a paper on this subject. Since the thesis written by M. Cruveilhier, it is generally agreed to assign the interepiphysary cartilage and pain at the seat of these abscesses as the clinical characteristic. This sign is correct; but the cartilage is not always the seat of pain. According to M. Gosselin it exists, sometimes higher, sometimes lower, in the joints of juvenile osteitis, termed epiphysary. They are almost always the signal of an anterior affection. The pain is far from being characteristic. M. Gosselin quoted four cases in which, as there was a painful affection of the extremities of the long bones, trephining was performed without any pus being discovered. Therefore, added M. Gosselin, pain does not always denote the presence

of an abscess; these are false abscesses, constituted by a cavity not containing liquid pus, and situated in the centre of an old ossifying osteitis. These false abscesses are neither the seat nor the cause of pain, which is due to neuritis by propagation. Something in this case goes on analogous to what is met with in neuralgia consecutive on dental caries. We must not, however, give up trephining, which is indicated, for it is not known if there is or is not pus. There is no danger in performing it; it has an almost certain effect on neuritis of bone.

Vertigo.—M. Piorry read the first part of a memoir on vertigo, followed by some considerations on migraine and other *neuropallies* (nervous vibrations). Vertigo has always been referred to cerebral disturbances, notably to congestion. This explanation is incorrect; the origin lies in the eyes (*visalgia*), whence spring morbid nervous vibrations (*neuropallies*) which affect either the nerves of the forehead or those of the stomach ("vertigo a stomacho laeso") or those of the limbs, when they give rise to the convulsions of hysteria, epilepsy, hydrophobia, etc. These initial ocular disturbances constitute true visual hallucinations. It seems as if objects were turning round and round, and that they are going to be touched, but the intelligence is not affected. The same facts are observed in migraine; the patient first feels a sensation as if all objects placed near him were out of their places; then the eyeball has involuntary vibratory movements, and at the end the eye is congested. Pain takes its rise from the eye to affect the occipital and frontal nerves and the stomach, where it brings on nausea. The nervous disturbances always correspond with the eye affected, but they may leave that eye and affect the other. Migraine is, therefore, only a vertiginous irisaigia. Something of an analogous character goes on in irisaigia. With regard to treatment M. Piorry recommended, as a preservative against it, not to fix the eyes too long and too fixedly on the same object, especially if it be luminous. As soon as the vertigo is felt the eyes should be closed, and the patient should lie down motionless in darkness. Cold water, or an opiated liniment, should be applied to the eyelid as an adjuvant. We may also work through the stomach, and administer bicarbonate of soda in large doses. If the spleen is enlarged, quinine or extract of barberry should be given. M. Leroy de Méricourt maintained that vertigo always originates in disturbances of the sight; it is thus that sea-sickness is observed in blind persons and persons asleep, in which visual disturbances cannot be concerned.

ACADEMY OF SCIENCES IN PARIS.

August 9. *Monobromated Camphor*.—M. Clin read a note on the preparation of crystallised monobromated camphor. M. Bourneville also read a paper on some points of the therapeutic and physiological properties of monobromide of camphor, of which an abstract will be found in the LONDON MEDICAL RECORD for October, 1875, p. 593.

August 30. *Action of Pepo Vulgaris as a Tannicide*.—M. Herkel read a note on the active part of the seeds of the pepo vulgaris, employed as a tannicide. As it is not rightly known what is the part of the seeds which acts upon the worms, the writer examined the different parts of which it is composed. The seeds, deprived of their perisperm, do not act, whilst the corresponding portion of the endopleura produced an excellent result, even in small

doses. This endopleura contains a resinous substance which is dissolved if castor-oil be previously given, and it is probably to this latter substance that the pumpkin seeds owe their tænicidal property.

August 30. *Malignant Pustule*.—M. Declat presented a note concerning eight new cases of cure of malignant pustule by carbolic acid and carbolate of ammonia.

Bankoul Oil.—M. Heckel communicated his researches on Bankoul oil. This oil is less purgative than castor-oil, and rather more so than oil of sweet almonds; at least 80 grammes of it are requisite to obtain two or three evacuations, and even then the action of the bowels is not regular.

Coagulation of the Blood.—MM. Mathieu and Urbain presented the results of their experiments on the part played by carbonic acid in the spontaneous coagulation of the blood. The slight coagulability of the blood saturated with chloride of sodium or exposed to low temperatures would, in their opinion, be only caused by the weaker solubility of the carbonic acid under these conditions. Similar experiments made with lime water give the same results. The writers, therefore, maintained their former conclusions; carbonic acid is the cause of the spontaneous coagulation of the blood; and during life the fibrine dissolved in the plasma is not coagulated, because the carbonic acid gas, like the oxygen, is combined with red corpuscles.

Histology of the Striated Muscles.—M. Rongon read a paper on the ultimate elements which can be arrived at by the histological analysis of the striated muscles. Numerous experiments undertaken to decompose the muscular fibrillæ into their elements demonstrated that they are very thin discs, animated by Brunonian movements, and which contract probably in the same manner as the sarcodes.

August 20. *Treatment of Uterine Deviations*.—M. Abeille read some cases of cure of uterine deviations by subvaginal uterine myotomy by the actual cautery. He credited himself with having obtained sixty-five successful cases out of seventy-one anteversions or retroversions, and a manifest improvement in the six other cases.

Pathology of Glanders.—M. Rénoul presented a note on the anatomical lesions of acute or chronic equine glanders. If glanders by its lesions shows any analogies with tuberculosis, these analogies are at least somewhat remote. Purulent infection is more like the disease in question. From the anatomical point of view pyæmia, glanders, tuberculosis, and syphilis, form a natural group; all these infectious diseases have as their anatomical characteristic the production of inflammations arranged in nodules and showing a marked tendency to caseification; they all spring originally from the impregnation of the animal economy by a more or less recognisable virulent agent. This community of origin in connection with the singular similarity of the anatomical lesions brought on by them is not the least interesting point of their history.

MEDICAL SOCIETY OF BERLIN.

July 14. *The Action of Croton-Chloral*.—Dr. O. Liebreich made a communication on this subject. More extended researches and observations had, on the whole, confirmed the opinions which he had formerly expressed, especially as regarded the difference between the action of croton-chloral and that of chloral-hydrate. The latter drug, as may be

concluded from experiments on animals and observations on man, produces first anæsthesia, then paralysis of the heart's action, and death, which cannot be prevented by artificial respiration. Croton-chloral acts quite differently. If some be injected under the skin or into the stomach of a rabbit, anæsthesia of the head is very rapidly observed, the eye becomes quite insensible, while the lower extremities show reflex action; then there follows a sleep-like state, without reflex action, and not until nearly the end does slowness of the breathing and pulse set in. After death, the right ventricle is found empty, the left full. That there is no paralysis of the heart here, is shown by the fact that the animals can be kept alive for a long time by artificial respiration, especially in summer; in winter, the lowering of temperature is injurious. The course of the phenomena is also quite another than with chloral-hydrate. Observations on man agree with the experiments on animals. Dr. Liebreich gave croton-chloral to a very restless insane patient in Dr. Levinstein's asylum. In ten minutes he sat quietly on a chair; his eyes did not react; the muscles of the extremities retained their tenacity, the pulse and respiration were unchanged, and in an hour the action had passed off. It had acted in a similar way in several other observations on man. Dr. Liebreich had expressed the theoretical supposition that the action of croton-chloral depends on the formation of dichlorallylen. If croton-chloral be treated with alkalies, a substance containing chlorine, insoluble in water, is produced, which, if inhaled, produces the same symptoms as croton-chloral. The therapeutic use of croton-chloral had corresponded in many cases to the results obtained by experiment. Dr. Liebreich had used it with good effect in severe neuralgic affections of the head. He related especially the case of a tobaccoconist, in whom the supraorbital nerve had been divided, but without effect for neuralgia. The patient was so tender, that, being troubled with a constant discharge from the nose, he was afraid to use his handkerchief. After one dose of croton-chloral, the tenderness ceased. A similar effect occurred in other cases. The remedy, however, is only palliative; for the absence of pain lasts only a short time. The medicine is well borne by the stomach. It has been used successfully in England. On the other hand, Dr. Herr von Mering has stated that he only found a state resembling intoxication to be produced by the action of croton-chloral; but he gave a mixture which contained three times as much of rectified spirit as of croton-chloral. An antagonistic action may be produced by alcohol, especially in cases attended with exaltation and violent irritation. Herr von Mering had also made a theoretically interesting observation. He had found that, after the administration of chloral-hydrate, as well as of croton-chloral, a substance containing chlorine appeared in the urine along with another unknown substance, which he did not find after the use of chloroform or of dichlorallylen, and he therefore concluded that Dr. Liebreich's theory was incorrect. But Dr. Liebreich did not think that his theory should be set aside on this ground. When mixed with blood, chloral yields chloroform; and when chloral passes through the blood, there must always be at least some that is not changed into chloroform. In concluding, Dr. Liebreich alluded to the experiments of Hermann and a lady-pupil of his, which were supposed to contradict his views regarding the action of trichloroacetic acid. When trichloroacetic acid is treated with

soda, chloride of sodium and formic acid are produced. Pure trichloroacetic acid acts as a calmative, not as a hypnotic, through the constant slow formation of small quantities of chloroform.

July 28. *Tumour of the Brain*.—Herr Hirschberg related the case of a man, aged sixty, in whom there was total defect of the right half of the field of vision in each eye, although the unity of vision was normal and the retina and papilla were intact. Aphasia, right hemiplegia, and death soon followed. The necropsy discovered a vascular gliosarcoma of the size of an apple in the left frontal lobe, and thinning of the left optic tract. The author showed the diagrams of the field of vision, and the preparation, which tended to support the view of a semi-decussation of the fibres of the optic nerve in the human chiasma. He also showed the brain of a rabbit one year old, in which he had extirpated the left eyeball a few days after birth, and in which the atrophy of the left optic nerve and tract showed that in animals with a limited field of vision there is a complete crossing of the fibres of the optic nerve in the commissure. Herr Remak asked what was the state of the function of the olfactory nerve. It had been stated by American authors to be interrupted in cases of right-sided hemiopia, aphasia, and right hemiplegia. Herr Hirschberg replied that no special examination of the sense of smell had been made. In reply to a question from Herr Landsberg, he said that not much fluid was found in the cerebral ventricles.

Extirpation of the Larynx.—Professor von Langenbeck described a case, the history of which was given at page 509 of the LONDON MEDICAL RECORD for September.

REVIEWS.

Diseases of the Female Sexual Organs. By Professor CARL SCHRÖDER. Being vol. x. of the *Cyclopædia of the Practice of Medicine*. English Edition. Edited by ALBERT H. BUCK, M.D. Pp. 575: illustrations, 147. Sampson Low and Co. 1875.

Although much has been done of late to advance the art of gynecology, too little attention has been devoted to the more scientific or pathological, as well as physiological, aspects of the question. This has doubtless led to much confusion, and brought discredit upon the department. Men have ranged themselves in opposite camps, promulgating certain theories and expressing their belief in various dogmata, apparently seeking for triumph more than for truth. Whilst one authority considers inflammation as the starting-point of nearly all uterine disorders, another declares as boldly that patients suffering from uterine symptoms are almost universally found to be affected with flexion, or alteration in shape, of the uterus, which flexion shows a marked tendency to perpetuate itself, and at the same time keep up a condition of chronic inflammation. Other theories of morbid ovulation, uterine irritation, and subinvolution, are entertained by others equally worthy of consideration. Between these various theories the difficulty is to decide; and though much has been written to prove the one and disprove the other, we are still left in doubt, and it is only by observing carefully, and dealing with facts in an impartial and liberal spirit that we can ever hope to settle the question and advance the scientific basis upon which all practice must ultimately rest.

To the Germans especially, during the present century, must we give credit for the patient laborious investigations that have been made in uterine pathology. The names of Klob, Kiwisch, and Waldeyer will be familiar to all. Schröder, the author of the present volume, has also done good work; but it is a question whether, in an undertaking like the present, intended to be international, it would not have been better to associate some other names with that of the author, and not give him the invidious distinction of being the only and sole contributor, who is responsible for an entire subject. Thirteen of the other volumes have many to divide the honours of authorship; one only, on diseases of the skin, is undertaken by Professors Rindfleisch and Von Ziemssen alone.

We are led to make these remarks from the unequal manner in which the subject has been handled. The sections treating of malformations and other pathological data are far more complete and valuable than the clinical or practical portion of the work, which is in many cases very meagre and very unsatisfactory. The treatment of acute vaginitis, pp. 493-4, occupying seven lines, is an instance. In fact, as a guide to practice, the work is deficient in many important details. The author depends mainly upon stating his own impressions, and does not seem to regard the opinions of others as worthy of being more than briefly alluded to, not even discussed, and seems to be more familiar with the results of disease as evidenced *post mortem*, than he is with the clinical details of treatment.

In his effort to make the work as complete as possible, he has been forced to draw upon his imagination for what in one instance at least will be regarded by many as a purely imaginary condition—hypertrophy of the uterus, *i.e.*, an equable increase in size and number of all its constituent parts—not due to subinvolution or inflammatory action. He admits that it is a very rare pathological condition, but still devotes over three pages to its consideration. 'The description of the symptoms is necessarily drawn rather from analogical deductions than from personal observation,' p. 74.

The author, in speaking of the various modes of examining patients, advises that 'the lateral position for the purpose of digital examination should be abandoned; the dorsal position is the only one in which conjoined manipulation is admissible.' In this we agree to only a limited extent; the lateral position is unquestionably far less objectionable to the patient, and is, in many respects, the most convenient for the employment of the uterine sound as also of the speculum, whether it be Sims's or Ferguson's. The author admits, in speaking of the dorsal position, that an examination with the speculum is exceedingly inconvenient; and to obviate this difficulty, in place of turning the patient on her side, suggests that a special couch must be prepared; this we regard as perfectly unnecessary.

He very properly lays much stress upon the importance of conjoined manipulation; and for this to be carried out thoroughly, there is no doubt that the dorsal position is by far the best. But a bed or couch is all that is needed; an examination-chair is an unnecessary refinement.

In examining with the uterine sound, he begs us to remember that 'the fingers are holding an exploring instrument which is to seek an already existing canal, and not to bore a new one.' He advises using it only 'when some especial, not otherwise ob-

tainable, information' is expected to be derived from its employment; and points out the dangers attending its employment.

The chapter devoted to malformations of the uterus is elaborate, its value being increased by the diagrams. It is evidently a subject congenial to the author's taste, and contains much that will be interesting pathologically.

We are inclined to think that the subject of hypertrophy of the cervix uteri has been worked up to an almost unnecessary state of refinement; its supravaginal, median, and infravaginal enlargement being more evident in the numerous diagrams accompanying the description than ever exist in practice.

In speaking of acute endometritis, we are told that 'usually there is no need of any special treatment' (p. 128). Further on, in giving the treatment of the chronic form, he tells us that 'in the first stage of the disease—clearly the acute—mere scarification of the vaginal portion may avail to end the whole process.'

'Many gynecologists have maintained that displacements, forward and backward (of the uterus), occasion no symptoms at all, and that the manifestations of disease in such cases are always owing to complications, especially to inflammation of either the mucous membrane or the parenchyma of the uterus. Even if this view be correct, yet it does not follow that it is irrational to treat the abnormal positions as such; for it may most properly be maintained that the displacements easily lead to inflammation of the uterus, and that the natural way to avoid this result is to correct the deviations. It is then desirable, even from this stand-point, to treat the displacements when existing without symptoms.'—P. 171. Conflicting theories (and consequent modes of practice) are still entertained on this subject. The author's views are here given *verbatim*.

Nearly thirty pages are devoted to the description of fibroids of the uterus. The various methods of attempting to arrest their growth by the hypodermic injection of ergotin are very briefly discussed; the author apparently justifying his brevity by the statement that 'all the means recommended usually fail, and we have no internal treatment from which, in any individual case, we are justified in expecting good results, with the least degree of certainty.'

The removal of fibroids through the vagina occupies but two pages; and considering the marked success that this method has met with of late, we should have expected in a work of this kind a more extensive and minute description of the mode of operation, its risks and difficulties.

'Respecting cancer: in the first place we declare that we neither separate the malignant papillary tumours from carcroids, nor the latter from carcinomata.' Waldeyer's views are accepted as correct; the origin of all forms of cancer being referred to the true epithelia. They are thus sharply defined from the sarcomata, which are pure connective-tissue tumours. According to the preponderance of either the connective-tissue framework or the nests of cancerous epithelium, the harder forms—scirrhus, and the softer—medullary cancer, are distinguished. He advocates operative interference 'even where we cannot hope to remove all the diseased tissue,' and does not agree with Spiegelberg that the depressing influence of the operation is greater than the advantage gained by it. Still better results have been attained by the after treatment with bromine, for in this way the chances of radical removal are improved, and, in any event, the local healing takes

place with wonderful rapidity. Chloral, too, will often procure a quiet night's rest,' is all that is mentioned of this valuable local and internal remedy.

Sarcoma of the uterus he agrees with Waldeyer in regarding as a pure connective-tissue tumour. It occurs in two forms, sarcoma of the mucous membrane and of the parenchyma of the uterus, and is found at every period of life from puberty onward. Recovery may occur if an operation can be performed through healthy tissue. The course of the disease is much slower than in carcinoma.

In speaking of dysmenorrhœa, the author 'excludes ovarian; the pains in the ovaries having nothing about them characteristic of menstruation as such.' 'Ovulation has an etiological significance in connection with perimetritis, but not with dysmenorrhœa. Nor ought we to include under the head of dysmenorrhœa those pains accompanying the period, and which are commonly designated as congestive dysmenorrhœa; for in these cases the regular symptoms of uterine disease are only intensified by the menstrual congestion.'

The differential diagnosis of ovarian cysts or cystomata in their various stages is fully and clearly given. Allusion is made in the text to various important cases, both English and foreign, where the diagnosis was obscure, as throwing light upon similar cases. The whole subject is well worked up, and is most exhaustively treated. Ovariectomy in all its details, and in all its various methods of procedure in dealing with the pedicle is fairly discussed.

The index is one of the least satisfactory parts of the book, and is practically of little avail. The arrangement is complicated and unsatisfactory.

Although the work is one in many respects of much merit, it will not compare with our best English treatises on the same subjects as a guide to practice. The plan of the work is more adapted to supply the wants of the pathologist than the requirements of the practitioner.

The science of gynæcology has been too exclusively considered to the detriment of what is equally important, the art of gynæcology.

Syphilitic Lesions of the Osseous System in Infants and Young Children. By R. W. TAYLOR, M.D., Surgeon to the New York Dispensary, Department of Venereal and Skin Diseases, and Physician to Charity Hospital, New York. William Ward and Co., New York; Sampson Low and Co., London.

The whole subject of infantile syphilis has been apparently so thoroughly worked out in all its varied aspects, and such comprehensive monographs have been written upon the disease, that any further discoveries of importance would be deemed in the highest degree improbable. Yet the standard works give little information with regard to lesions of the osseous system in congenital syphilis, except that they are extremely rare. This statement has been generally acquiesced in, and small attention paid to the point. Ranvier was apparently the first to trace out the pathological processes of syphilitic disease of the bones in children; but the earliest systematic description founded on the actual observation of a considerable number of cases was supplied some years later by Dr. Wegner, of Berlin. In 1870, Dr. Wegner published an account of the microscopic appearances observed in lesions of the bones met with in twelve cases of infantile syphilis, in which he showed that the pathological processes

were distinct, and further declared that such lesions were not rare, but tolerably constant. These observations and statements were subsequently confirmed and extended by Professors Waldeyer and Kobner in Germany, and later still by Parrot, Violet, and Poncet, in France. By all these authors, however, the subject has been treated chiefly from a pathological point of view, Parrot alone dealing with the clinical aspect of such cases, and that in a very partial manner.

The literature of the subject has hitherto been wanting in this special element; and, indeed, there has been no work dealing with the whole question of the bone-lesions of infantile syphilis in a complete and comprehensive manner. Dr. Taylor has given a very able contribution towards meeting the deficiency; but the reliable materials available are yet too limited to permit any authoritative definition of the subject.

The foundation of the treatise consists of fourteen cases which have been under the author's personal observation, with the addition of a large number of others collected from various sources. The data thus brought together appear to include all the observations which have been recorded, and the collection is sufficiently comprehensive. The cases gathered abroad are, however, not equally satisfactory, some being assumed to be syphilitic on slender and imperfect evidence.

The fourteen examples observed by Dr. Taylor himself are, on the other hand, nearly all of an unexceptionable kind. In every instance one or both parents were positively ascertained to be syphilitic, and in all but two cases the children bore unmistakable marks of the disease, such as the specific eruption and catarrh. In all but four cases (in one of which the disease was acquired) the children were between two and three months old, *i.e.*, the age at which, as a rule, the external signs of congenital syphilis are first developed.

The treatise is arranged in a very systematic manner, and the subject discussed in minute detail. A separate section is devoted to the lesions of each bone or set of bones, to the various consequences which result, to the pathological anatomy, the diagnosis between the bone-affection of syphilis and that of rickets, to treatment, and numerous other points of interest which arise in a thorough examination of the question in all its bearings.

The most striking and frequently occurring changes are found in the long bones, at the junction of the epiphyses with the diaphyses. The bones most frequently affected are the radius and ulna, and of these the distal in preference to the upper ends. The swelling may not be visible to the eye, but if the tips of the fingers be passed along the shafts, there is encountered, just at or above the commencement of the epiphysis, a quite abrupt elevation, which is found to encircle the bone or bones. Usually this swelling can be felt on all the surfaces, except that which is in combination with its companion bone. The enlargement, or swelling, may be limited to the portion of bone which corresponds to the ossifying layer between the diaphysis and epiphysis, or may extend further and merge into an expanded epiphysis. If both radius and ulna be affected, there appears to be also an union of the two epiphyses, as if the two bones were soldered together, so that the usually well defined furrow between them cannot be distinguished. No impairment of pronation or supination of the limb has, however, so far been observed.

The swellings may be symmetrically developed on both bones of both arms, or both bones of one arm may be affected, or one bone of both arms, or one bone of one arm only involved. The upper epiphyses are less frequently affected than the lower, and swellings there may, or may not, co-exist with similar swellings of the distal ends. Corresponding lesions are met with, but less commonly, on the other long bones, on the clavicle, sternum, ribs, bones of the wrists and ankles, the phalanges, the bones of the skull and face. The period of development of the swellings on the various bones has been ascertained with tolerable accuracy to be from two to six weeks, and when multiple they usually appear synchronously and run the same course. In some cases which have not been submitted to treatment, a second crop of swellings has been observed. These appeared within a year of the first series, and usually at an interval of about three months. The course of these syphilitic enlargements varies according to the original severity of the affection and its modification by treatment. In favourable cases resolution takes place, in others degenerative changes set in. The former leaves behind no perceptible impairment of the structure of the bone or neighbouring parts. The latter may be limited simply to a destruction of the superficial portions of the swellings to a greater or less extent, or they may be so severe as to involve, in the case of the long bones, the whole diameter of the swelling in destruction or liquefaction; in which case the epiphyses become separated from the diaphyses.

In the superficial forms the swelling opens and discharges a thick brownish secretion, containing leucocytes, granular matter, and a few myeloid cells, but at first usually free from pus. Ulceration goes on until it occupies a space corresponding to the necrotic spot on the bony tumour, having no tendency to spread beyond these limits, attaining a size of half an inch to an inch and a half, and of a round or oval figure. The sore resembles very much an ulcerating gumma of the skin, but the fact that the base of the ulcer is bony tissue distinguishes it from a mere lesion of the derma.

The separation of the epiphysis from the diaphysis in the more extensive form of degeneration has been found *post mortem* in many reported cases, but has been recognised during life only in two cases reported by Dr. Taylor.

In the fatal cases recorded by others it was found that the bones and tissues about the joints had become disorganised, the epiphyses extended, and the limb left in a state of permanent deformity. But in Dr. Taylor's cases the detached segments reunited, the process being described as effected by the formation of a bony tube under the periosteum for some distance up the shaft. This, acting as a splint, supports the parts and keeps them in position, and as the softened morbid tissue beneath is absorbed or extruded, bony formations jut inwards between the two detached segments; then, as healthy nutrition is developed in them, the two become gradually welded together, so that eventually hardly anything abnormal can be detected in the parts.

The morbid changes observed microscopically in the long bones are, first an increase in the width of the ossifying layer of cartilage or 'couche chondroïde,' which is less even and regular than usual, and its cells more abundant. In the second stage the morbid changes—which Dr. Taylor gives in detail—may be summed up as increased proliferation of car-

tilage-cells, premature sclerosis of the intercellular substance, formation of bone in the form of processes beyond the normal layer, and delayed bone-formation elsewhere, *i.e.* irregular ossification, premature in one spot, retarded in another.

The third stage shows general enlargement of the epiphysis, with thickening of the periosteum and perichondrium. In the layer nearest the bone are seen nucleated cells, spindle-cells, and granular detritus, the layer consisting in fact largely of granulation-tissue. This tissue is found at the end of the shaft in great abundance, and follows the vessels into the medullary spaces. These appearances are very imperfectly shown in a wood-cut which accompanies the description, the value of which would be greatly enhanced by a better illustration.

In the flat bones the lesion appears to be a periostitis, closely analogous to that found in the acquired syphilis of adults.

Among the most important and interesting sections of Dr. Taylor's work are those which treat of the relation between rickets and congenital syphilis, and the diagnosis of the enlargement of the extremities of the long bones, met with in one disease, from the similar condition in the other. The author is of opinion that there is no specific relation between the two affections; but that where rickets appears as a sequel of syphilis, it is simply a result of the cachexia induced by that disease—not a direct product of the syphilitic poison. There can be no doubt that the rickety condition does frequently supervene in children suffering, or who have suffered, from congenital syphilis. But in such cases it does not come on during the active evolution of the syphilitic lesions in the integument, but later, and is like the similar condition which may follow chronic diarrhoea, or other drain on the system, the result merely of imperfect nutrition.

The diagnosis of the osseous swellings in syphilis from those of rickets may usually be arrived at from the general symptoms and history of the case. Those of syphilis, moreover, are developed almost invariably in the first few weeks of life, while rickets comparatively seldom appears until towards the close of the first year. In rickets, again, the bone affection is much more general, the skull and ribs rarely or never escape; while in syphilis the swellings affect a certain number of bones only, and the cranium and ribs are seldom implicated. All these points, and many others, such as the diagnosis from rheumatoid arthritis, scrofulous periostitis, etc., Dr. Taylor works out, with a minuteness which it is impossible to follow here.

The treatment he advocates, it need hardly be said, is mercurial, with local applications to the parts where surgical interference becomes necessary. Medication of the child through the mother is condemned as utterly ineffectual. Altogether, the treatise will well repay careful study. It contains honest and original work, and a very thorough exposition and examination of what has been previously written on the subject. W. B. CHEADLE, M.D.

On Stricture of the Male Urethra, its Radical Cure. By F. N. OTIS, M.D.

In this interesting paper, Dr. Otis informs us that he has examined more than 100 urethrae with regard to the size of the urethra in relation to the flaccid penis, and he has found a constant relation between the circumference of the flaccid organ and

the capacity of the urethral canal. When the circumference of the former was three inches the circumference of the latter was thirty of the French scale.

3½ penis	.	.	.	=	32 urethra.
3½ "	.	.	.	=	34 "
3½ "	.	.	.	=	36 "
4 "	.	.	.	=	38 "
4½ "	.	.	.	=	} 40, or more.
4½ "	.	.	.	=	

The measurements were made by the urethrometer, for in a considerable majority of urethræ examined the meatus was contracted, either congenital or from inflammatory changes. By means of the instrument and the metallic bulbous sound a thorough exploration of the urethra may be made, and in any given case the number, size, and locality of the strictures determined. He feels sure that a true stricture always and of necessity completely surrounds the urethra, and that it always forms a resilient band.

Dr. Otis believes in the true curability of stricture, and considers there has been a very curious and important oversight in the investigation of the subject. 'The mechanical relations of the stricture to the urethra have not been considered.' Strictures have been dilated or rapidly distended, or divulsed or divided, up to a purely imaginary standard (no. 9 of English scale, no. 21 French). In his opinion, complete freedom from stricture can only be demonstrated by the easy passage of a bulbous sound of a size fully equal to the normal calibre of the present-urethra.

To ensure reasonable expectation of cure, the stricture or strictures must be completely divided; and this cannot be with certainty accomplished without a knowledge of the normal urethral calibre. This must be first determined by the urethrometer or by measurement of the flaccid penis. Whether dilatation, divulsion, or division be practised, the operation must be carried far enough to completely rupture or divide every constricting fibre, or subsequent recontraction is certain. He says neither divulsion alone nor simple urethrotomy is capable of effecting this with any certainty. It requires a combination of these two methods to accomplish the desired result.

In ordinary stricture, he advises the use of his improved dilating urethrotome. After this has been withdrawn a full-sized bulb should be passed, to institute an examination for results. If any fibres of stricture be then detected, the operation must be repeated at the contracted point until perfect freedom to the passage of the bulb has been secured. In all his instruments the incisions are comparatively slight. The tension to which the strictures are subjected render them thin, and brings them into a condition to be completely severed by an incision of the least possible depth. If the superior wall of the urethra be always cut upon, and in the median line, hæmorrhage is usually slight and ceases almost immediately.

In certain long-standing dense fibrous strictures, he has sometimes experienced great difficulty in effecting their thorough division, and occasionally had to employ several kinds of cutting and dilating instruments before the desired object was effected.

In all cases of stricture at or near the meatus, Dr. Otis divides them on the inferior wall of the canal and very thoroughly, with a straight bulb-pointed bistoury. The utmost freedom to the passage of the bulbous sound must be insisted on. The after-treatment of this class of strictures requires much more care to prevent recontraction, than of those

in the deeper parts of the urethra. The supervision of the slightest inflammation must be prevented, otherwise a recontraction is likely to ensue. In none of the reported cases has any dilatation been attempted after the healing of the wound made during the operation. The use of sounds subsequently to the operation is simply to separate the cut surfaces, and not for the purposes of dilatation.

Recontraction is due to incomplete division. Strictures of calibres less than No. 18 of French scale must be brought up to that capacity by some other method (gradual dilatation, divulsion, or Maisonneuve's urethrotome) before Dr. Otis's dilating urethrotome can be employed.

Of 100 cases, comprising 203 operations upon 258 strictures, hæmorrhage (we are to infer severe hæmorrhage) occurred in four; prostatic abscess in three; chordee in three; urethritis in two; a diphtheritic state of the wound in three; urethral fever in seven; retention in one case.

Of the 258 strictures, fifty-two were in the first quarter-inch of the urethra; sixty-three in the following inch; forty-eight from 1¼ to 2¼; forty-eight from 2¼ to 3¼; nineteen from 3¼ to 4¼; fourteen from 4¼ to 5¼; eight from 5¼ to 6¼; six from 6¼ to 7¼ inches.

Statistical tables are added to the pamphlet, and these tables show the age; number of strictures; locality of stricture; size of stricture; normal calibre of urethra; condition at date of operation; complications; number of operations; accidents after operation; results and re-examination.

Thirty-one cases were re-examined, and found free from recontraction, and therefore cured; fifty-two were perfectly well when last heard from; four were re-examined on account of return of symptoms after a length of time, and reconstrictions were discovered; five had return of symptoms after long relief, but were not re-examined; in three the result is unknown. Four remained under treatment; three enjoyed partial relief; in one the result was unknown.

Drawings of the ingenious instruments illustrate the pamphlet.

JOHN CROFT.

Typhoid Fever; its Causes and Prevention. Illustrated by the Recent Epidemics in Crosshill and Eaglesham. By EBEN. DUNCAN, M.D., Fellow of the Faculty of Physicians and Surgeons, Glasgow; Surgeon to the Deaf and Dumb Institution.

Dr. Duncan's pamphlet is avowedly written for the public, his object being to awaken public interest to the importance of sanitary work, as he believes that much of the apathy shown about this subject is due to the inability of all but a few to understand the papers written on it. He, therefore, commences his pamphlet with a short account of enteric fever, detailing the usual symptoms, with the order of their occurrence, and concluding this chapter with the statement that, after a careful consideration of the evidence adduced on both sides, he has come to the conclusion that typhoid fever has never a *de novo* origin.

Dr. Duncan is evidently a-head of his time here; few sanitarians will care to come to conclusions so readily on this point. Our knowledge of the ways in which enteric fever spreads must be much larger than it is at present, before we can speak positively on so vexed a question. All we can do now is carefully to investigate each outbreak and if, after a thorough inquiry, we are unable to find a first cause, simply to

leave the matter for the present as unsolved, in the hope that future cases may throw some light upon it.

The epidemic of which Dr. Duncan gives us the history commenced in January, although for some time before this sporadic cases had occurred. During this month the cases were not very numerous, and it was only at the end of February that the numbers began to assume serious proportions. By the end of March 280 persons had been attacked.

It is impossible, in so short a notice as this, to follow Dr. Duncan through all his arguments. It is sufficient to point out that he confined his investigations to—1. The nature of the soil on which Crosshill is built; 2. The atmospheric conditions at the time of the outbreak; 3. The sewerage and its connections; 4. The water-supply; 5. The milk-supply. 6. The influence of contagion by personal contact, and by infected clothing.

After referring to Professor Pettenkofer's views of the way in which enteric fever is produced in Munich, Dr. Duncan states that the fact of Crosshill being built on an impervious clay soil makes it impossible for this district to be affected in the manner in which Professor Pettenkofer believes Munich, with its pervious soil, to be affected.

Without here discussing the truth of Pettenkofer's theory as applied to Munich, it is quite clear that the soil conditions of Crosshill are totally different.

Passing by atmospheric conditions, which throw no light upon the cause of the outbreak, Dr. Duncan shows that particular parts of Crosshill, where the sewerage was specially defective, were particularly free from enteric fever, and he therefore concludes that there must be some other cause for its occurrence, although he admits that this may have been the origin of a few cases.

In considering contamination of the water-supply as a possible cause, he quotes the outbreak which occurred at Caius College, and erroneously states that Dr. Buchanan attributed it to the admission of sewer-air into the water-supply. If we remember correctly, Dr. Buchanan clearly showed in this case that water from a water-closet pipe containing organic matter was sucked up into the water-supply, and he absolutely found organic matter in the small pipe which, passing from the larger water-supply pipe, supplied the trap of the water-closet with water.

There is no doubt, as Dr. Duncan shows, that the water was not to blame at Crosshill, this district being supplied with the same water as others which remained quite free from fever. Dr. Duncan, however, gives us no explanation of his reasons for concluding that no local contamination took place.

Dr. Duncan's inquiry into the milk-supply soon led him to connect it with the outbreak of typhoid. Of sixty-eight cases, he found that sixty-four were in the habit of receiving it from some dairies at Eaglesham. Of the four exceptions one had only come into the neighbourhood within a fortnight, and therefore disease must have been contracted elsewhere.

In two no connection could be traced between the fever and Crosshill; and the remaining patient had been in the habit of taking tea in a house at Crosshill in which a case of typhoid was running its course.

An interesting account of the condition of the Eaglesham dairies follows, and the question how they became impregnated with enteric poison is discussed. The first case occurred in August, 1874, the patient being taken ill in Glasgow and brought to Eaglesham. After this several others became affected, one of them being the grandchild of a

dairyman. This man had a dungstead which drained into an open well, the water of which was used for washing purposes, and this was in communication with a second open well, the water of which was used for washing the milk-cans.

Dr. Duncan may be congratulated for having taken great pains in the investigation under notice, and for having arrived at a solution of the difficulties. His paper is an useful and interesting lesson.

ALEX. COLLIE, M.D.

On Addison's Disease, being the Croonian Lectures for 1875. By E. H. GREENHOW, M.D., F.R.S. Physician and Lecturer on Medicine at the Middlesex Hospital. London: Longmans and Co., 1875.

In these three lectures, delivered before the Royal College of Physicians of London, the author gives a very complete account of the symptoms and pathology of Addison's disease of the suprarenal capsules; and in two appendices are contained, first, the details of thirty-three typical cases of the affection, and secondly, references to 333 cases, either of true Addison's disease or of other affections of the suprarenal capsules, distributed in groups according to their nature.

The first lecture contains a very full and detailed description of the symptoms and morbid anatomy of the disease, which is shown to be due to one particular affection of the capsules, characterised by the infiltration of the organs by an interstitial fibro-nuclear growth of low type, portions of which, with the proper structure of the capsules, undergo caseous transformation; and together with this there is always implication in the morbid process of the neighbouring semilunar ganglia and solar plexus, with the nerves passing from them to the capsules.

The second lecture is mainly critical, and is devoted to the discrimination of true Addison's disease from various other affections attended by bronzing or other discoloration of the skin, which have been erroneously published as cases of Addison's disease; the author also shows that other affections of the capsules, as cancer, amyloid infiltration, fatty degeneration, do not give rise to the symptoms characteristic of Addison's disease. He also points out that bronzing of the skin is by no means the most essential symptom, as it is sometimes not present, and bears no necessary relation to the development of the constitutional symptoms, but may precede or follow these at a considerable interval.

In the last lecture, the author discusses the relation between the morbid anatomy and the symptoms, and comes to the conclusion that the latter cannot be ascribed to the disorganisation and consequent arrest of functions of the capsules themselves, but to the implication of the sympathetic ganglia; and he attributes many of the symptoms of the disease to paralysis of the vaso-motor nerves of the abdominal viscera, and consequent accumulation of the blood in those organs, with corresponding drawing away of the blood from other parts, thus in fact producing a condition of the vascular system resembling that to which the effects of 'shock' are now generally attributed. In this he agrees with Dr. Risel and other observers; but, in opposition to many German pathologists, he considers that the suprarenal disease is always the primary affection, and the implication of the nerves secondary.

In discussing the etiology, he points out the frequency with which it is associated with caries of the

spine, and psoas or lumbar abscess, or follows some sprain or injury to the back, and consequently considers it probable that in many cases the disease is due to extension to the capsules of inflammation of surrounding parts, or is the result of direct injury. With regard to treatment, not much can be expected from it, as the disease appears to be inevitably fatal; though remissions, which may last a considerable time, are often observed. Of actual remedies he seems to find glycerine one of the most useful, and in this he is in accordance with other observers.

The lectures are extremely well and clearly written, and contain a vast amount of information bearing on the subject, collected from all sources, and thoroughly worked up and systematised.

A Study of the Movements of the Unimpregnated Uterus. By ELY VAN DE WARKER, M.D., Syracuse, N. Y., pp. 26. New York, 1875.

In this pamphlet the author gives the results of a graphic manometer in a series of experiments undertaken in order to demonstrate uterine movements. 'It is,' to quote his words, 'an attempt to obtain data having mathematical value, and thus raise many of the questions in diseases of women above the plane of pure speculation and theory.'

The manometer used may be very briefly described as an U-shaped glass tube containing mercury, connected by an India-rubber tube with a water-bag placed in the vagina; the readings are marked off on a revolving cylinder by a pen attached to a float on the mercury in the distal end of the glass tube.

The experiments were made on seventeen women, of whom some were in good health, some affected with uterine or vaginal disease.

Fourteen tracings are given which are interesting to examine; but the briefness of this notice prevents a detailed account of them from being given.

The points most worthy of remark are (1) that respiration movements are accurately recorded, these movements being modified by the position of the body of the subject; (2) that the uterus is not too far off to be influenced by articulation, so that a wave of respiration may be modified (a) by the position of the woman, and also (b) by articulation, so as to leave wavelets produced on its surface. [Query, with improved instruments, might not articulated words be made graphically visible to the deaf?]

The most interesting table is that which shows the different degree of pressure (weight) exerted by the uterus in different positions of the body. We will give one instance as an example. 'No. 3. Vaginal water-bag distended with 3vj. of water. Subject on her back, = zero; sitting, = '6; standing, = 1'1; squatting = '2.'

Now, it seems to us that in the position of the pelvis which a woman's ordinary sitting angle gives, there should be an increase of pressure instead of a decrease, as the pubes and anterior abdominal wall receive less of the superincumbent weight than in the upright posture; but the author afterwards explains that in the sitting posture the subjects leaned forwards, and in the squatting necessarily still more so. None of the subjects experimented on were over forty-four years of age; but it would be interesting to have some observations made on old women at the time when—the lumbo-sacral curve tending to become obliterated, and the vaginal wall to lose some of its sustaining power—the uterus begins to fall. Dr. Van de Warker finds the contractile power of the vagina increases from within outwards,

and its contractility being a measure of its power as a supporting organ, it follows that old age in women that have had many children is a very favourable factor in prolapsus uteri.

We consider the summing up of the practical utility of such a paper as the foregoing to be the demonstration that natural forces producing a given result, normal or morbid, are weaker than we generally suppose—that the production of changes which have pathological importance are not the results of the application of considerable force, or impulses, but an alteration in the balance of, or a prolonged persistence in, the action of normal, and by no means considerable, forces.

The Inflammatory Origin of Phthisis; a Clinical Lecture. By JAMES H. HUTCHINSON, M.D., Physician to the Pennsylvania Hospital. 1875.

In this lecture the author supports Niemeyer's view that phthisis is commonly due to catarrhal pneumonia, and that tuberculosis is secondary to the inflammatory changes. He also agrees with Niemeyer in holding that pulmonary hæmorrhage may be the cause of phthisis, from the irritation set up by the decomposition of the blood impacted in the air-cells. There is nothing new in the arguments he adduces in favour of these opinions.

The subject of the lecture was a man, aged thirty-three, of intemperate habits, without any hereditary or constitutional predisposition to the disease, in whom consolidation and softening of the left apex followed taking cold, with a relapse after a second exposure to cold and wet. The author states that out of seventy-three cases of phthisis which had been under his care in the hospital, fifty-three patients were able to trace back their illness to a definite commencement, and in thirty-one of these this followed upon getting wet or chilled.

Catarrhal pneumonia he considers to be the form of inflammation of the lungs to which persons of debilitated constitutions are especially liable; and except in the very young the inflammation usually extends insidiously from the bronchial tubes to the alveoli, the epithelium of which proliferates and desquamates; these cells may, he says, be found in large numbers in the catarrhal expectoration. He accounts for the apices being the parts of the lung usually affected by the fact that the respiratory movements are naturally much more feeble in them even in health, this comparative immobility being much increased in badly formed chests with weak muscular development. In consequence of this, the bronchitic secretions are apt to stagnate in the upper parts of the lungs, and so cause irritation.

The blocking of the alveoli with epithelium causes arrest of the circulation in the capillaries by pressure, and gives rise to caseation and softening. The greater or less rapidity with which tubercle becomes developed, he thinks, may depend upon the amount of the reactive interstitial inflammation, which causes the formation of fibrous tissue, by which these caseous deposits may become encapsuled; if this take place, absorption of the caseous matter, and consequent tuberculous infection, is hindered.

In the treatment of catarrhal pneumonia, if anti-phlogistic remedies be required, those should be employed which reduce the temperature without depressing the strength. He finds especially useful six or eight grains of quinine daily, either alone or combined with opium and digitalis.

Zoology for Students. A Handbook. By C. CARTER BLAKE, D.Sc. London: Daldy, Isbister & Co. 1875.

In a handy little volume of nearly four hundred pages, Dr. Carter Blake has provided for students an excellently written and very readable account of the animal kingdom. Though it is modestly entitled merely 'zoology,' it is in fact a comparative anatomy also, an enumeration of the leading points of structure of the larger groups. The 'students,' to whom it is addressed, must necessarily be medical students, since the first chapter takes for granted that its reader understands what is meant by the terms 'diaphragm,' 'mammary glands,' 'apophysis,' etc. We think the author has done well to avoid troubling beginners with the more recently proposed classifications of Birds; but we cannot approve of his junction of the Batrachians in one class with the Reptiles, or of his separation of Man in a subclass Archencephala, in which he has, of course, followed Professor Owen.

The union of the Crustacea with the Arachnida is one which some recent observations have done much to justify; but we think that if so large a mass of forms be so united in one great class, the Cirripedia should not be excluded from it.

These, however, are matters of opinion; and the mode the author has followed in these instances, though it is not the one we should have adopted, is not calculated to mar the real value of a book which, we are sure, will be of much utility to a large class of readers.

We regret that the illustrations are not more numerous and of a better character; they certainly are not so good as the matter of the text merits.

PUBLICATIONS OF THE MONTH.

Messrs. J. and A. Churchill have issued this month the first fasciculi of some valuable illustrated books, which will be published in parts. First among these must be ranked Mr. JONATHAN HUTCHINSON'S *Illustrations of Clinical Surgery*. The first fasciculus, Plates I. to IV., price 6s. 6d., contains admirable portraits of cases of Encephalocele, Ivory Exostosis of the Orbit, Rodent Ulcer, and different varieties of Chancre. The beauty and fidelity of the illustrations are worthy of the highest commendation, and the commentaries are, as might be expected, judicious, learned, and suggestive. This will be a book of great value.—Dr. TILBURY FOX'S *Atlas of Skin Diseases*. Part I., price 6s. 6d. The part contains four large coloured lithographic plates of Erythema and Urticaria, including seven figures. This Atlas will be largely founded on the well-known plates of Bateman and Cullan, completing and correcting their delineations. The commentary is excellent, though perhaps a little too dogmatic and self-important.—We have no other words than of praise for a new work on *Medicinal Plants*, of which Part I. has just been issued by the same publishers. The price is 5s. The text gives a description of the principal plants employed in medicine, and an account of their properties and uses, by Professor BENTLEY and Dr. HENRY TRIMEN. The illustrations are lithographed by Stanhart, from original drawings by Blair, and the whole book, which was one greatly wanted, is excellently conceived and executed.—Mr. WAGSTAFFE'S *Manual of Osteology*, from the same publishers, is illustrated on the plan of Holden's book; the descriptions of bones are very clear and systematic,

but very much condensed. A good deal of attention is given to the mechanism of the bones, a good, and in some degree a novel feature in a work of the kind.

Messrs. Smith, Elder, & Co.'s publications include a volume of Dr. RUMSEY'S *Essays on Vital Statistics*, and others subjects interesting to the students and practitioners of public medicine. Dr. Rumsey's writings have greatly influenced the legislation and formed the public opinion of his age; and almost more than any one he has founded and led the movement towards the cultivation of State Medicine, by which the British Medical Association forced on the Government the appointment of a Royal Sanitary Commission, and laid the foundations of a new department in health legislation. Dr. Rumsey's essays are classic, and should find a place in the library of every statesman, and of every local administrator of health, as well as of sanitary officers.—Dr. KLEIN'S *Anatomy of the Lymphatic System*, No. II., is, like the first part, based on researches undertaken for the medical department of the Privy Council. It describes and illustrates, by plates of singular beauty, the normal and pathological conditions of the pulmonary pleura and the lung proper, as regards its lymphatic system, in health and under the influence of acute tubercular disease.—Dr. CAMPBELL BLACK'S book on the *Functional Diseases of the Urinary Organs*, appears, we are sorry to see, in a second edition. Scientific men do not need such a book; to any others, the perusal of details of the kind here collected must be hurtful. The subject is amply treated in systematic works. And discussions and collections of this kind, although peculiarly attractive to non-medical readers, are, in our opinion, more calculated to do harm than good.—Mr. SPENCER WATSON'S *Diseases of the Nose and its Accessory Cavities* is a totally complete monograph, but somewhat too bulky and undigested. The nose, it seems, has hitherto wanted its 'vates sacer.' Mr. Watson is very painstaking, and has occupied the field very completely. The book includes five plates, and thirty-six wood-cuts. It is a stout octavo of 472 pages. Not only are complaints of the bones, mucous membrane, nerves of sense, etc. treated, but the skin-diseases of the nose have a chapter, and there is a final chapter on the function of smell, in its relation to hygiene, sanitary science, and medico-legal questions.

Dr. LEISHMAN'S recent *System of Midwifery* (Maclehose, Glasgow), appears in a new edition, which is not only revised but cheaper. It sells now for twenty-one shillings; the former price was thirty shillings.

Air and its Relations to Life. By WALTER NOEL HARTLEY, M.D. (Longmans) is a clear and popular exposition of the relations of the atmosphere to man, including the bases of the doctrine of ventilation, and a review of Pasteur's work. The methods of air-analysis are detailed, and the modern discussion of atmospheric germs is clearly rendered.

NEW INVENTIONS.

ALLEN'S IMPROVED TUBULAR BEDSTEAD.

We have pleasure in drawing attention to a great improvement in the manufacture of invalid or hospital beds, which has been made by Mr. Allen of Bristol.

Mr. A. Allen, in his patent bedstead, places the laths along the entire length of the bedstead instead of from side to side; the great advantages of this system being that fewer laths are required, and those few are easily shifted for cleansing or for removing a patient, a more thorough ventilation of the bed is obtained, and, what is of greater importance, the laths themselves in this position possess sufficient elasticity to secure ease and comfort to the patient without the extraneous aid of metal springs. The great saving of expense which the omission of this item alone will effect is at once apparent. The laths themselves are made of pitch pine, which material is said to possess an immunity from vermin, and the construction of the bed necessitates a much smaller number of groves or lath-rests, as the possible harbour of dirt, vermin, or the germs of disease. The frames are made of metal tubing, and the joints are close fitting, so that they are readily cleansed, easily taken to pieces and put together again, and the wear and tear of the bedding is reduced to a minimum. These advantages render these bedsteads specially adapted for use in hospitals, lunatic asylums, and other large institutions, where cleanliness, economy and comfort are of the highest importance. They have been in use in several asylums for some years past, notably in the Kent County Asylum, Bristol General Hospital, and are highly spoken of by Dr. Horace Swete, Dr. H. Bryden, of the Stockport Infirmary, Mr. Thos. Hogg, of the Bideford Infirmary, and others who have been supplied with them.

The London agent for supplying these bedsteads is Mr. H. Craik, of Mincing Lane, E.C.

ARNOLD'S NEW STETHOSCOPE.

An exceedingly ingenious modification of the stethoscope has just been introduced by Messrs. Arnold and Sons, of 35 and 36 West Smithfield, the design having been given by Drs. Reid and Morison, of Canonbury. This form of instrument is alleged by the inventors to possess many advantages over that in ordinary use. Amongst others are: 1. The ease with which patients may be auscultated in otherwise inaccessible positions; 2. The comparative safety from infection; 3. The possibility of carefully regulating the pressure on the chest-pieces, especially in the case of aneurism, blood-vessels, etc., and in

children and sensitive patients; 4. The construction of the ear-peg; 5. The ease with which the observer may use his eye and ear at the same time. The instrument is composed of a piece of silk-covered tubing of an almost uniform diameter, two feet in length, provided with a chest-piece and ear-peg made of polished vulcanite of such a form that it will fit the opening of any ear without entering so far as to cause tinnitus, and hence misleading the auscultator.

The instrument is constructed on sound philosophical and acoustic principles, and gives excellent results. One other very great advantage possessed by this instrument is, that it avoids the necessity of

too close a contact with an infectious or uncleanly patient, and thus to a great extent removes the consequent danger to the operator.

MILLIKIN'S IMPROVEMENTS IN TRUSSES.

Messrs. Millikin, of St. Thomas's Street, Borough, have introduced an important improvement in the mechanism of trusses. The improvement is due to the introduction of a ball-and-socket adjustable screw to the pad of the truss, which is affixed to the ordinary C spring.

This arrangement enables the pad to be readily adjusted to suit varying conditions of the rupture, as the pad can be applied at any angle which may be required, so that these trusses are suited equally to inguinal, scrotal, or femoral hernia.

Messrs. Millikin deserve special praise for the perfection and finish which they have brought to bear upon all their various appliances for the cure and relief of surgical diseases.

QUINETUM.

Mr. Thomas Whiffen, of the Quinine Works, Battersea, introduces to the notice of the profession a preparation of this name, which contains the whole alkaloids separated from East India red bark.

Quinetum is a finely granular, non-adherent powder, of a pale buff colour. The proportions of the various alkaloids present of necessity vary with the sample of bark used. Sulphate of quinetum is a white crystalline body, with a faint pink tinge, greatly resembling sulphate of quinine. It dissolves readily in dilute acids, and the solution exhibits a strongly marked fluorescence.

A preparation corresponding to quinetum has been used for some time in India with marked success, particularly in the hospitals; and it has the advantage of being about half the price of quinine, whilst it is stated to be nearly equal to it in efficiency.

NEW ETHER-INHALER.

This inhaler has been manufactured by Mr. Millikin, the surgical-instrument maker, from suggestions furnished by Mr. Golding Bird. The advantages claimed for it are simplicity and cheapness, as compared with the usual ether-inhalers. The waste of the anæsthetic by evaporation is reduced to a minimum by the fact that the inspired air enters by the aperture at the apex, guarded by a valve opening inwards; and the expired air passes out by that just above the nose, where there is a valve which opens outwards. The mouthpiece includes all, from the

bridge of the nose to the chin, and is so arranged as to be practically air-tight to all faces. The instrument is light; is lined with a waterproof material, and its edge is bound with soft leather, either of which will wash; but, if desired, a thin flannel bag, carrying the sponge, can be inserted, and its mouth

be turned up all round outside the mouthpiece of the inhaler, and so each patient can have the advantage of a clean instrument. It is used, not only for ether, but also for the mixture of alcohol (one part), chloroform (two parts), and ether (three parts). It is designed to embrace some of the advantages of the more elaborate inhalers, and to do away with the waste of the anæsthetic that is always caused where a sponge and towel, or felt inhaler, is employed.

DIETZ'S LAMPS AND STOVES.

The disadvantages inseparable from the use of gas in dwelling-rooms have of late greatly stimulated the manufacture of improved lamps adapted to consume the hydro-carbon oils, as they are termed; as, for instance, Strange's crystal and Driver's petroleum oils. In the first rank of these lamps may be placed the 'Paragon' lamp, patented by Messrs. Dietz and Co., which possesses the advantages of being strong, durable, simple in form, yields an intense light, needs but little trimming, is quite inodorous, owing to a perfect combustion of the oil, and is economical in use. This lamp is constructed on scientific principles, and its essential portion is so compact that it can be put by during the day, and placed upon the most delicate china vase, when in use, without soiling it. It is also adapted for burning in chandeliers, where a multiplicity of lights is desired. Each wick will last, as a rule, a month; the lamp only burns two ounces of oil per hour, and therefore needs replenishing about every twelve hours; the oil will cost one farthing per hour; and the light yielded is equal to twenty-three sperm candles. An ingenious and novel arrangement whereby the lamp can be filled with oil without removing the burner, is another good feature in these 'Paragon' lamps.

An adaptation of the 'Paragon,' called the 'Hurricane' lamp, will be found useful for the farm, stable, cellar, or yacht; it cannot be extinguished by any amount of violent swinging to and fro, nor can the oil in it be spilt.

A stove named the 'Climax,' also patented by Messrs. Dietz, is made in two varieties, and in several sizes. One kind is applicable for heating purposes, and will be found especially useful for the warming of small rooms, and for greenhouses and

conservatories. Another kind takes the form of a clean and portable apparatus, capable of cooking a bachelor's meal, or of producing a hot dinner of several dishes for a dozen persons.

RECENT FRENCH BOOKS.

Published by Germer-Baillière.

- Sarcocèle et phthisie cancéreuse; par le docteur G. M. Picard. In-8. Prix: 1 fr. 50.
- L'Ecole de Salerne, avec la traduction burlesque du docteur Martin, nouvelle édition, revue par Philibert Le Duc, membre de l'Académie de Lyon, etc. 1 vol. petit in-8. Prix: 3 fr.
- De la glycosurie dans le cas d'obstruction totale ou partielle de la veine porte (glycosurie alimentaire de Cl. Bernard); par le docteur L. Couturier. In-8. Prix: 1 fr. 50.
- De l'opportunité de l'anus artificiel, dans les cas de tumeurs du rectum; par le docteur Richard. In-8. Prix: 1 fr. 50.
- Contribution à l'étude des lésions syphilitiques des artères cérébrales; par le docteur Rabot. In-8. Prix: 1 fr. 50.
- Du bruit de souffle mitral dans l'ictère; par le docteur L. Gangolphe. In-8. Prix: 1 fr. 25.
- Des progrès que l'histologie a fait faire au diagnostic des tumeurs; par le docteur Pénier. In-8. Prix: 2 fr. 50.
- Des troubles psychiques qui peuvent se présenter dans le cours de la phthisie pulmonaire chronique; par le docteur Le Mat. In-8. Prix: 1 fr. 50.

MISCELLANY.

MORBID APPETITES OF THE INSANE.—The Journal of *Psychological Medicine* for October contains an article on the morbid appetites of the insane, by Dr. W. A. F. Browne. To show how general are these morbid instincts when there is mental disease, we subjoin the following as the proportions of the different classes treated of in the paper. Out of 355 patients treated in the lower walks of life, 73 were fæcophages, 12 sarcophages, 11 lithophages, and 29 phytophages. Of 155 patients of the affluent classes, 4 were fæcophages, 5 lithophages, and 8 phytophages.

LUNACY IN ENGLAND.—According to the twenty-ninth annual report of the Commissioners of Lunacy, on January 1 of the present year there were on the official books of the Commissioners 63,793 registered lunatics, showing an increase of 1,766 on the preceding year. Of this number, 7,390 were registered as private lunatics, and 56,403 as pauper lunatics. The increase during the year of private patients was ninety-eight, and of paupers 1,668. It is a matter of congratulation to find that the recoveries were 4 per cent higher than they were last year, and 2 per cent. above the average of the last sixteen years, whilst the rate of mortality has remained stationary.

THE PROGRESS OF MEDICINE IN JAPAN.—A communication published in the *New York Medical Record* of October 9 gives a very favourable account of the progress of the arts of surgery and medicine in Japan. By order of the chief surgeon to the Japanese army, a translation of Professor Gross's *Manual of Military Surgery* has been made, and a copy of it forwarded to the author, with a very complimentary letter. The same communication states that small-pox, which for ages has been a terror and scourge in Japan, has been checked by the introduction of vaccination. It is stated that a Japanese physician, aided by his assistants, has within three years vaccinated no fewer than 70,000 persons in the city of Yeddo.

At the last meeting of the Society of Biblical Archaeology, Professor Flower read a paper, 'Some Osteological Notes on the Egyptian Mummy in the collection of the Duke of Sutherland.' The paper contained a detailed report by the eminent osteologist of the condition of the skeleton of the mummy, from which it was shown to have been the skeleton of a man in advanced years, of short stature—i.e., 5 ft. 4 in. The left ulna had been fractured near its lower end at some period long before death; the bones of the trunk and legs showed traces of chronic rheumatic disease, the lumbar vertebrae being partly ankylosed; what teeth remained were in good condition, and the shoulders were distinguished by that remarkable squareness of form which was characteristic of the Egyptian race.

SMALL-POX MARKS A PASSPORT TO HEAVEN.—According to the *Tour du Monde*, the population of Yucatan amounted to 600,000 in 1848; two years afterwards it was reduced to 300,000, partly in consequence of the war with the Indians, and specially through an epidemic of small-pox. In order to avert the return of this terrible scourge, the Government decreed that vaccination should be compulsory; but up to the present time this decree has remained a dead letter. The reason is this: the inhabitants of Yucatan believe that the inoculation marks are the sign by which the Virgin Mary recognises her votaries, and to those, and none other, will she open the gates of Heaven. Consequently the Indians have the greatest horror of vaccination, and even go so far as to cut out the mark in the case of those of their body who have been persuaded to be inoculated.

THE VITALITY OF THE JEWISH RACE.—In the lecture on 'National Vitality,' delivered by Dr. Richardson at Brighton, during the meeting of the Social Science Association, he stated that the natural duration of life, physiologically, was fairly ninety years; it might be more, but not less; that 128,000 persons were living who had nearly attained that age; and that the highest authority in the kingdom had represented that 100 years would not be too long to represent the perfected life. But turning to the solemn fact of the actual standard in the country, it was positively thirty-two years; in our present circumstances only one-third of this period was actually lived. There was, however, an exception to this rule, owing to a difference in the vital value of different races. Though the differences arising from race in our country had not yet been collected, it was found, from the mortalities of other countries, such as France and Prussia, which were nearly the same as those of Britain, that the Jewish race possessed an exceptionally longer life than those around them. Neufville had shown that in Frankfort, while the

mean duration of life in the Jewish community was 49·9 years, that of the other population was 37·7; that a fourth of Jews born lived to be twenty-eight years and three months, while the same number born of the other population attained but six years and eleven months; that during the first five years of life 12·9 Jews died, of the other population 24·1. These figures showed that, though the modern Jews were still living far away from the natural standard of health, they were advanced beyond their fellows even in the midst of many surrounding disadvantages. Dr. Richardson also spoke of the comparative immunity from disease enjoyed by the same people, and referred it to the strict manner in which they examine their animal food, and, above all, to their remarkable temperance—a virtue which is, no doubt, referable to their oriental origin.

THE WATER OF THE NILE.—In the Health Section of the late Social Science Congress at Brighton, Mr. Wanklyn read a paper on the waters of the Nile, showing the amounts of chlorine and of hardness at different periods. The rise of the Nile commences at the end of May, and lasts through June, July, and August, up to about the middle of September, when the decrease continues till Christmas. From Christmas till May the amount is tolerably constant. Just at the time of the beginning of the rise of the waters the chlorine is 1·8 grains per gallon, but at the time when the Nile has attained its greatest size it is only 0·3 grains, and it remains very little above that proportion to the end of the year. In marked contrast with the variableness of the chlorine is the constancy of the hardness. Mr. Wanklyn's explanation is that the storm-water which adds so much to the bulk of the Nile sweeps over the country without penetrating far below the surface, and such water passing over a country long ago denuded of salt could convey but little chlorine. He thinks that the *débris* carried down mechanically by the flood-water contains abundance of finely divided carbonate of lime, so that the storm-water would always be saturated by carbonate of lime. Hence the constant hardness. The water which feeds the Nile, apart from the storm-water, contains 1·8 grains per gallon; and it is the accession of storm-water with chlorine that causes the relative reduction. Similar features will probably be found in other large rivers which have a flood period.

TRINITY COLLEGE, DUBLIN.—There are three professorships in Trinity College, Dublin, which by the School of Physic Act (40 Geo. III., chap 84), become vacant at the end of every seventh year from the date of election; but it is also provided that every professor shall be capable of re-election. The three professorships are those of Anatomy, of Chemistry, and of Botany. The London and Dublin *Gazettes* announce that the least of these will be vacant on January 23, 1876, and that on January 29, 1876, the Provost and Senior Fellows will proceed to the election. All candidates are required to send their names, with the places of their education, the universities where they have taken their degrees, to the Registrar of Trinity College, Dublin, before January 22, 1876, and for further information are to apply to the Rev. Dr. Haughton, F.R.S., Medical Registrar of the School of Physic. The emoluments of the professor consist of 300*l.* a year, for which he is required to deliver, first, a course of lectures on Botany in the Arts School during each of the three college terms. Michaelmas Term commences early in October, and Trinity Term sometimes lingers on until the month of July. Secondly, he has to give a course of not less than forty lectures on Botany in the Medical School, commencing on April 1 and ending on July 1 in each year. As curator of the College herbarium, there is an additional salary of 50*l.* per annum. The professor being his own assistant, the whole work of arranging and sorting this well-known collection, as well as the correspondence incidental to such a charge, falls on the curator. The fees average a sum of about nine guineas a year, as the lectures are free to all students of the University. The present Professor, Dr. E. Perceval Wright, being eligible, is a candidate for reappointment.

CURRY-EATERS, BEWARE !—Dr. Henderson, of Lahore, in a letter to the *Indian Medical Gazette* of August 2, suggests that the jaundiced look which used to be peculiar to old Anglo-Indians was probably due to the quantity of curry they ate, rather than to the effects of climate. He asserts that Anglo-Indians in Upper India do not now acquire this peculiar tint, curry not being now eaten to anything like the extent it formerly was; indeed, scarcely at all, except at the tables of very old Indians. Some papers published by Dr. Garden, in the *Indian Medical Journal*, on 'Disorders of Pigmentation,' first drew Dr. Henderson's attention, he tells us, to the effect likely to be produced by a daily consumption of turmeric, which enters largely into the composition of curry. Dr. Henderson thinks it probable that the turmeric dye will tinge all the tissues of a yellow colour, if eaten daily for a number of years—a view in which he is supported by Mr. C. Wood, officiating professor of chemistry in Calcutta.

UNIVERSITY OF CAMBRIDGE EXAMINATION IN STATE MEDICINE.—The following list was issued on October 14. 'Examined in part I. only, and approved: Simpson, J., M.D. Examined in both parts and approved: Bird, P. Hinckes, F.R.C.S.; Britton, T., M.D.; Carpenter, A., M.D.; Cunningham, J., M.B., C.M.; Drew, S., M.D.; Dunlop, A., M.D.; Earle, B. N., M.B.; Fosbroke, G. H., M.R.C.S.; Harrison, C., M.D.; McBeath, W., M.D.; Mason, H. H., M.R.C.S.; Morison, J., M.D.; Nicholson, E., M.R.C.S.; Phillips, H. H. E., M.D.; Saunders, C. E., M.D.; Steele, S. T., L.R.C.P.E.; Swete, E. H. W., M.D.; Turner, G., L.R.C.P.L.; Underhill, A. S., M.B., C.M. Signed—G. E. Paget, A. W. Barclay, E. A. Parkes, and James Dewar, Examiners. The following form of certificate has been adopted to be given to candidates who pass both parts of the examination in State Medicine:—'Know all men by these presents that . . . having been duly examined by . . . the examiners in that behalf appointed by the chancellor, masters, and scholars of the University of Cambridge, and having approved himself to the aforesaid examiners by his knowledge and skill in sanitary science—to wit, in chemistry and physics, in the causes and prevention of epidemic and infectious diseases, and in the means of remedying or ameliorating those circumstances and conditions of life which are known to be injurious to health, as well as in the laws of the realm relating to public health—is certified to be well qualified in respect of his knowledge and skill aforesaid to fulfil the duties of a medical officer of health, in testimony whereof the Vice-Chancellor of the said University, by the authority of the said chancellor, masters, and scholars, has hereto set his hand and seal.'

MR. FRANCIS GALTON ON TWINS.—Mr. Francis Galton has been instituting inquiries into the subject of twins, 'as a criterion of the relative powers of nature and nurture.' He sent circulars of inquiry to persons who were either twins or the near relations of twins, containing thirteen groups of printed questions, of which the last asked for the addresses of other twins known to the recipient who might be likely to respond if he wrote to them. In this way Mr. Galton had a continually widening circle of correspondence, sufficient to provide him with a number of curious facts, which he has embodied in a paper published in *Fraser's Magazine* for November. The following passage from it refers to the question of likeness. 'One would have expected that twins would commonly be found to possess a certain average likeness to one another; that a few would greatly exceed that degree of likeness, and a few would greatly fall short of it; but this is not at all the case. Twins may be divided into three groups, so distinct that there are not many intermediate instances; namely, strongly alike, moderately alike, and extremely dissimilar. When the twins are a boy and a girl, they are never closely alike; in fact, their origin never corresponds

to that of the above-mentioned double-yolked eggs. I have received about eighty returns of cases of close similarity, thirty-five of which entered into many instructive details. In a few of these not a single point of difference could be specified. In the remainder, the colour of the hair and eyes were almost always identical; the height, weight, and strength were generally very nearly so, but I have a few cases of a notable difference in these, notwithstanding the resemblance was otherwise very near. The manner and address of the thirty-five pairs of twins is usually described as being very similar, though there often exists a difference of expression familiar to near relatives but unperceived by strangers. The intonation of the voice when speaking is commonly the same, but it frequently happens that the twins sing in different keys. Most singularly, that one point in which similarity is rare is the handwriting. I cannot account for this, considering how strongly handwriting runs in families, but I am sure of the fact. I have only one case in which nobody, not even the twins themselves, could distinguish their own notes of lectures, etc.; barely two or three in which the handwriting was undistinguishable by others, and only a few in which it was described as closely alike. On the other hand, I have many in which it is stated to be unlike, and some in which it is alluded to as the only point of difference.' Mr. Galton has a number of cases in which mistakes have been made about twins, and some of these show a great degree of likeness. Here is another interesting passage. 'Among my thirty-five detailed cases of close similarity, there are no less than seven in which both twins suffered from some special ailment or had some exceptional peculiarity. One twin writes that she and her sister "have both the defect of not being able to come down stairs quickly, which, however, was not born with them, but came on at the age of twenty." Another pair of twins have a slight congenital flexure of one of the joints of the little finger; it was inherited from a grandfather, but neither parents, nor brothers, nor sisters show the least trace of it. In another case, one was born ruptured, and the other became so at six months old. Two twins at the age of twenty-three were attacked by toothache, and the same tooth had to be extracted in each case. There are curious and close correspondences mentioned in the falling off of the hair. Two cases are mentioned of death from the same disease; one of which is very affecting. The outline of the story was that the twins were closely alike and singularly attached, and had identical tastes; they both obtained Government clerkships, and kept house together, when one sickened and died of Bright's disease, and the other also sickened of the same disease and died seven months later. In no less than nine out of the thirty-five cases does it appear that both twins are apt to sicken at the same time. This implies so intimate a constitutional resemblance, that it is proper to give some quotations in evidence. Thus, the father of two twins says: "Their general health is closely alike; whenever one of them has an illness, the other invariably has the same within a day or two, and they usually recover in the same order. Such has been the case with whooping-cough, chicken-pox, and measles; also with slight bilious attacks, which they have successively. Latterly, they had a feverish attack at the same time." Another parent of twins says: "If anything ails one of them, identical symptoms nearly always appear in the other; this has been singularly visible in two instances during the last two months. Thus, when in London, one fell ill with a violent attack of dysentery, and within twenty-four hours the latter had precisely the same symptoms." A medical man writes of twins with whom he is well acquainted: "Whilst I knew them, for a period of two years, there was not the slightest tendency towards a difference in body or mind; external influences seemed powerless to produce any dissimilarity." The mother of two other twins, after describing how they were ill simultaneously up to the age of fifteen, adds, that they shed their first milk teeth within a few hours of each other.'

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

ON THE CLINICAL IMPORTANCE OF FATTY EMBOLISM. BY PROFESSOR V. CZERNY, M.D., DIRECTOR OF THE SURGICAL CLINIC IN FREIBURG.*

The prognosis in simple fractures of the long bones is, under the present very complete methods of dressing, so favourable, that it usually does not occur to a medical man that an injury of this kind, without any further complications, in a man in the vigour of life, may quite unexpectedly and suddenly lead to death. The most frequently read treatises and manuals, the most celebrated general surgeons, do not, on account of this rareness, find it worth their while to refer to this most unpleasant complication of the course of a simple fracture. It is then very intelligible that such a case of death should make no small stir among the public. This was the case some time ago in the neighbourhood of Freiburg, where, some days after the burial of a man who had died after a fracture, the authorities ordered the body to be exhumed, and a *post mortem* examination to be made. I am indebted for the following particulars to the kindness of the medical man who had charge of the case.

R. W., aged twenty-four, strongly built, who had satisfactorily gone through his term of military service, was on November 16 buried above the chest by a fall of earth. When he was dug out it was found that his right thigh was broken obliquely in the upper third. The surgeon, who was at once called, applied a bandage, and observed that the patient complained very little of the local pain at the seat of fracture; but much of great difficulty in lying, especially on his back, saying that his breathing was impeded. During the subsequent nights, distressing sleeplessness was the most troublesome symptom. Beyond cold applications, no medicine was used. On November 18, the swelling, which was at first very great, had essentially abated, and a starched bandage was applied, during the application of which the patient was evidently distressed, being able only with difficulty to keep himself in a half-sitting position. On the night of the 20th and 21st, dyspnoea set in, without any inflammatory symptoms or rigors, but with strong symptoms of compression of the brain, which increased in spite of antiphlogistics. He died on November 22.

At the *post mortem* examination made on December 5, the following were the principal appearances. 1. The broken ends of the bone were in normal position. 2. Both lungs were full of venous blood. 3. The membranes, substance, and vessels of the brain were charged with venous blood. The medico-legal report stated that (1) The death of R. W. stood in causal connection with the accident; (2) The pressure

to which he was subjected was so powerful that the thigh must have been bent and then broken, and the thoracic organs crushed; (3) The results of the injury were reduced innervation, disturbed circulation, effusion of blood, total abolition of nerve-power, paralysis, and death.

The reporter acknowledges that the account of the necropsy is rather a description of the circumstances than a scientific proof of the cause of death. He is, however, not to be blamed for this, since, as has been said, the handbooks most in use are silent regarding these cases of sudden death, and, even in very recent reports, the cases have been explained by other complicating injuries, or by affections of the central nervous system (shock, delirium, trismus in rare cases). Other authors seek the cause in alcoholism, diabetes, or some unknown dyscrasia.

It was through the doctrine of thrombosis and embolism that some cases were explained on another material basis. In 1863 Meissner (Schmidt's *Jahrbücher*, Band cxvii.), and 1864 Azam (*Ibid.* Band cxxxi.), collected several cases in which, after relatively unimportant injuries, either sudden death or sudden dyspnoea occurred, which could with more or less probability be explained by pulmonary embolism, as from a dislodged clot of fibrin.

In 1863, Zenker (*Beiträge zur normal. und patholog. Anatomie der Lunge*) and E. Wagner (*Archiv für Heilkunde*, vol. iii.) described fatty embolism of the lungs: the former held it to be of no practical importance; while the latter, observing it to occur most frequently in connection with metastatic abscesses, pointed out a connection between it and these abscesses. In Wagner's first edition the anatomical description was so sufficiently given, that nothing new could since be added in that direction. In his second edition (1865) he expressed the opinion that sudden fatty embolism might indeed give rise to hyperæmia of the lungs, œdema, and death; but he could not adduce sufficient proof.

The first case in evidence was published by F. Busch, of von Recklinghausen's Institute (Ueber Fettembolie, Virchow's *Archiv*, Band xxxv.). By his researches, Busch ascertained that the fat of the broken up marrow, having been taken up principally by the veins, but also by the lymphatics, produced embola in the lungs and caused death. But these important facts were not sufficiently put forward, and were lost in a criticism of Wagner's opinions. This may have been the reason why the article did not attract so much attention as it deserved. Bergmann (*Zur Lehre von der Embolie*, 1863, and Schmidt's *Jahrbücher*, Band cxxxi.) has established by experiment that pure fat, as such, is not capable of producing inflammatory foci in the lungs. Cohnheim (*Untersuchungen über embolische Processe*, 1872) has sufficiently explained under what circumstances fat, when it obstructs the pulmonary capillaries, may produce hyperæmia and even hæmorrhage.

Cases have, indeed, now and then been reported (as by Lücke and Feltz) in which sudden death has been ascribed to fatty embolism; but so rarely, that it must be concluded that physicians have not yet become thoroughly convinced of the importance of fatty embolism. Not a syllable is said on this possibility in works on sudden death after trivial injuries (Verneuil, Bell, Tillaux). Even the abundant material in fractures during the last war has not advanced our knowledge of fatty embolism; although, indeed, Fischer, in his *Kriegschirurgie*, has referred to the importance of von Recklinghausen's

* *Berliner Klinische Wochenschrift*, November 1 and 8.

observations. As far as I can see in the surgical literature of the last war, Klebs alone mentions fatty embolism as occurring during osteomyelitis, and expresses the opinion that it frequently attends osteomyelitis, and is so extensive as to be essentially capable of producing death. It can be confidently affirmed, that fatty embolism has not yet become a fact in pathological anatomy, the importance of which in clinical and forensic medicine has been recognised. The following case may, perhaps, contribute to the removal of this disregard.

Death from Fatty Embolism after Simple Fracture of the Femur.—Josef S., aged thirty-two, a healthy strongly built man, fell, on the afternoon of November 14, 1874, while working as a mason, from a height of fifty or sixty feet, striking against the wooden scaffold once or twice in his fall. He was not unconscious, did not vomit, and was at once brought into the surgical clinic. On examination, the right thigh was found to be much swollen; the bone was apparently broken obliquely, just below the middle; the skin was uninjured. There was shortening to the extent of less than an inch, which was easily removed by simple extension. The limb was placed on a Petit's splint, reaching to the pelvis, and ice-bladders were applied to the thigh; the patient did not complain of any pain. On the chin there was a wound about an inch and a half long, at the bottom of which, for about three-fourths of an inch, the bone could be felt to be laid bare. The wound was washed with a 5 per cent. solution of carbolic acid, sewed with catgut sutures, and dressed antiseptically.

On the 15th I demonstrated the case in my clinic, calling attention to the absolute absence of any expressions of pain on the part of the patient, although the prognosis was quite favourable. The demonstration of abnormal mobility and of crepitation was most easily borne by the patient, although chloroform was not given. An extension-band of adhesive plaster was applied, the thigh fixed in three padded splints, one in front and two at the sides, and the patient was taken back to bed. In my clinical remarks I pointed out that the patient, having been previously free from fever, had this morning a temperature of 39.3° Cent. (102.74° Fahr.), and that in such severe injuries the prognosis must at first be very guarded, as possibly changes of internal organs might occur, which we could not diagnose.

At the evening visit, the patient did not complain of pain; but his pulse and respiration were rather quickened; temperature 39.7° Cent. (103.45° Fahr.). As he could not sleep in the evening, and was restless, a centigramme (.15 grain) of morphia was given to him at 9 o'clock; and, as this dose had no effect, the same quantity was given him shortly before midnight.

Some hours after midnight, the nurse, observing that his breathing was unusually loud and rattling, and finding that she could not rouse him, sent for the two clinical assistants, Dr. Berns and Dr. Deahna. The patient lay in a state of profound coma; his respiration was deep and frequent; the breath-sounds were masked by a loud coarse rhonchus; the stroke-sound was clear, with tympanic resonance. The pulse was 100, full and strong; the pupils were much contracted, and did not react; the face was cyanotic; reflex irritability was lost. Sinapisms, emetics (which were not properly swallowed) and friction with flannel, remained without

effect. Nor did any result follow venesection to nearly eleven ounces, which was performed on account of the cyanosis, with full pulse. His condition now became worse; he had convulsive twitchings of the upper limbs, profuse sweat, and tracheal râles; and died at 7.30, about thirty hours after the accident.

A necropsy was made on November 7, by Professor R. Maier. The body was strongly built. There was no exudation or extravasation in the peritoneal cavity. Both pleural cavities contained a small quantity of clear serum; on both sides were old circumscribed adhesions and thickenings, which had partly undergone watery infiltration. The pericardium contained clear serum. The lungs were voluminous; their surface was marbled, of a reddish white colour, covered with numerous bright red punctiform spots and streaks of the size of pin's heads, often confluent. Both lungs, especially the right, showed patches of a brown-red thickening, but were throughout pervious to air, a large quantity of froth and blood escaping on section. The left cavities of the heart were contracted, and the edge of the bicuspid valve was somewhat thickened. The muscular structure was brown-red, firm. The cavity contained a few masses of loosely coagulated dark blood. The right cavities contained a larger number of coagula, partly white, partly red. The arterial orifices were normal. The skull was thick and the dura mater tense; the longitudinal veins contained much fluid blood. On incision, some fluid escaped from the dura mater. The pia mater presented old thickenings; its vessels were very full, and in them were rather numerous ecchymoses of various sizes. The cerebral substance was firm, and presented numerous puncta vasculosa on section. In the cortical substance were small hæmorrhagic spots, rather numerous in some parts. The kidneys were brown-red, firm. The liver was of a clear brown colour. In the right thigh, the subcutaneous areolar tissue, from the hypogastric region to the knee, was filled with blood, and even the sheath of the ilio-psoas muscle was surrounded with dark masses of blood. The femoral artery and vein were uninjured; the muscles, as far as the point of fracture, were surrounded with extravasated blood. At the fractured part was a large extravasation, on which coagulated drops of fat floated in large quantity. The marrow, for about an inch and a-half above the fracture, was mixed with blood, and firm; and at a greater distance it was softer, and of a reddish-yellow colour. No further lesion was visible.

On microscopic examination, small portions of the lung-substance, removed by scissors from any part of the organ, showed that the smaller arteries and capillaries were filled with clear fluid fat. In many parts the vessels were completely inundated with fat, so that the fatty masses presented a complete injection of the pulmonary capillaries. I could ascertain no essential difference as regarded the fat, between the apex and the base, the surface or hilus of the lung. The fat was perhaps more abundant in the right lung than in the left; although even in the latter scarcely a small portion could be found in which some of the capillaries did not contain drops of fat. At many points, the deposits of fat could be traced into the arteries of the third size from the smallest. Both the microscopic appearance, and the circumstance that small portions of lung could be freed from the deposit by treatment with ether, proved that the embolic masses were fat. In the

alveoli lay detached epithelial cells, more rich in protoplasm and provided with more distinct nuclei than is generally found in the normal lung.

In the smaller branches of the pulmonary artery were found rather numerous coagula, which, after being washed with water, showed distinct drops of fat under the microscope. Fat drops were also found in blood removed from the femoral vein by means of a pipeter; while in the blood of the right ventricle only a few scattered drops were to be found. By the naked eye, fat could only be seen in the extravasation at the seat of fracture.

In the brain, a considerable number of branched embola were distinctly seen within the vessels, generally corresponding to the small ecchymosis.

In the kidneys the vessels of the cortical substance, and especially the glomeruli, were here and there distended with fat. In the liver, there were numerous drops of fat, about the size of blood-corpuscles, in the intra-lobular vessels. I did not see any fatty embola in the substance of the heart.

The fatty embolism of the lungs had reached so high a degree, that it must be regarded as a perfectly sufficient cause of death. It gave rise to disturbances in the pulmonary circulation, which produced œdema and poisoning with carbonic acid. How far the embola in other organs, especially the brain, may have contributed to hasten death, I cannot determine.

The reasons which led me to form the diagnosis of fatty embolism before the necropsy was made, were the following.

1. There were no evident symptoms of injury of internal organs. 2. I believed that shock must be excluded, since the current theories of shock are not in accordance with those cases in which the patients recover from the immediate effects of the violence, then fall into a state of collapse and die, without external cause, after twenty-four hours or more. 3. Poisoning with morphia could be safely excluded, as the first dose of one centigramme had no effect; and even the two doses, given with an interval of four hours, would be far from capable of producing fatal poisoning in a healthy man. There could have been no mistake on the part of the dispenser, as the remaining powders in the box were found to be correctly made up. 4. The symptoms which ushered in the death-agony were distinctly indicative of disturbances in the pulmonary circulation. Embolism by a detached venous thrombus could with presumptive certainty be excluded, as, according to the observations which we possess, its detachment would probably not take place before the eighth day. On the other hand, the experiments of F. Busch have shown that fatty embolism begins within the first few hours after injury of a bone. I could not understand the large full pulse, which appears to have been present until shortly before death; as a small arterial pulse would rather be expected as the result of disturbance in the pulmonary circulation. Perhaps an explanation is given by the experiments of Danilewsky (Pflüger's *Archiv*, Band ii.), who observed retardation of the pulse and increase of the blood-pressure after faradic irritation of portions of the brain; and we must look to the embola found on section of the brain for an explanation of this phenomenon.

These reasons, which I explained in my clinical remarks, make it probable that the first-mentioned case, that of R. W., was also one of fatty embolism.

The question now arises, whether fatty embolism can be detected during life, or, to speak more cor-

rectly, whether it can be predicted that life will be endangered by it. Unfortunately, clinical observations are as yet so scanty, that I must limit myself to merely indicating some points which demand special investigation in the future. In the first place, my patient had a high temperature— 102.74° Fahr. on the morning after the injury, and 103.45° the following evening. Lücke says, that his patient was brought into hospital in a febrile state. As, according to the researches of Bergmann, Stricker and Albert, and Billroth (*Archiv für Klinische Chirurgie*, Band xiii.) pulmonary embolism with chemically indifferent substance as a rule gives rise to fever, and as, according to E. Wagner and F. Busch, slight fatty embolism of the lungs very frequently occurs in cases of fracture, it might be assumed that the slight fever which generally accompanies simple fractures, depends perhaps on this embolism, and that a considerable increase of fever points to danger from this source. That impediment to respiration should be a hazardous symptom, is readily to be understood. Whether the small sensibility to pain during perfect consciousness, observed in my patient and in R. W., is to be regarded as a bad symptom of fatty embolism, I must leave to be determined hereafter by a larger series of observations. Perhaps this phenomenon may be explained, by assuming that the fatty embola in the cerebral vessels interfered with the functional activity of the brain.

As experimenters have hitherto had the clinical aspect of fatty embolism less in view than the anatomical, and the manner in which it occurs, I made some experiments in order to ascertain whether a certain series of symptoms from which the existence of fatty embolism might be inferred, could be observed in dogs. From what has been above said, it will be readily understood that the points to be specially observed were the temperature, the pulse, and respiration, and the reaction of the central nervous system.

As regards temperature, my expectation that a rise of temperature would be produced by fatty embolism of the lungs was not confirmed. In thirteen experiments, from half a drachm to an ounce of pure olive-oil or clear hog's lard were injected at a temperature from 86° to 104° Fahr. into the jugular veins of seven dogs. The injections were in general the more easily borne, the more slowly they were made, and the smaller the quantities injected. A strong hunting dog exceptionally bore repeated injections of five drachms of hog's lard, which were at once injected in a centripetal direction into the jugular vein; and on one occasion it could be concluded with certainty from the symptoms and the ophthalmoscopic appearances, that the fat had partly passed through the lungs and reached the central nervous systems.* So far as a conclusion can be drawn from

* As this experiment is of great interest on account of the embolic hæmorrhages in the retina, I will briefly relate it. Feldmann, a strong hound, had on January 23, 1875, at $3\frac{1}{2}$ P.M., a temperature of 39.4° Cent. (102.72°) in the rectum; respiration quiet, 36; pulse 132; fundus of the eye normal. At 4 P.M., twenty grammes (about five drachms) of hog's lard, at a temperature of 104° Fahr., were inserted into the jugular vein. Soon afterwards he barked violently, moved his fore-feet as if running, there were convulsive extensions of the back and hind feet, he discharged his feces and urine, and was unable to stand. The pulse was retarded; but could not be counted, on account of restlessness. The respiration was much accelerated. At 4.30 P.M., temperature 39.6° Cent. (103.28° Fahr.). The convulsive movements had ceased; the dog lay unconscious. Reflex irritability was present, but was not increased (it was so in some other experiments).—7 P.M. :

experiments on animals with regard to the condition in man, I must relinquish the opinion that a marked increase of temperature is characteristic of fatty embolism.

What may be the reason that lowering of temperature is produced by fatty embolism of the lungs, and raising of temperature as a rule by embolism with starch and powdered charcoal, I cannot determine. It might be thought that the supply of oxygen was diminished through the disturbances in the pulmonary circulation by embolism, and that therefore the oxidation processes in the body were arrested (Cohn, *Klinik des embolischen Gefasskrankheiten*, 1865); or that, through impediment to the circulation, the giving out of warmth to the air in the alveoli is hindered. A preponderance of one or the other factor might produce either lowering or raising of temperature. I therefore am not surprised that other experimenters here and there found a rise of temperature and altered fatty embolism of the lungs. Perhaps the more ready suggestion is, that, when fat is injected, embolism and disturbances of the circulation in the brain are generally produced, and that the regulation of heat is impaired, just as happens in morphia poisoning in the dog, which is often accompanied by a considerable fall of temperature.*

As in the few clinical observations on fatty embolism a rise of temperature was observed, I had still to inquire whether the high temperature did not perhaps favour the production of fatty embolism. But as the melting point of human fat lies between 35° and 43° Fahr., the slight increase of the body-temperature to fever-heat can scarcely assist the passage of fat into the vessels. Thus no conclusion can be drawn from experiments on animals as to a causal connection between fatty embolism and the rise of temperature in man; and the rise of temperature observed in man must have some other ground which does not stand in direct connection with fatty embolism.

temperature 37.5° Cent. (99.5° Fahr.). The dog ran with a tottering gait, and had taken food. The respiration was still quick. Pulse 140.—9 P.M.: temperature 37.7° Cent. (99.86° Fahr.).—January 24, 6.30 A.M.: Temperature 38.6° Cent. (101.48° Fahr.).—11 A.M.: temperature 38.3° Cent. (100.94° Fahr.). In the evening, the temperature was the same; he ate and ran well, but was still depressed. The respiration and pulse were somewhat quickened.—January 25: There was pneumonia of the right lung. The breathing and pulse were much accelerated. In the left eye, especially to the inner side and upwards, the ophthalmoscope showed numerous dark-red, generally round, hæmorrhagic spots with a lighter areola scattered in the retina, raised distinctly above the metallic green tapetum. Their size varied from being scarcely visible to the diameter of the papilla. In the right eye the blood-points were less numerous.—January 27: The hæmorrhage in the retina had become somewhat more extensive.—6 P.M.: temperature 39.4° Cent. (102.92° Fahr.); respiration 40; pulse 140. His general condition was improved.—January 30: The contour of the hæmorrhagic spots was less sharp. The dog appeared to be perfectly well.—February 25: Only very insignificant traces of the extravasation were left. The choroidal epithelium was not changed at these parts; and only a slight turbidity of the retina could be detected. The dog was in good health. In all my experiments, I have only seen these embolic hæmorrhages of the retina, but much less extensive, a second time in this same animal; while in the examination of animals which died of fatty embolism, similar hæmorrhages are often found in the brain, tissue of the heart, and lungs; and in their centre an obstructed vessel is generally easily found.

* In dogs narcotised by subcutaneous injections of morphia, I have repeatedly seen the temperature fall more than two degrees (3.6° Fahr.), and have found the pulse to fall to below fifty in the minute and become irregular, the respirations being slow.

The pulse was retarded soon after the injection, often irregular, and was frequently not again quickened until some hours afterwards.

The respiration was considerably changed by the injection. In general it was much quickened, irregular, and expiratory. After direct injection of fatty emulsion into the carotid, it was slow and stertorous. When large quantities of fat were injected into the jugular vein, death was produced by œdema of the lungs. The œdema was in many cases so severe, that fatty serum escaped in great quantity from the mouth and nose.*

The phenomena on the part of the central nervous system were various. In many cases the injections only produced some restlessness and quickened respiration. In others, there was considerable dyspnœa, there was great prostration, and at last the animals lay unconscious, and died with marked lowering of temperature. In others again, the injection was soon followed by clonic and tetanic convulsions, discharge of feces and urine, vomiting, paralysis, and coma. In the earlier cases, œdema of the lungs and poisoning with carbonic acid appeared to be the cause of death, while, in the later cases, death was directly caused by embolism of the brain. It is easily to be understood that the symptoms may vary according to the region of the brain in which the masses of fat are chiefly arrested.

As, according to these experiments on animals, the symptoms of fatty embolism may be very various, we must take a glance, in the diagnosis especially, at the conditions which may give rise to fatty embolism. It is observed after injuries, especially of bones, in acute and chronic suppurations, with or without metastatic abscesses, in Bright's disease (H. Müller, Lancereaux), in icterus gravis (Feltz), and in fatty degeneration of thrombi in the heart (Eberth). As far as I can see, it appears to be of essential importance clinically only in injuries of the bones, and perhaps in osteomyelitis. In cases of injury of bone, where, without apparent cause, a rapid deterioration of the patient's condition sets in during the first days, marked by disturbances in the circulation in the lungs and similarly in the systemic capillaries, fatty embolism must be borne in mind. But it can only be said to be a sufficient cause of death when the necropsy shows it to be so extensive as to affect such important organs (as the brain and tissue of the heart) that it must have produced considerable functional disturbance. The cases are, especially by English authors, reckoned among the deaths caused by shock; but, as I have already remarked, according to the present prevailing theory of shock, we must exclude all cases in which there is an interval of several hours between the receipt of the injury and the death-agony, in which the patient feels tolerably well. Perhaps many other cases of death belong to the category of fatty embolism, which it has been attempted to explain by the assumption of traumatic delirium or disturbance of the brain.

The mechanical conditions for the occurrence of fatty embolism have been well set forth by F. Busch.

* At first I thought that there was an increased secretion of saliva; but the fluid when collected was reddish, like water in which fresh meat had been washed, had a strongly alkaline reaction, and was nearly completely coagulated by the addition of nitric acid, or by boiling after acidulation with acetic acid. On examination, the bronchi were quite loaded with the same kind of fluid, while the salivary glands were dry.

Free fluid fat, arising in injuries of the bones from the crushed marrow, must be present somewhere in the body; and this is passed into the torn veins by the pressure of the arterial extravasation or of the muscles. That these favourable conditions for extreme fatty embolism fortunately do not often occur is easily intelligible; but slight fatty emboli are formed in almost every fracture of bone, and are evidently easily overcome.

It is a question whether we can do anything in the severe cases. As, according to C. O. Weber, the injection of fatty emulsion produces only slight effects, as fluid fat mixed with warm solution of carbonate of soda is readily changed into a fine emulsion by shaking, it might be thought that fatty emboli might be emulsified and rendered harmless by the injection of a soda solution. But the circumstance that this emulsion (one volume of fat and two volumes of a two-per-cent. solution of carbonate of soda) when injected into the carotid artery of a dog in a peripheric direction has caused death, even when used in small quantities, greatly lowered the expectation. In fact I have never succeeded, in my experiments, in overcoming severe dyspnoea by the injection of carbonate of soda into the jugular vein, although the distress several times appeared to me to be lessened for the moment.

Ligature of the veins absorbing the fat, which has been repeatedly done for the prevention of metastatic thrombosis in cases of venous thrombosis, is a proceeding that no surgeon would conclude to perform, even with all respect for the results of the antiseptic method; and no result can be expected from it, since the danger must always be recognised too late to cut off the source of the fat in this way. According to the researches of F. Busch, the fat is taken up in the first hours after the injury of the bone; while he also admits that its absorption may, under special conditions, occur later. Venesection for the purpose of relieving the venous congestion dependent on the disturbance of the circulation in the lungs, was, in our case at least, of no evident use.

ON THE SEMEIOLOGY OF CHILDREN'S DISEASES. BY DR. A. CUZZI, ASSISTANT IN THE CLINICAL DEPARTMENT OF THE OBSTETRIC INSTITUTION OF TURIN.*

(Concluded from page 609.)

Respiratory Apparatus.—This must be examined by inspection, auscultation, palpitation, and percussion.

1. *Inspection* gives the rhythm and the mode of respiration. Between the different acts which constitute a complete respiration, there are the same relations during sleep in the infant as in the adult; but, when it is awake, the rhythm is altered. The number of respirations during sleep is twenty-six (Vogel); in pulmonary and cardiac diseases, it may rise to seventy or even 100 in a minute. The number of respirations is, on the other hand, diminished in diseases which produce pressure on the encephalon (large tubercular masses, chronic hydrocephalus, etc.); the respiration is slow at first, but rapidly becomes quick and even sighing. The respiration is of the abdominal type, which is much exaggerated in pulmonary diseases.

2. *Auscultation* ought to be done quickly; immediate auscultation is preferable to the use of the stethoscope, so as not to frighten children with an instrument of which they cannot understand the harmlessness. Auscultation is difficult, because the infants sometimes refuse to be examined, and sometimes, when one has succeeded in applying the ear, they suspend or diminish the respiratory movements, and sometimes make irregular movements which alter the stethoscopic signs. Both sides of the chest should be examined, since disease at this early age is almost always bilateral, in order to be able to compare the intensity of the murmurs. Commence the examination at the base of the lungs in acute diseases, at the apex in chronic diseases.

Auscultation should precede percussion. In normal cases, we shall perceive the so-called puerile respiration of Laennec, due to the greater velocity with which air enters the pulmonary vesicles and to the thinness of the thoracic walls, which renders the sounds more distinct. According to some, however, the vesicular murmur remains weak up to the age of two years; it then increases because the lung becomes more permeable to air, giving rise to the stethoscopic sign described by Laennec. This respiratory murmur may be increased or diminished under the influence of various pathological conditions. All diseases which give rise to dyspnoea increase it; on the other hand, it is diminished in cases of pleuritic effusion. It is continuously diminished in true croup, because a smaller quantity of air passes through the larynx, the calibre of which is contracted by the false membranes. In false croup, on the other hand, it is heard commonly between the paroxysms. It is a valuable sign in the differential diagrams of these two diseases which are very often confounded.

The rhythm may be changed or perverted; thus, in severe pneumonia, we may see expiration more prolonged than inspiration. The respiration becomes harsh in the first stage of tuberculosis, but only in certain cases.

One of the most important signs revealed by auscultation is the bronchial or tubular souffle, which indicates condensation of the pulmonary parenchyma by pneumonia or by hydrothorax; with this difference, however, that in pneumonia the souffle is heard at the centre of the region of dulness, in hydrothorax above it.

I do not speak of cavernous râles, because generally in infants tuberculosis proves fatal before caverns have been formed. Diffuse râles, spread over the two sides, without great impediment of the respiration, indicate bronchial catarrh, which, if it be not at once treated, may give rise to true pneumonia. Remember that catarrh of the small bronchial tubes is as dangerous as pneumonia, through the smallness of the calibre of the air-passages, which may readily become obstructed, and give rise to collapse of the lungs. A true crepitant râle pathognomonic of pneumonia does not exist in the lobular variety, which is the most frequent. However, in the infant, pneumonia impresses such an appearance on the patient, that even an imperfectly practised eye will easily recognise this disease by simple inspection.

The best position for practising auscultation is to have the infant on the knees, or in the arms of the mother; and to apply the ear to the back covered only with a linen cloth, without its perceiving what is done; if the infant be very small it may be raised

* Concluding lecture of the Course of Obstetric Operations. (*Gazzetta delle Cliniche*, July 13, 20, and 27, 1875.)

with the hand and brought near the ear. It is sometimes convenient to make it cry in order to hear certain sounds which would otherwise escape the ear.

3. *Palpation* gives us not unimportant signs, and sometimes takes the place of auscultation. It gives us information regarding the vibrations of the thoracic walls under the influence of the voice, of cough, and of rhonchi, the manner in which they are produced during respiration, etc. The local resonance is best preserved at the anterior part of the chest, less at the hepatic and cardiac regions, and posteriorly between the scapulae.

4. *Percussion*.—The semeiotic value of percussion is much inferior to that of auscultation, and ought to be the last mode of examination practised. Direct percussion is to be preferred to that with the plessimeter, since the fingers are more easily fitted to the chest-wall, of which they also detect the degree of elasticity, which may be increased or diminished in different diseases.

In all cases, digital percussion should be practised with gentleness, during both inspiration and expiration, since some parts of the chest present different signs according to the stage of evolution of the lungs. Thus, for example, the thoracic viscera are carried downwards in inspiration, and the area of clear percussion-sound is increased; while during crying the abdominal viscera, and especially the liver, are thrust upwards, thus increasing the dullness.

Sonorousness is increased in emphysema (very rarely chronic in children), and in pneumothorax; on the other hand, it may be diminished or even abolished when the density of the lung is increased, in cases of pleural exudation, and in hypertrophy of the thymus gland.

To complete the study of the respiratory apparatus, we will add some remarks on the cry and on the cough.

The *cry*, in the first years of life, is the only word spoken; it may almost be called a function, since the *infant*, who *non fatetur*, expresses through it all its wants, its sensations, its pains. Percy and Billard have made a detailed and complete study of it. This sign is of especial interest to those who have to treat children. The cry is the most apparent expression of pleasure or of pain. It is produced in expiration; sometimes inspiration is accompanied by a more or less hoarse sound, which Billard calls *reprise*, due to the air rushing into the lungs after forced expiration, the glottis being still narrowed. There is, indeed, a vocal sound, a whistle during inspiration, in certain pathological states, as in Kopp's asthma or in croup. A cry of pain is not so much an indication of mental suffering as a check on the nervous apparatus (Moleschott). To produce a cry abdominal contraction is necessary; the glottis is contracted, the air is compressed in the chest, the pulmonary circulation is performed with greater difficulty, the blood is less oxygenated, the brain consequently receives imperfectly arterialised blood, and is less sensible of painful impressions; at the same time, there is arrest of blood in the veins, the face becomes livid and ingested, the infant, who appears threatened with suffocation, makes a slight inspiratory movement, giving rise to the *reprise*, and begins to cry again. Thus the intensity of the cry is, so to speak, the measure of the intensity of pain. We have here only to occupy ourselves with the infant's cry (*vagitus*); I leave aside the cry of the adult during surgical operations, and that of the partu-

rient woman. The first cry, in consequence of the effort which it demands, has very salutary results; it thrusts the abdominal viscera downwards, fully dilates the pulmonary vesicles, and unloads the fauces and larynx of the mucus which obstructs them. The physiological cry, which sometimes serves as a pulmonary gymnastic exercise, as the expression of some want, will be distinguished from the pathological cry by the resemblance of the latter to groaning or weeping, and by the alteration of the *timbre*. A strong and prolonged cry may, nevertheless, be perceived in robust children, the expression of severe pain or of intestinal colic; but it is not an indication for a guarded prognosis. In febrile diseases, the infant whines; the cry is weak or absent, or hoarse and peculiar in diseases of the larynx (simple laryngitis, croup, and diphtheria): an isolated cry at long intervals indicates hydrocephalus and meningitis; a single cry indicates an epileptic attack; multiple and disordered cries, hysteria; when the *reprise* only is heard, and the cry is suppressed, there is imperfect introduction of air into the chest, as in severe affections of the lungs and pleura. In proportion as the infant becomes weak, the intensity of the cry is diminished. Luton, in the *Dictionary of Medicine and Surgery*, edited by Jacoud, admits four principal kinds of cry: the cerebral; the thoracic (where the cry is suppressed and the *reprise* alone is heard); the laryngeal (hoarse or muffled); and the abdominal (strong, violent, indicative of colicky pains).

Cough is sometimes useful in the perception of the thoracic sounds in infants who breathe feebly; the ear should then be applied to the chest during a paroxysm of cough. We must, however, bear in mind that the stethoscopic sounds heard in this way are exaggerated. When the cough is easy and moist, there will be only bronchial catarrh; if it be interrupted and restrained by the infant, there is pneumonia; if it be continuous, and with very brief intervals, there is tuberculosis. Very small children do not know how to expectorate, and an abundant quantity of mucus may be arrested in the bronchial tubes and obstruct them so as to threaten suffocation. In these cases, nauseating expectorants are indicated, which, by provoking a violent contraction of the abdominal and respiratory muscles, freely expel the contents of the bronchi along with those of the stomach. Ipecacuanha is to be preferred, as its effects can be graduated, and it does not produce rapid and profound depression like tartrated antimony. At a more advanced stage, when the child can expectorate, examinations of the sputa may be of some advantage.

Digestive Apparatus.—This is to be examined in order, commencing with the mouth and proceeding downwards to the stomach and intestines. You know how the infant seizes the nipple in the physiological state; if it be strong it will seize it with force, and the sound of deglutition will be heard at a distance; if it be weak, it will suck with less energy. When an infant is feverish, the mouth is hot and there is much thirst; in cases of cerebral disease the breast is taken in an irregular manner; if the child do not take the nipple on account of want of strength, your prognosis must be very guarded. The quantity of milk which a good nurse is capable of furnishing in twenty-four hours amounts, according to Natalis Guillot, to 1,500 grammes ($3\frac{1}{2}$ pints), while an infant may take at each sucking from 80 to 200 grammes (about three to seven ounces). The age of the nurse

and of the child, and pathological influences, may cause great variations in the quantity of milk secreted, and also of that taken by the child. The infant should be suckled every two hours during the first months of life, and every three hours a little later; the intervals at night between the acts of sucking may be longer.

I have somewhat prolonged my remarks on these matters on account of their importance. In his treatise on obstetrics, Hubert has said that menstruation is the barometer of health in women; and in like manner we may say that the daily weight is the barometer of health in infants. If the child take the nipple, and after some efforts at sucking, leave it, and if the sound of deglutition be not heard, you should suspect that the nurse has not a large quantity of milk; and, in order to be better assured, examine the child after sucking. The milk may coagulate on the dorsum of the tongue, and present a certain resemblance to aphthæ; this is almost always coincident with fissures of the nipple. Sometimes small granulations are observed at the union of the bony with the soft palate, which in very young infants are often the starting-point of small ulcerations. The tonsils are more developed in early life, and inflammation more readily occurs in them. In the diagnosis of diphtheria, you will remember that herpetic angina will be sometimes confounded with it. When the inquiry into the causes of the deposit in the pillars of the fauces, and the concomitant phenomena, leave any doubt in your mind, act as if the diagnosis of diphtheria were certain.

Before proceeding to the examination of the stomach, never omit the state of the dentition.

You are aware that in infants the stomach has a more vertical direction, since the great *cul-de-sac* is less developed, and the small lobe of the liver almost entirely covers it. With these data, the examination of the symptoms which this organ furnishes will be more easy; they may be reduced to three—appetite, thirst, and vomiting. The appetite diminishes in febrile diseases, and increases more slowly during convalescence; the weight of the infant decreases in disease, especially of the digestive organs, and increases anew when convalescence is established.

Thirst is severe in febrile diseases; the mouth becomes hot and dry and the lips dry; this is perceived by the nurse when the child takes the breast. Vomiting is not always an indication for fear; if it occur a few minutes after the child has taken milk, without being accompanied by distortions of the face indicating pain, it depends on excessive distension of the stomach, or is the result of the child lying on the left side, so that the stomach is compressed by the liver, which is large at this time of life. Vomiting is of still less importance when the child continues to have a healthy appearance and to increase in weight. Greater importance, however, must be attached to vomiting if it occur half an hour or an hour after sucking, and if it be accompanied with painful contractions of the face; if there be also constipation, it is a sign of incipient meningitis.

Inspection, palpation, and percussion of the abdomen, and examination of the fæces, will afford us other diagnostic symptoms. Inspection reveals increase of size of the abdomen, which, even in the normal state, is larger than in the adult, in consequence of the greater proportional development of the abdominal viscera. Tympanitis, ascites, tubercular

mesenteric disease, hypertrophy of the liver, etc., distend the abdominal walls; cerebral diseases, meningitis, and progressive marasmus depress the belly. Palpation, by defining the limits of a tumour or the area of a viscus, or by provoking a pathological pain, and percussion, by indicating whether the contents of the abdomen are fluid or gaseous, will complete the results obtained by inspection. If there be no pathological pain, the abdomen can be compressed without provoking a cry; in ascites, it is best to practise palpation and percussion while the child is erect, in order to avoid the error in diagnosis which may arise from the fluid gravitating to the posterior part, while the intestines come into contact with the anterior abdominal wall. Be careful to examine the anal region; in cases of slight spasmodic diarrhœa there will not be the erythema characteristic of entero-colitis. If the infant do not allow you to examine it, being restless and agitated, use Valleix's artifice of taking it to an open window; the bright light astonishes it, and you must take advantage of this moment of calm to complete your examination.

Never omit the examination of the fæces; their colour, odour, density, constitution, and quantity, must all be passed in review. Two or three stools daily are normal in a sucking infant; one or two daily after weaning. The stools become more abundant, odorous, green, of less consistence, and contain masses of coagulated milk in inflammatory disease of the intestines. The coagula of milk in the fæces will be larger if the infant takes cow's milk.

Nervous System.—With a few words on the nervous system, I will conclude. I have already spoken of cerebral auscultation, and have pointed out some of the symptoms of disease of the encephalon in examining the various organs; I will, therefore, only mention that Bouchut has endeavoured to create a peculiar and quite new form of semeiology in these diseases by means of the ophthalmoscope. He sums up his researches in these three laws.

1. All diseases which retard the circulation in the cavernous sinus (tumours, inflammation, thrombosis in the sinuses) are manifested in the eye by lesions of the choroid, retina, and papilla.

2. Certain diseases of the brain and spinal cord, in consequence of the influence which they exercise on the trigeminal nerve, give rise to lesions in the retina and papilla analogous to those which are produced by section of the great sympathetic in the neck.

3. Disturbances of the nervous system attended with simultaneous change in the papilla and retina, indicate structural alteration in the cerebral matter.

These few remarks, gentleman, on infantile semeiotics, will, I hope, aid you in your examination of the general pathology of early infancy.

LABOULBÈNE ON THE SUCCUSSION-SOUND, OR HYDRO-AËRIAL BRUIT WITH METALLIC TONE, IN ABDOMINAL TUMOURS.

Amongst the original memoirs of the *Archives Générales de Médecine* for September, 1875, there is one by Dr. Laboulbène, physician to the Hôpital Necker, on the production of a succussion-sound in tumours of the abdomen; in continuation of a short communication to the Paris Academy of Medicine (Session of January 26, 1875, *Bulletin de l'Académie*, pp. 113-116), in which he mentioned having heard this sound in an abdominal tumour

a female patient. The patient having recovered, he endeavoured to determine the situation of the tumour (Session of August 3, *Bulletin*, p. 396). One of his pupils, M. Gaston Deny, has furnished a case of an encysted (probably ovarian) tumour with similar auscultatory phenomena—the details of which are given in this memoir, and are briefly as follows.

A washerwoman, aged fifty, was admitted an in-patient at the Hôpital Necker on November 6, 1875. Her father died of some stomach-affection at fifty-nine, her mother died at sixty-seven from a tumour in the left side of the abdomen, of about twelve years' duration. A sister, aged forty-seven, was also said to have had an abdominal tumour for fifteen years. She herself had had nine children, the first at seventeen, the last at thirty-six. She never miscarried. She married again two years ago, and from that time the catamenia had been irregular, and for the last six months she had never menstruated at all. From November last she had noticed a swelling in the left side. It had, however, never given her very much pain. She had not suffered from vomiting; but there was local tenderness. On admission, a tumour about the size of an adult head was felt in the left ovarian region and left flank. It could be moved from side to side without any abnormal sound. It was dull on percussion, and fluctuation was tolerably distinct. Fifteen days afterwards, the tumour was more prominent, the skin over it adherent, and slightly red at the most prominent part. There were dull pains. A sonorous sound was obtained by percussing the tumour; and, on seizing the mass with two hands and shaking it briskly, a splashing noise could be heard even at some distance, like that produced by shaking a water-bottle half or three quarters full of water. On applying the ear, and shaking briskly three or four times, this splash was very evident, and there was a metallic tone with it. On the 26th the tumour burst spontaneously, much fetid gas and greenish pus escaping, to the great relief of the patient. Only pus-corpuscles were found in this fluid. An India-rubber tube was placed in the opening, but on March 20 there was neither sinus nor tumour, except a hard lump of the size of a hen's egg, lying obliquely near the iliac spine. M. Depaul remarked, in the discussion on this case, that it was rare for simple cysts of the ovary to contract adhesions to the abdominal wall, or to terminate in abscess. He could not understand the formation of gas in a closed cavity. In a case of extra-uterine foetation, in which he had performed gastrotomy, and removed a dead foetus, he found adhesions between the cyst and the intestines, and a fistulous opening from the bowel, explaining the tympanic resonance of the tumour. In the case related above, he and M. Bernutz were at first inclined to consider the tumour malignant, because the uterus was much displaced, and its posterior lip ragged. M. Laboulbène believed that the gas produced in the cyst was from simple decomposition of its own contents, without any fistulous communication. He believed the tumour to have been an abscess close to the left ovary, situated between the posterior abdominal wall and the coils of intestines. The second case was that of a working woman, aged twenty-seven, who had always enjoyed good health, and had no family. In 1870, she noticed her abdomen enlarge. At the close of 1872, she was admitted to the Hôtel-Dieu, under M. Frémy's care, and was tapped six times in three months. The third, fourth,

and fifth tapplings were followed by injections of iodine. In January, 1873, she left the hospital pretty well, but was re-admitted in July, 1873, and again tapped and injected with iodine on the 17th. These measures were repeated in fifteen days (eighth tapping). All these tapplings were done with Castiaux's aspirator. The first time seven pints, afterwards from thirty-five ounces to about five pints of fluid were removed. She said it was always thick, and the last time of a dirty grey colour. In August, 1874, she was again twice tapped. In October, 1874, she was under the care of M. Péan at the Hôpital Saint-Louis. A tumour was found occupying the whole of the left abdomen as high as the umbilicus; it was freely movable, dull on percussion, and obscurely fluctuating. Its surface was unequal. A multilocular tumour of the ovary was diagnosed at this hospital, as well as at the Hôtel-Dieu. A few days after admission to M. Péan's wards, she was attacked with phlegmonous oedema of the legs, which did not yield to treatment. On November 15, the tumour, increased in size, was found sonorous on percussion; and on giving it little quick jerks towards the pelvis, there could be plainly heard, even at some distance, a splash, or hydro-aërial bruit, just like the Hippocratic succussion-sound of hydro-pneumothorax. On applying the ear, this sound was found to be distinctly metallic ('bruit d'airain,' brass-like in tone). She died a few days afterwards, but this phenomenon could be easily produced as long as she lived. No *post mortem* examination was allowed.

Did the gas proceed from the decomposition of the fluid itself in this case? M. Laboulbène thinks this probable. M. Hérard has published a memoir on the spontaneous formation of gases in closed cavities (*Actes de la Société Médicale des Hôpitaux de Paris*, 2^e fascic. pp. 105-112), and this contains three remarkable observations: (1) of empyema, with pneumothorax without perforation of the lung, in a man aged thirty-three years; (2) of enormous dilatation of the left kidney, and admixture of gas and pus without any communication with the external air, in a woman aged thirty-nine years; (3) of a suppurating ovarian cyst, with mixed pus and gas, not derived from without, in a woman aged twenty-five years. This observation was followed by a necropsy. MM. Barth and Roger both heard the succussion-sound in this case (*Traité pratique d'Auscultation*, etc., 8^e ed. p. 527. 1874). See a discussion on this subject in the *Bulletin de la Soc. Méd. des Hôpitaux de Paris*, tome i. p. 186-188; and another case of hydro-pneumothorax without perforation of lung (in the same volume, p. 289); also a case of Demarquay's, in which gas and matter escaped from puncturing an ovarian cyst for the first time (*Bulletin de la Société de Chirurgie de Paris*, 2^e Série, tome x. Dec. 8, 1869; *Bulletin Général de Thérapeutique*, tome lxxviii. p. 86, 1870.) Demarquay, in his *Pneumatologie Médicale, Recherches Physiologiques, Cliniques, et Thérapeutiques sur les Gaz*, p. 104 (1866), discusses the same subject. Scanzoni gives a case of spontaneous formation of gas in a cyst (*Traité pratique des Organes Sexuels de la Femme*, French translation, p. 372, ed. 1858). Neither Spencer Wells, nor Bernutz, Courty, or Puech give any examples of it. Scanzoni (*loc. cit.* p. 373) says 'that in large ovarian cysts one often hears a *bruit de glou-glou*.' M. Gosselin has given an example of an abdominal abscess (terminating in recovery, with a faecal fistula), which furnished this splashing sensation when rather suddenly and sharply compressed.

It was resonant on percussion. M. Roux opened it, and let out a quantity of gas and pus. M. Laboulbène concludes that this succussion-sound may be heard over abdominal tumours of various kinds, and that it does not necessarily indicate any communication with the external air, or with the intestines.

W. BATHURST WOODMAN.

COMBAL AND CHALOT ON A CASE OF DOUBLE HYDRONEPHROSIS IN AN ADULT, FROM OBSTRUCTION OF THE BLADDER BY FOUR CALCULI.

The *Montpellier Medical* of July 18, 1875, contains a long and minute account of the following case, with a copious bibliography. The patient, whose name was André Delon, aged fifty-seven years, was admitted on April 18, 1875, about 3 P.M., into the Saint-Vincent ward of the Montpellier Hospital, under the care of Professor Combal. He had been a railway superintendent, and had been twice married. Born at Nîmes, he had resided chiefly at Alais. On admission, he was noticed to be in great agony. There was orthopnoea, and his chest was alternately raised and depressed with great rapidity. The face had a dirty yellow colour, and the eyeballs were somewhat prominent. His appearance suggested cardiac disease of malarial origin. His wife, however, stated that he had never had any febrile attacks, but that for some days past he had complained of a sharp pain in the left side of the chest; and for as much as nine years past of a dull dragging pain in the lumbar region; further, that for some weeks he had passed no urine, only flocculent, greyish white masses like chalk and water. Thus attention was directed to the lungs and urinary organs. His chest was barrel-shaped. On each side of the sternum in front there was diminished tactile vocal fremitus; these portions were abnormally resonant. There was slight dulness on percussion at the lower and inferior part of the left lung, with broncho-ægophony at the same part; elsewhere compensatory respiration. He had occasionally a dry cough, and for three or four days his sputa were blood-stained. He was much depressed, but his temperature was only 38.4° Cent. (101.1° Fahr.). These physical signs of a pleuro-pneumonia of low type were justly said by M. Combal to fail in explaining the gravity of his general condition—his intense dyspnoea and debility, his anxious and restless expression, severe general headache, absolute want of appetite, mucous vomiting, hiccough of four months' duration, flatulence without diarrhoea, swelling at night of the backs of his hands, and of the ankles, wandering pains in the joints, most marked in the left knee. These symptoms pointed to the urinary organs. He had in fact come to the hospital to be cut for stone by Professor Courty, who transferred the case on account of the urgent dyspnoea. In the hypogastric region there was neither tumour nor dulness above the pubes. An elastic catheter met with obstruction from a hard body at the neck of the bladder. This obstacle could not be forced, even with a silver catheter. A rectal examination showed that there were several stones. The prostate was small for his age. The penis was very short, the testes like those of a boy of twelve. Coitus had long been impossible. As the bladder seemed spasmodically contracted, the lumbar regions were examined. There was no unusual bulging either before or behind; but in the lumbar region there was extreme tenderness on pressure. On percussion there

was neither fluctuation nor much dulness; finally, on auscultation with succussion, no typical urinary splash ('clapotement rénal proprement dit'). Indeed, except the pain and tenderness in the loins, there were no renal symptoms. The difficulties of diagnosis were therefore great. There were the absence of urine in the bladder, the presence of calculi, and the peculiar dyspnoea, which might be uræmic. It was said, too, that he had had sudden and shifting pains in the back and loins for some years, and had often been obliged to keep his right hand pressed against his loins in walking. His pulse was now only forty-eight; the pupils dilated and insensible to light. He appeared to see things through a mist; was increasingly deaf, and grew more and more stupid; in fact, had symptoms of chronic uræmia. Two blisters were applied, one to the chest, the other to the top of the right thigh; and the following mixtures were ordered: R. Hoffman's liquor, and tincture of benzoin, of each twenty drops; syrup of Tolu, one ounce; orange-flower water, and linden-water, of each equal parts to make a four-ounce mixture. A tablespoonful to be taken every hour; and in the intervals an antimonial linctus. He was ordered veal-broth and wine; with orange-leaf tea. The catheter was ordered to be used night and morning. Towards night he had monotonous delirium with sighs and groans, and was somewhat comatose. The coma deepened in the morning, and he died at 11 A.M. [twenty hours after admission].

Only a partial *post mortem* examination was permitted. The bladder was found somewhat on the left side, and had the form of a lozenge with blunted angles. It only extended about $1\frac{3}{8}$ inches above the pubes, and the parietal peritoneum covered this entirely. On examining the bladder, four stones about the size of chestnuts were found, corresponding to the four blunt angles of the lozenge. These and the bladder together weighed $10\frac{1}{2}$ ounces troy, including the prostate and the fluid contents. On opening the bladder carefully, the four stones appeared as four bodies rounded on their borders, and with two smooth lateral facettes corresponding to the lateral surfaces of the bladder. All together, they formed a quadrilateral figure. The first or uppermost calculus was greyish-white, of chalky consistence, ellipsoidal, slightly irregular on the surface, except the two facettes, which were polished like the finest marble. The second stone was cuboidal with blunt angles, slightly narrowed about the middle of its longest diameter. The third stone, situated posteriorly, resembled it, as did the fourth, situated obliquely in front, but posterior to the level of the neck of the bladder, except that these were not pinched in any of their diameters. The following are the chief dimensions of these stones.

The first stone weighed 587 grains. Its long diameter was two inches. Its short axis at the larger end was $1\frac{7}{16}$ inch; the other short axis was $1\frac{1}{4}$ inch. Its greatest circumference was $4\frac{3}{4}$ inches; circumference at larger end, 4 inches; at smaller, $3\frac{1}{4}$ inches. The second stone weighed 572 grains. Its long diameter was $1\frac{7}{8}$ inch, its short one $1\frac{3}{8}$ inch; its greater diameter $5\frac{1}{8}$ inches, its lesser $3\frac{7}{16}$ inches. The third calculus weighed 756 grains. Its long axis was $1\frac{3}{4}$ inches, its lesser $1\frac{1}{16}$ inches. Its larger circumference $5\frac{1}{4}$ inches, its lesser $3\frac{7}{16}$ inches. The fourth weighed 710 grains. Its long axis was $1\frac{3}{4}$ inches, its short one $1\frac{1}{16}$ inches, its greater circumference $5\frac{1}{4}$ inches, its lesser $3\frac{3}{4}$ inches. The first and third calculi were cut transversely, and showed a nucleus

of rusty yellow, composed of uric acid and cystine combined; outside this a brownish circle of porous matter, consisting of thickened mucus; beyond this a larger greyish-white mass, bordered by a clear brown, of oxalate of lime, then stratified layers of carbonate and phosphate of lime; outside all there was again a layer of mucus. The bladder contained some minute lithic concretions, and between the four stones a quantity of soft chalky matter, of phosphate and carbonate of lime. Both ureters were obstructed by the same (fourth) calculus.

The right side of the bladder was atrophied; the left had the muscular fibres and mucous membrane hypertrophied. The prostate 'cried under the knife,' was firm, leathery, small, and contained few blood-vessels. The middle lobe was slightly prominent at the neck of the bladder, probably from congestion chiefly. An enormous mass of fatty tissue, a true capsular lipoma (Virchow) enveloped both kidneys. They were separated from the intestines by the thinnest of serous membranes. The left kidney was double the ordinary size, with rounded and breast-like projections. It was mainly divided into three portions corresponding to the antero-superior, middle, and inferior portions of the kidney; the middle was the smallest. The measurements were—length, 7 inches, diameters of each principal pouch, $3\frac{3}{8}$, $2\frac{5}{8}$, $2\frac{1}{2}$ inches; medium thickness $3\frac{3}{8}$ inches; weight, with liquid contents and pelvis, 16 ounces nearly. The urine itself, slightly albuminous, and containing free fat, weighed 10 ounces. The whole of the interior of this kidney was lined by a membrane like that described by Rayer. The left ureter was converted into a cord for two inches of its length at the vesical end. The pelvis and upper end of the ureter were much dilated. The right kidney was somewhat smaller, and divided into four principal pouches. Its true structure was still more atrophied than that of the left—the whole of its wall being only about one-fifth of an inch in thickness. Its contents amounted to eight ounces; its own weight, with the pelvis, was only about three ounces. It was six inches long, three wide, two and seven-eighths thick. A minute description is given of both kidneys, for which we must refer to the original. The liver was somewhat cirrhotic, the spleen small. Nothing else abnormal was noted in the abdomen. Further examination of the body was forbidden.

In commenting on this case M. Chalot points out the distinctions from cystic disease of kidneys, and observes that hydronephrosis is most common in the fœtus, and may even be a cause of dystocia. He refers to cases by Rayer, Mansa (1836), Oesterlen (1841), Horing, Gailleton, and Ollier (*Gazette Médicale de Lyon*, 1853), Virchow, Siebold (1855), Chevance (*Union Médicale*, 1857), Chevandîé, Levi (*Gazette Hebdomadaire*, 1857), and others. In the adult, cases have been observed by Virchow, Rayer, Lebert (*Traité d'Anatomie Pathologique*, tome ii.), by Hirtz and by Jaccoud. [Dr. Little's case at the London Hospital was in a young lad, but the obstruction was probably congenital.—*Rep.*] Any obstacle to the flow of urine may cause hydronephrosis. It may be single or double, general or partial, simultaneous or successive, according to the site of the obstructions, etc.

The direct or occasional causes are either (1) those of the cavity or calyces, as calculi depending on clots of blood, hydatids, mucous coagula, foreign bodies, fibrinous concretions and the like; or (2) parietal, including most of the malformations and

congenital cases, strictures, folds of membrane, etc.; or (3) peripheral, such as those produced by external pressure of tumours, the gravid uterus, Pott's abscess, etc., ovarian disease, or prolapse of the uterus [cases by Rayer, Stadfeld, Virchow, Laboulbène, the last read before the Société de Biologie in 1850; Bourdillat, 1868]; aneurism, cancer of the rectum, etc. Chronic pyelitis must also be mentioned as a cause (Moreau and Vigla, 1868). Whenever hydronephrosis is unilateral (simple hydronephrosis of Rayer) the other kidney becomes congested and hypertrophied, to supply the lack of its fellow. A great number of unilateral cases are on record, such as Bonet's (1679); one in the *Journal des Savants* (1698), Morgagni's (1760), Van Döveren (1763), Haller (1777), Sandifort (1782), Walther (1789); others by Hoffmann, the first to diagnose the disease in life; Ruysch, Rudolphi, Frank, Chopart, and more recently Howship, Howison; the *Journal de Médecine* of Corvisart, Leroux, Boyer, König, Reynaud, Piorry, Glass, Rayer (*Obs.* ii., iii., tom. 3), Cruveilhier, Th. O. Heusinger, 1862, Zambaco (v. Lebert, tom. ii., pl. cxxxviii., *Traité d'Anatomie Pathologique*). Sestîé described a case from vegetations of the right ureter. In 1868, Bourdillat, for Demarquay, one on the left side from uterine cancer. Broca (in 1851) had a case from a valve-like disposition of the opening from the kidney into the ureter. Virchow has noted cases in which, although the ureter was permeable, there was extreme hydronephrosis. Here again the valve-like disposition of the superior insertion of the ureter was to blame. In 1869 Heller noted a case of partial hydronephrosis, in which there were two ureters to one kidney. The segment corresponding to the lower ureter had become distended. Rare in men, this has more often been noted in the ox. Potain and Choyau's lumbar tumour (*Thèse de Moreau*, 1868) may have been a cyst of another kind. Hydronephrosis is more common in females than in the male sex. Double hydronephrosis is very rare. Ruysch observed it in a sheep, Billard (*Traité des Maladies des Nouveau-nés*), Moreau (*Bulletin de l'Académie de Médecine*), and Cruveilhier have noted it in the newly born. One female infant lived thirty hours. P. Jalon quotes a case in a boy of ten years; Hallé in a female aged forty, consecutive to renal calculi. The *Histoire de la Société royale de Médecine* (1780-81) has an account of one in a female aged forty. Rayer describes one in a lad aged seventeen (in 1836). W. Roberts (*Brit. Med. Journal*, 1868), and Prompt describe each one. Bourdillat, in 1868, gave the history of a case of double hydronephrosis in a man aged fifty-six, who had in his bladder a stone weighing nearly six ounces (180 grammes). He was cut by Demarquay and Ségalas above the pubes, but died three days afterwards. Like the case recorded above, he only passed a drop or two of urine for some weeks, according to his wife's statement. There were also other points of resemblance in the two cases.

Is it possible to live after all trace of true kidney structure has been destroyed? We have no materials for an answer in the adult. But the infant cited by Moreau survived its birth thirty hours, in spite of complete destruction by ectasis of both kidneys. Instead, therefore, of saying with Rayer, 'an infant born with double hydronephrosis is not viable,' we should say, 'cannot live long.' This complete case is analogous to extirpation or congenital absence of both kidneys. Pigné, in the *Bulletin de la Société Anatomique de Paris*, speaks of complete absence of

both kidneys in a fœtus at full term. Moulon, of Trieste, made the same observation on a girl fourteen years old. Comhaire had many dogs live three days after extirpation of both kidneys. After their extirpation, or after ligation of both renal arteries, Prévost and Dumas, Legallois and Bernard found that the animals did not die very quickly. The indications for treatment in hydronephrosis once diagnosed must be to remove the cause, if possible, and to empty the tumour by paracentesis (König, Little, and others), or to do nephrotomy (Hillier and Thompson) at the posterior part of the eleventh intercostal space, or manipulations of different kinds as proposed by W. Roberts. Infiltration of urine can scarcely happen if care be taken that the varied tissues are all perforated in parallel planes. Rayer, Rosenstein, and Lécorché have given excellent recommendations as to therapeutics in these cases. The diagnosis is difficult, since the slow progress and the urinary fluid are no longer deemed unequivocal symptoms (Rayer, Krause, Rose). Hydronephrosis has been taken for a gravid uterus (*Histoire de l'Académie des Sciences*, 1732), for ileus (Howison), for splenic tumour (Virchow), for ovarian dropsy (Johnson, Virchow), and for ascites. The celebrated ovariologist, Spencer Wells, was misled for a moment by the tradition (handed down by Rostan) that the bowels float in front, if the tumour be renal, and behind and above when the tumour is ovarian. A natural cure by formation of a fistulous opening is so rare that Rayer had never heard of a case. [A supplemental bibliography of recent cases is added, for which reference must be made to the original. A case has recently been under treatment, with favourable results, at the Southampton Infirmary. It is much to be wished that the details were communicated to the profession.—*Rep.*]

W. BATHURST WOODMAN.

ANATOMY AND PHYSIOLOGY.

O'CONNOR ON CLIMACTERIC CHANGE.—In the *Dublin Journal of Medical Science* for July, is an article on climacteric change, by Dr. O'Connor, read before the Cork Medico-Chirurgical Society. In it he says:

The term 'climacteric,' as applied to certain periods of life at which sudden changes in health, either favourable or unfavourable, occur, without any assignable cause, is seldom found in medical writings at the present day. It is, perhaps, too much the custom to disregard the consideration of diseases not founded on known pathological changes, many of which are found in the old nosological works on medicine. We recognise disturbances in the system at the periods of dentition and puberty, and at the cessation of menstruation, which test the stability of the constitution. Might we not expect, *à priori*, that the decline of life, like its development, may proceed, not at a uniform rate, but arrested or precipitated at certain stages, which are called climacteric? Sir Henry Hallford, and one or two other writers, have endeavoured, apparently in vain, to revive the consideration of this subject. No doubt, it is not so easy to observe with precision changes in the late period of life as in the early, owing to the many artificial disturbing elements in the course of life in the latter, when free-will gives free play to the passions, and care, grief, or anxiety, may obscure the

milder action of natural changes, which is hard to eliminate from the more powerful agencies with which it is associated. Nevertheless, any physician in much practice must have seen many a person about the age of sixty-three, the great climacteric, falling away from health, without being able to find any assignable cause on the most careful inquiry. His friends notice a great change in his appearance, and believe he is approaching his end; and soon afterwards the same individual is seen in full vigour—regretting, perhaps, that in his previous despondency he had given up his business, or the practice of his profession, for which he now feels himself equal. A characteristic of this condition is a gloomy foreboding of poverty, without grounds, or extravagant grief carried beyond the ordinary bounds. If the patient be well guided, and if organic disease do not establish itself during the stage of debility, a reaction takes place, which establishes the health on a firm basis. Strange stories are told of white hair becoming again dark, of new sets of teeth springing up in old sockets, of sight so improved that spectacles are no longer needed. I will bring under the notice of the society a few cases less striking than these asserted facts. A gentleman, very delicate all his life, had a considerable discharge of blood from his stomach, about sixty years of age, and continued many months apparently approaching his end. He rallied into health suddenly, and now, at the age of eighty-five, goes to mass at half-past seven o'clock every morning, and never uses spectacles when reading.

An old lady, who died only recently at the age of ninety, assured me she had very poor health till she had passed sixty years of age.

The following case I give in the words of the patient himself, a physician. 'When I was about sixty-three years of age, I felt an unaccountable languor and a debility in walking. In ascending a hill, or going upstairs, the muscles of the thighs and legs were as painful as if they were in a state of inflammation. All candid people who met me said I was very much changed in my features; that I must have been ill; that I should eat more and work less. Though my sincere friends were more delicate in their remarks, I could see from their countenances that they had much anxiety about my condition. On rubbing my hand over my face I found it rough, as if grains of sand were embedded in it. My nights were miserable, being constantly visited by nightmares of an uniform character—always feeling myself in some exposed place, lying in a state of utter prostration, unable to move. These dreams, I believe, were produced by a weakness of the heart's action—a sort of fainting in sleep. I never have had similar since or before. In the month of November the tops of the fingers of one hand were slightly scorched by handling a hot object. The charred cuticle was unremoved until the following June. The feet and hands were always cold. My voice became husky, not through a cold or inflammation, but nervous debility, and speaking or reading aloud distressed me much. I felt no symptom of illness, except a general languor, in which the pulse partook. The urine was normal. When I had been in this state several months I visited a medical friend in Dublin, being on my way to the Continent, not intending my visit to be professional. He expressed surprise at my changed appearance, and asked, with more frankness than was pleasant, whether I had any hæmorrhage from the bowels, kidneys, or lungs; whether my legs were swelled;

whether I had syncope. Being answered in the negative, and finding, on examination, my heart was weak, but not unsound, he said with some satisfaction, and, as the result proved, with truth, 'Then your disease is sixty-three.' Having spent a month on the Continent, not submitting to any efficient treatment, I soon became thoroughly well, with a degree of sound health which I did not enjoy for years previously. The roughness was removed from my face; the cuticle on my fingers was renewed; some scaly exudations on other parts of the body fell off; my voice was restored. It appeared to me as if the nutritive changes had ceased during the period I have referred to, and the tone of every bodily organ was temporarily depressed.'

From the reaction towards perfect health which took place in this and similar cases, it is evident the early symptoms did not depend on any structural changes in the arterial system which arise in advanced life; still the lowered state of the vital power makes it a favourable opportunity for the invasion of organic disease, to avert which should occupy the care of the physician, by prescribing such regimen and laying down such rules of life as would increase nutrition, diminish waste, and prevent mental shocks; and by these means give a new term of life, however short.

HUIZINGA ON THE INNERVATION OF THE VESSELS OF THE WEB OF THE FROG'S FOOT.—D. Huizinga (*Pflüger's Archiv*, xi. 207), in his paper, confirms the results of Goltz, Tarchanoff, Putzeys, etc. As is well known, the doctrine of the innervation of vessels has undergone remarkable changes within even a short period. At first it was a tolerably simple affair, so long as it was imagined that the vaso-motor centre for the entire body lay in the medulla oblongata, and that the vaso-motor fibres were distributed in all directions through the sympathetic. Later discoveries have, however, necessitated changes in this relatively simple theory. First there were the vaso-dilator nerves; then the vascular reflex action upon sensory stimulation; then facts that seemed to show that the vaso-motor centres are distributed throughout the whole spinal cord; and, lastly, the view, supported on more or less good grounds, that the lumen of the vessel does not depend upon spinal nerve-cells alone, but is also controlled by peripherally situated nerve-cells.

The author's experiments were made upon the web of freshly caught strong examples of *Rana temporaria*, which is preferable because it contains fewer pigment-cells to obstruct the view of the vessels. The animals were curarised with a solution of curara, which took twenty to thirty minutes to operate. Sometimes, though rarely, a solution of strychnine was employed to increase the reflex activity; and in an animal previously curarised, a larger dose of strychnine was required to produce the result. The size of the arteries was measured either by an eyepiece micrometer, or the size of the vessels was drawn by means of a camera lucida. The animals must not be too strongly curarised, else the rhythmical movements normally to be observed in the arteries are not to be observed, although the vaso-motor nerves retain their excitability undiminished.

In order to test the independence of the rhythmical contractions in the arteries of the spinal vaso-motor centres, the sciatic plexus and, for greater security, the sciatic nerve on one side were divided,

or even a part of the nerves excised, and the animal left to itself for one or two days to recover from the effects of the operation.

In the web of the foot so operated on, the most beautiful rhythmical contractions are to be observed, whilst the reflex contraction, on pinching the fore-foot, is entirely absent, thus showing that the contraction is completely abolished with the destruction of the spinal centres. On the uninjured side the reflex movements occurred. Further, this experiment shows that the rhythmical movements of the vessels do not proceed from the spinal cord, confirming the results of Gunning on the web of the frog's foot, of Roeber on the ear of the rabbit, and of Asp on the splanchnics. In addition, the rhythmical contractions do not occur in all the arteries of the web simultaneously. The author is, therefore, of the opinion, like Lister, Goltz, Tarchanoff, Putzeys, that the cause of these movements is to be sought for in local nerve-centres, leaving it, however, undecided whether the impulse for these movements proceeds from peripheral nerve-cells placed along the vessels, or arises independently of such organs in the muscles of the vessels.

Beyond the rhythmical movements, very pronounced reflex movements of the muscles of the vessels are to be observed. The author finds that when stimuli (mechanical or electrical) are applied to the skin, whether the application be followed by contraction or dilatation of the arteries of the web depends, on the one hand, on the distance of the stimulated area from the web, and, on the other, on the intensity of the stimulation; so that with diminishing distance and increasing strength of stimulus dilatation prevails.

In an experiment on a frog whose lumbar portion of the spinal cord was destroyed the day previous, the author observed that a reflex contraction which occurred on stimulating the fore foot was entirely abolished, when the sympathetic nerve accompanying the aorta was divided between the third and fourth ganglia.

In a frog whose spinal cord was destroyed the day previous from below the fourth vertebra, no reflex contraction of the vessels was produced on pinching the posterior extremity, though this result followed pronouncedly when the anterior extremity was pinched. A weak solution of amyl-nitrite, suspended in water and applied to the web of the foot, was followed at once by dilatation in the vessels of the web, which reached its maximum in a few seconds, and lasted for ten to twenty minutes. The vessels then returned to their normal calibre. At the maximum of dilatation, pinching the fore foot was followed by a normal reflex contraction of the vessels of the web.

From this experiment the author draws the following conclusions.

(a) Amyl-nitrite does not paralyse the muscular tonus of the vessels.

(b) Neither does it paralyse the vaso-motor nerves, nor their end-organs.

(c) The dilatation of the vessels after the application of amyl-nitrite cannot otherwise be explained than that this substance extinguishes the tonus of the peripheral nerve-cells (the so-called local vaso-motor centres) placed along the vessels.

ROSSBACH ON THE RHYTHM OF THE HEART-BEATS.—M. J. Rossbach (*Ber. d. Sächs. Ges. d. Wissensch.*, 1874, 193, and *Centralblatt*, no. 28, 1875) investigated first the influence of the systolic cardiac pressure on the formation of groups of beats.

Luciani found that a considerable and continued increase of the pressure which the heart had to sustain during the diastole accelerated the occurrence of fatigue, and rendered the pulse curve irregular; as to the influence of the systolic pressure he obtained no results. Rossbach, instead of a mercury, employed a water manometer. The systolic pressure could be diminished or increased by leaving the free end of the manometer open, or by compressing it more or less. In hearts which were fed with clear rabbit's serum, the formation of groups occurred both with high and low pressure; but with low systolic pressure the formation of beats was much more irregular than with very great pressure. These irregular groups passed at once into regular ones, when the systolic pressure had diminished. By the term 'heart' is meant one whose auricles are ligatured off after the manner of Luciani.

On using serum as free from corpuscles as possible for filling the heart, the formation of groups occur in a pronounced manner; the groups disappear when the pure serum is removed and defibrinated blood or blood serum is employed instead. Also when the heart is filled with a 0.6 per cent. solution of common salt, the grouped arrangement of the beats disappears. If the heart be filled with very red serum or defibrinated blood, it never shows a trace of grouped arrangement of its beats. If the defibrinated blood, without renewing it, be allowed to remain in the heart till it has lost its red colour, the formation of groups begins again, and in such a heart the periodic rhythm cannot again be brought to disappear by repeated filling with fresh blood or blood serum. A heart filled with blood, and beating and acting regularly, at once forms groups on a weak solution of veratrin being added to its contents. The different conditions in the succession of beats can be produced in one and the same heart. If a heart be filled with solution of salt, its beats follow each other at always regular intervals; if this solution be exchanged for pure serum, the contractions arrange themselves in groups; and if this solution be in turn displaced by serum containing blood-corpuscles, the heart then acts again with a regular succession of beats. The number of beats, however, is not always the same. A heart filled with solution of salt beat six times per minute, with pure serum in the first group seven, in the second ten times, with blood on the contrary twenty-three times. Rossbach cites various explanations for these different actions, and for the phenomena of the periods. It is possible that in pure serum a substance is formed, which on the one hand has an influence similar to veratrin, and on the other is destroyed when it comes into contact with bright red blood-corpuscles; or serum acts as a stimulus; under its influence the energy of the conditions under which the grouped arrangement of the beats is active becomes greater, and then diminishes to the stage of the so-called 'crisis,' during which the heart-beats occur in regular but slower succession. Blood, however, is able to stimulate an excitable heart more strongly than serum, and causes the pauses to disappear, whilst solution of salt stimulates less than the serum, so that by its presence the heart, from the first, passes into a state which corresponds to the stage of 'crisis' in the serum-heart. The similarity in the action of blood and of salt solution, are therefore only apparent. In the course of his investigations, Rossbach often succeeded in restoring apparently dead hearts by increased diastolic pressure and by heating.

HARNACK ON THE ACTION OF EMETICS ON THE TRANSVERSELY STRIPED MUSCULAR FIBRES.—E. Harnack (*Archiv für Experiment. Pathologie*, iii. 44, and *Centralblatt*, no. 35, 1875) remarks that a large number of the substances which act as emetics and nauseants have also a paralysing action upon the voluntary muscles. To this group belong emetin, apomorphia, tartar-emetic, cyclamin, asclepiadin, and sanguinarin, delphinin, veratrin, and digitalin. The author tested the copper and zinc salts, and some drugs obtained from the vegetable kingdom.

We have very few experimental results on the action of the copper salts. To avoid local disturbances by the substance, and specially to avoid coagulation of the albumen, the author chose for his experiments a soda double salt, viz., tartarate of cupric oxide and soda. In the frog, copper acts eminently in paralysing the voluntary muscles. A quantity of the solution of the copper salt, which contained half to one milligramme of copper oxide injected subcutaneously into a frog, produced, after a few hours, complete paralysis, and with 3 milligrammes of oxide of copper the same result after one hour. In rabbits 0.05 gramme of oxide of copper injected subcutaneously, or 0.01 to 0.15 into the veins caused death, with the phenomena of paralysis of the heart and respiration; in the former case, after a few hours, in the latter, after a few minutes. The voluntary muscles, specially those of the posterior extremities, lose their excitability completely, so that the strongest induction-shocks are without effect; there is neither dyspnoic breathing nor convulsions. The pupils are dilated. The result is similar in dogs on introducing 0.4 to 0.025 gramme of oxide of copper subcutaneously or into the veins. By this method of exhibition vomiting does not occur, which is in opposition to Orfila's result, but in unison with Daletsky's (*St. Petersburg Dissertation*, 1857). To produce vomiting, 0.6 to 0.7 gramme of oxide of copper required to be introduced into the stomach, whereby of course the general action was prevented.

The zinc-salts conduct themselves similarly to the copper-salts. The author employed the phosphate of zinc oxide and soda and the valerianate of zinc. The animals resist the zinc salts better than the copper salts. The minimum dose of oxide of zinc is 0.002 gramme for the production of complete muscular paralysis in frogs, and with small doses the animals recover. In dogs, 0.4 to 0.5 gramme given subcutaneously or injected into the stomach produce vomiting; 0.1 to 0.12 gramme of oxide of zinc injected into the veins, death.

Various other metallic salts, which do not possess a specific emetic action, as the salts of lead, manganese, and tin, do not extinguish the muscular irritability when they are not employed in too large lethal doses. Mercurial salts, on account of their violent local action, are not well suited for comparison.

In addition to these salts, the author investigated asaron and colchicin. The former is derived from *Asarum europæum*. In doses of 0.01 gramme introduced into the stomach, it acts as a powerful paralysing of the muscles in frogs. Frogs must receive internally 0.05 gramme of colchicin in order to obtain muscular paralysis. Even then it occurred late, and the heart is also affected late.

Regarding the connection between the emetic and the muscle-paralysing action, only this is certain, that these two phenomena do not stand in the relation of cause and effect.

NASSE ON DIFFUSION BETWEEN BLOOD-CORPUSCLES AND SERUM.—O. Nasse (*Sitzungsber. d. Marburger Ges. Z. B. d. g. N.*, 1874, no. 4), of Marburg, investigated how far the presence of carbonic acid and oxygen influence the diffusion between blood-corpuscles and serum. The defibrinated blood of a horse was allowed to stand till the corpuscles fell to the bottom, and then mixtures of serum and cruor in varying quantities were prepared. From one and the same mixture one portion was treated continually with carbonic acid, another portion with oxygen. As the chief result of the carbonic acid mixture, increase of the specific gravity of the serum, diminution of water and chloride of sodium. The extent of this change increases directly with the quantity of cruor. As the mean, 1,000 grammes of serum weighed 2.5 grammes more, contained 4.45 per thousand more solid constituents on the whole; on the contrary, 0.57 less of chloride of sodium. Water and chloride of sodium therefore pass into the blood-corpuscles, which thereby increase in volume. The carbonic acid also takes part in the increase of the specific gravity, but still this is not great enough to account for the entire change. Blood flowing directly from an artery of a horse was defibrinated at one time with air, the next time with exclusion of air. The serum of the latter was 0.3 gramme per thousand heavier. Further, the author investigated how other cells conducted themselves towards carbonic acid and serum. He employed for this purpose minced flesh and freshly rubbed down liver. In all cases the specific gravity of the serum increased considerably, nevertheless more pronounced in the presence of carbonic acid than in the presence of air, and the chloride of sodium diminished in the same sense. The author refers the phenomena to the coagulation of the protoplasm by the acidulation, which must be more pronounced in the presence of carbonic acid, as the tissues were all employed fresh.

PFLÜGER ON THE PHOSPHORESCENCE OF DEAD ORGANISMS.—E. Pflüger (*Pflüger's Archiv*, xi. 222), in a paper partly experimental and largely historical, discusses the cause of the phosphorescence exhibited by dead organisms. On observing by daylight a surface which has been luminous, it is always found to be covered by a whitish dirty slime, which may sometimes be from two to four millimètres in thickness. It is this slime or its constituents which possess the property of phosphorescence. The most important fact connected with this luminosity is, that it depends upon the presence of oxygen. As one experiment made by the author, showing the consumption of oxygen, may be mentioned the following. A solution of crystallised hæmoglobin of such a strength that the two absorption-bands were clearly to be observed spectroscopically, was treated with a few cubic centimètres of luminous salt water, and the whole placed in a hatching apparatus and warmed for a few minutes. The oxyhæmoglobin absorption-bands totally disappeared, and the single reduction-band of Stokes was present. On shaking the mixture a little, the two absorption-bands again reappeared. Heat alone, as is well-known, only causes the oxygen to disappear from a solution of oxyhæmoglobin after a long time. Here excessively small quantities of oxygen caused an increase in the phosphorescence of luminous water. Experiments were then made with substances which destroyed fermentation and putrefaction by killing the organisms. Alcohol

and carbolic acid rendered the luminous water at once dark. Fresh water fish are not phosphorescent unless they have come into contact with salt water fish; and in the few cases where they have been observed to be phosphorescent this may be explained by infection from some sea fish.

The microscopic structure of the slime covering the bodies of phosphorescent fish was then investigated. It was found to consist of lower organisms, the so-called schizomycetes, which are the proper luminous materials. This was shown by a filtration experiment, where the organisms were retained upon the filter (fine thick non-sized printing paper; Swedish filtering paper does not do) which remained luminous, while the perfectly clear filtrate was absolutely non-luminous, this clearly showing that the small living cells of the schizomycetes are the cause of the luminosity; and further, the author's experiments furnish strong proofs that the schizomycetes do not arise 'spontaneously,' but from spores.

In framing any theory of physiological phosphorescence, the following chief points must be kept in view.

1. The intensity of the light is generally extraordinarily weak, and therefore the phosphorescence can only be well observed by a retina which has become very excitable by being long in darkness. The retina is, then, in such a case, of almost endless sensibility.
2. The development of light is caused by oxidation.
3. According to our present knowledge, there is no living cellular substance which is so darkly coloured by perosmic acid as the 'light-cells' (lampyris). Nowhere, therefore, do the atoms which bind the oxygen in the living cell-substance lie so densely as in the light-substance.

TARCHANOFF ON THE CONTRACTILE ELEMENTS IN THE BLOOD- AND LYMPH-CAPILLARIES.—F. Tarchanoff (*Pflüger's Archiv*, ix. 407, *Centralblatt*, no. 30, 1875) has studied the properties of the contractile elements in the walls of the blood- and lymph-capillaries with regard to stimuli. He employed for the most part the transparent tails of young larvae of frogs, and as a stimulus the induced current of different intensities and duration. For narcotisation and to render the animals passive, he employed a three per cent. mixture of alcohol, in which after about fifteen minutes the animals became quite passive. The voluntary muscles no longer reacted to strong stimuli, whilst no disturbance of the circulation was to be observed. If a blood-capillary with lively circulation and clearly obvious spindle-shaped nuclei be placed under a very high power, and then stimulated by a moderately strong current for fifteen or twenty seconds, a shortening and thickening of the spindles soon becomes obvious, by which the lumen is narrowed and sometimes completely obliterated. If the stimulus act for two or three minutes, the elements retain their contracted form, and the capillaries remain impervious to the current of blood. If the stimulating current be soon interrupted, however, the spindle elements soon regain their original shape; the blood-current returns to its normal condition. The same experiment can be repeated several times on the same elements, until at last the cells no longer return to the normal. By the closure of the capillaries, a slowness of the current is produced in

the corresponding artery with consecutive dilatation, whilst in the veins stasis begins.

Mechanical and chemical stimuli produce the same changes; and the freshly excised webs and membrana nictitans of adult frogs conduct themselves analogously. Further, in employing the electricity, it was found that the spindles at the point of origin of the capillary from the artery contracted first and generally very early. The lymph-capillaries showed the same phenomena. If, however, very strong currents were employed, the spindle elements of the walls of the lymphatic capillaries were not only simply thickened as with the blood-vessels; they rather became pale, their contours disappeared, and their nucleus appeared in a rounded form. Twice the author observed that the protoplasm of those cells which had become pale fell into fine particles which fell into the passing lymph-current. The author further believes that the rounded nuclei of the disintegrated cells, which remain at first, are ultimately removed by the lymph-currents. The changes in the spindle-elements of the capillary wall the author, in opposition to Golubeff, regards as a vital process.

In the course of his investigations, Tarchanoff had also an opportunity of proving that the body of the fixed connective-tissue corpuscles also becomes thicker after long-continued electrical stimulation; the change is clearly but slowly produced. With gentle inflammatory stimuli the spindles, after they have been shortened for a day, gradually resume their original form. The out-wandering of the colourless blood-corpuscles and the other phenomena continue. The author concludes that the hypothesis of Golubeff—that all inflammatory phenomena are caused by the change in the capillary wall—is incorrect.

BERNSTEIN ON THE HEIGHT OF THE MUSCULAR TONE UNDER ELECTRICAL AND CHEMICAL STIMULATION.—The tetanic contraction of a muscle, whether produced voluntarily or artificially during life, consists in a vibrating motion of small particles in the interior of the muscular fibre. This is shown by the negative variation of the muscular current discovered by Du Bois-Reymond, and by the muscular tone which, according to the investigations of Helmholtz, consists of as many vibrations as the number of stimuli applied. The normal muscular tone, which is heard during voluntary contraction, consists of, according to Helmholtz, only 18 or 20 vibrations per second, but by means of an electrical tuning-fork much higher tones could be produced. In the human forearm he produced a clear tone with 240 vibrations.

J. Bernstein (*Pflüger's Archiv*, xi. 191), investigated the muscular tone produced by a greater number of stimuli per second. A special form of electrical tuning-fork was employed. The shocks were applied to the muscles of the leg of a rabbit, where the muscular tone can be easily heard when a stethoscope is applied over the skin. Three hundred and thirty vibrations gave a tone of the same height, tolerably strong, and of the same *Klangfarbe*; 418, 561, and 748 vibrations per second gave each corresponding tones. With 1,056 vibrations no distinct tone was to be heard in the muscle, although the muscle still contracted; instead of the tone, ill-defined noises occurred. When the nerve instead of the muscle directly was stimulated, 1,056 vibrations still gave a distinct tone, audible in the muscle; but

this tone no longer corresponded with the vibrations of the tuning-fork, but was a fifth, sometimes an octave, deeper. It now remained to determine the upper limit to which the muscular tone could be increased by the present apparatus. This was perfectly fixed when the tuning-fork gave the tone $b'' = 933$ vibrations, in which case the muscular tone of similar pitch was softly but distinctly audible.

There is a relation between the muscular tone, contraction, and the negative variation. With 300 vibrations per second, the muscular tone was of almost constant moderate pitch. With 300 to 400 vibrations it began to be weaker. Now, as a negative variation of the muscular current corresponds with every vibration of the muscular tone, so it is very probable the weakening of the tone depends upon the duration of the negative variation, which lasts about $\frac{1}{300}$ second. Chemical stimuli (saturated solution of chloride of sodium) applied to the nerve also gave a distinctly audible muscular tone.

MERING ON THE ACTION OF CHLORAL-HYDRATE AND CROTON-CHLORAL-HYDRATE.—J. V. Mering (*Archiv für Experimental. Pathologie und Pharmak.*, iii. 185, and *Centralblatt*, no 37, 1875) states from his experiments, that croton-chloral-hydrate, when given in small doses to rabbits before the cessation of the reflex action from the cornea, considerably retards the respiration; and when the corneal reflex action is extinguished, the number of respirations is diminished by a half. The substance (0.6 gramme) was introduced subcutaneously, or divided in scarcely half as large total doses and injected into the veins. Similar results were obtained with parallel experiments with chloral-hydrate. Croton-chloral-hydrate acts upon the frog's heart similarly to chloral-hydrate, even small doses (0.025 gramme given subcutaneously) causing cessation of its action. Blood-pressure experiments upon dogs, cats, and rabbits were performed with both substances. Small doses diminish the blood-pressure temporarily, and large doses diminish it continuously, till the blood-pressure curve reaches the abscissa. The pulse-beats are at first increased by both drugs, and this increase lasts somewhat longer with croton-chloral-hydrate. At a certain stage of the experiments the blood-pressure remained continually low, in spite of great blood-movements. This seems to show that the croton-chloral-hydrate extinguishes the arterial tonus, the heart's energy still continuing; this being, as is known, asserted of chloroform and chloral-hydrate. From these and former experiments, there seems to be a great similarity in the actions of the three above-mentioned drugs.

Lastly, the author combats Liebreich's theory of the action of croton-chloral-hydrate. According to this theory this substance in alkaline blood splits up into dichlorallylen, hydrochloric acid, and formic acid, and the former, analogous to aethyliden chloride, is the active factor.

The author employed only the trichlor-crotonate of soda, which even in the cold in dilute alkaline solutions passes into dichlorallylen. This substance was injected into rabbits, and even when five grammes were injected, it had no effect.

STEINER ON THE IMMUNITY OF THE TORPEDO AGAINST ITS OWN SHOCK.—J. Steiner (*Reichert and Du Bois' Archiv*, p. 684, 1874) reinvestigated this subject in the zoological laboratory of Naples. As larger animals give a more powerful shock, the author investigated the relation of the body-weight to that

of the organ, and found this relation nearly constant (about four to one). He concludes from this that the intensity of the shock in the body of the shock-yielding animal must be almost independent of the size of the animal. Whilst the shock of small rays freshly taken out of the water is clearly perceptible when one touches the posterior aspect of the organ, nothing is felt in large animals on touching any other part of the body where no organ is placed, not even on a spot lying between both organs and over the capsule of the brain. Nevertheless, a frog contracts with every shock when it is placed on the tail of the fish. A small ray also contracts when it is laid upon the posterior part of a larger one. In quite fresh animals, Dr. Steiner observed that their own body-muscles contracted with each shock. The immunity in the sense as at present accepted, therefore, does not exist. If two animals lie in the water favourably situated one over the other, it may be observed that the one contracts through the shock of the other, just as every fish does by its own shock when this is not too weak. The rays were also sensitive to the electric currents of a Bunsen's battery and to induction-shocks, but in a less degree than other fishes and than frogs.

DÖNHOF ON CO-ORDINATING CENTRA IN THE BEE.—Dönhoff (*Reichert and Du Bois' Archives*, 1875, Heft i. 47) observes that if the head be suddenly cut off a bee, and honey applied to its proboscis, sucking movements are made. The centra for co-ordinating the sucking movements must be in the head. If the body be separated from the head, the bee makes instinctive movements as if collecting pollen. If the body be placed on its back, it is turned over, so that the bee comes to stand on its feet. The centres for these movements lie in the thorax. If the abdomen be cut off and pressed up, the sting is pushed out and retracted, just as by an intact bee when it is touched on any part of the body. The centre for these stinging movements lies in the abdomen. The co-ordinating centres are therefore distributed over the brain and the ventral cord of the thorax and abdomen.

PREYER ON SLEEP PRODUCED BY FATIGUING-STUFFS.—W. Preyer, of Jena, in a preliminary communication to the *Centralblatt*, no. 35, 1875, records the results of some experiments with salts of lactic acid in the production of sleep. He finds, when a concentrated watery solution of lactate of soda is injected subcutaneously, or introduced in large quantities into the empty stomach, that the feeling of fatigue, of drowsiness, and a condition similar to or identical with natural sleep, very frequently occurs, provided that strong stimulation of the sensory apparatus be withheld. In many cases also yawning and sleep may occur when no sodic lactate is introduced directly, but when the conditions are present for the abundant formation of this substance in the intestine, as by drinking highly concentrated sugar solution, etc. There are great variations both in the period of occurrence, duration and intensity of the sleep. It differs with the age, size, and reflex activity of the animal.

TARCHANOFF ON A NEW MEANS OF ARRESTING THE HEART OF A FROG.—J. Tarchanoff (*Arch. de Physiol.*, 1875, p. 408) pulled out a loop of intestine with its corresponding piece of mesentery from the left abdomen of a frog, and exposed the loop to the air for a few hours until it became in-

flamed. The slightest touch of the inflamed loop sufficed at once to produce still-stand of the heart. The time of arrest varies from a few seconds to half a minute. The experiment does not succeed by gently touching the loop of intestine when pulled out at first, and while it is still uninflamed, nor after section of the vagus or poisoning with curara. The arrest takes place through the same mechanism as in the experiments of Goetz and Bernstein.

PERREYMOND ON COMMUNICATION BETWEEN THE CARDIAC AURICLES IN THREE FEMALES WITH CURVATURE OF THE SPINE.—M. Perreymond, interne at the Hôtel-Dieu Hospital of Toulon, sends an article to *L'Union Médicale* of August 7, 1875 (no. 93), containing an account of the occurrence of patent foramen ovale in three deformed females. The cases are briefly as follows. The first, aged thirty-three, a street-sweeper, was brought cyanotic to the hospital of Toulon, on March 7, 1873, and expired almost immediately. Her neighbours said she had frequent attacks of dyspnœa, in which she became almost black. She took a good deal of brandy, because she said that she was always cold. The spine was found curved greatly forward in the dorsal region, with slight lateral (right-sided) curvature. The lumbar spine was curved to the left. The left side of the chest was badly developed, and the lung of that side was scarcely one-third the usual volume. The heart was of great size, and placed on the right side and upper part of the chest, its base corresponding to the third right ribs. It covered the greater part of the right lung. The right half of the thorax descended lower than the left, forming a sort of narrow excavation, which lodged the right lung; which was thus subjected to the pressure of the ectopic heart above, and in its lower two-thirds to that of the posterior surface of the liver. The venous system was gorged with dark blood. The right auricle of the heart presented a large coagulum, communicating by means of an interauricular canal, with the blood coagulated in the left auricle; this canal, large enough to admit the little finger, was formed by the anterior and posterior semilunar folds of the membrana ovalis not being united; this was attached to the inferior cava by the greatly developed Eustachian valve. The right auricle was very large, and the tricuspid valve atrophied. The pulmonary artery was dilated.

The second case was observed in a woman thirty-four years old, who had spinal curvature. She died at the Maternité, of puerperal metro-peritonitis. Her spine was twisted to left, to right, and to left again. The pelvis was much deformed, obliquely ovate, and its conjugate diameter was only 2½ inches. At the lower part of the fossa ovalis of her heart there was a punched-out opening, round and with

smooth edges, about a quarter of an inch in diameter. The pulmonary artery was rather dilated; the tricuspid valve was incompetent, and the Eustachian valve atrophied. A month before her death, she was attacked with urgent dyspnoea with præcordial pain, in consequence of which the face and extremities became cyanotic. Auscultation was negative as far as regards the heart.

The third case relates to a poor hump-backed woman, aged thirty-seven years, who was about eight months advanced in pregnancy. She was attacked with pneumonia during the induction of premature labour, and died at the Maternité on February 25, 1875. Her spinal deformity was monstrous, resembling a wimble. The pelvis was much deformed. The right heart had eccentric hypertrophy, and the tricuspid orifice was dilated. In the anterior part of the foramen ovale, there was an opening a little bigger than a goose-quill. Her breath had been short, and from time to time she had attacks of dyspnoea, and was cyanotic. No cardiac bruit was noted. These facts, says M. Perreymond, do not stand alone. Amongst others similar there is one in the *Bulletin de la Société Anatomique* (2e série, tom. xii. p. 525): *Gibbosité rachitiques: Accès de dyspnée et de cyanose: Congestions pulmonaires: Persistance du trou de Botal*, by Dr. Chantreau.

The question arises, Is this co-existence of spinal deformity and interauricular communication a mere coincidence, or do they stand in relation of cause and effect to one another? We do not know all the causes which produce this patency of the foramen ovale. It generally goes along with stenosis of the pulmonary artery, and this, according to Louis, Bouillaud, [Peacock], etc., leads to the persistence of Botal's foramen. In these three cases the pulmonary artery was not contracted. Ought we to think that in rachitic humpbacks the heart is very early affected on account of the difficulties of the respiratory organs?

Dr. Bouvier says [*Leçons cliniques sur les maladies chroniques de l'appareil locomoteur*, p. 448] 'that the peculiar affections of the respiratory organs in cases of spinal curvature, affect the whole of their physiology. This influence is greatest in the heart, whose right cavities have great difficulty in unloading themselves of the venous blood which rushes into them.' In this way, he says, the right cavities become dilated. This dilatation is purely mechanical, being brought about by the greater tension of the blood in the right heart, owing to the embarrassment of the pulmonary circulation. May we not suppose then, knowing as we do that the closing of the foramen ovale is scarcely ever absolute in the most healthy, that the stress on the pulmonary circulation in these cases of rachitic spinal deformity either prevents the closure of the orifice between the two auricles, or may even reopen the communication when once closed? W. BATHURST WOODMAN.

HAMILTON ON THE PATHOLOGY OF MYELITIS.—An interesting inquiry into the morbid processes of myelitis by Mr. D. J. Hamilton is published in the current number of the *Quarterly Journal of Microscopical Science*, in which the author describes the microscopical appearances presented by the spinal cord after artificially induced inflammation, for he is of opinion that 'many diverse conditions have been described' as inflammatory 'which no doubt owed their origin to entirely different pathological processes.' One great source of fallacy he points

out as 'the inability to distinguish between the lesions known as "secondary degenerations" produced by failure of the trophic or nutritive nervous action exerted by the nerve-cells on the fibres to which they are attached, and those which are localised to a certain spot.' The most marked tissue-change was observed to occur in the axis-cylinders of the nerve-tubes, which were found to be swollen at intervals to four or five times their normal diameter. In some cases they formed oval tumours detached from each other, in others they were joined together by attenuated portions of the axis-cylinders. Most of the detached portions were homogeneous, but a few of them seemed to be marked by rings. These free masses were observed to undergo fissiparous division, and to give rise to little colonies of cells which invaded the adjacent tissues, leaving the distended nerve-tubes empty, and appeared to be identical with the colloid masses which are found in certain chronic nervous affections of the cord. In regions where the inflammatory process was less acute, the altered axis-cylinders did not pass beyond this colloid stage, but in parts more remote they gave rise to pus-corpuscles.

The most noticeable change in the nerve-cells was a 'swelling or molecular transformation of the cell-substance, by which its outline became indistinct;' the nucleus persisted for some time, but finally suffered a similar degeneration. No fissiparous division of the cell was observed.

The neuroglia simply presented an increase in the number of its protoplasmic nuclei.

Numbers of clear corpuscles were visible in the perivascular spaces and tunica adventitia of the blood-vessels of the pia mater, near the seat of lesion; some were also to be seen adhering to the inner coat of the vessels, and scattered through the grey matter. These were probably migrating white blood-corpuscles.

The author lays it down as a rule that, wherever the above-mentioned colloid bodies occur, the medullary sheaths are generally found to be distended and the axis-cylinders absent, as in those lesions of the nerve-centres which accompany locomotor ataxy, epilepsy, etc.; and he draws the conclusion that these and other diseases of the nervous system are essentially of a chronic inflammatory nature.

MEDICINE.

JANEWAY ON VOCAL FREMITUS IN PLEURISY AND PNEUMONIA.—Dr. E. Janeway (*New York Medical Record*, June 15) writes:—The value of vocal fremitus as a physical sign in the diagnosis of pleurisy with effusion from pneumonia is, it seems to me, not infrequently rated too highly. Some, in fact, appear to consider it an absolute means of distinguishing the one from the other condition. My reasons for not esteeming it as much as those who hold this opinion, are based upon the observation of cases in which such a belief would have been or proved to be a mistake. Let me first give a brief record of two cases of pleurisy with effusion, in which vocal fremitus was present over the affected portion.

The first of these was a male patient in Ward 8 of Bellevue Hospital last summer (Simms), aged thirty-three. He was taken sick two days before admission with rigors and a pain in the left side. When admitted the physical signs of interest were: Flatness on percussion on the right side of chest below the angle of the scapula, increase of vocal fremitus over the affected portion, feeble and distant respiratory sounds, ægophonic vocal resonance.

June 3, two days later, distinct vocal fremitus was present over the affected portion, and a hypodermic syringe withdrew clear serum from the pleural sac at this part.

Aspiration of the affected side was performed several times, with only partial relief, and in consequence of obstruction to the needle, or failure of the apparatus, on two occasions but little fluid was obtained. After the second aspiration, air was detected in the pleural cavity above the level of the remaining fluid, but below this vocal fremitus persisted. Later seropus and pus formed in the cavity, and it was decided to make an opening in the pleura, and allow the fluid to drain off. The reasons for the operation were the great dyspnoea, the existence of pus in the sac, the failure of aspiration to afford relief which was more than temporary, the increasing weakness of the patient, and finally paroxysms during which the patient would pass almost into a state of collapse. The day following the incision vocal fremitus disappeared from the affected portion. On November 12 the patient was discharged.

The second patient was a male, fifty years of age, admitted to Bellevue Hospital on November 17, 1874. His illness had commenced one month before, with symptoms which pointed to the existence of pneumonia on the left side. When admitted he was thought to have a chronic pneumonia, pleurisy with pneumonia on the left lower lobe, extending into upper. Of this man I made a careful examination about a week before his death. The following physical signs were then present. Flatness on percussion existed over the lower lobe of the left lung, except near its most anterior portion; here there was some resonance. Bronchial voice, whisper, and respiratory murmurs were heard over this part more distinct above, more distant and feebler below. Measurement showed the two sides to be of equal size. The heart was not displaced, and vocal fremitus existed over the affected portion, and was increased as compared with the opposite side. There was no change of the level of flatness on percussion, and this line of flatness corresponded very closely to the interlobar suture.

The character of the bronchial breathing and voice made me suspect fluid, and at my request the house physician, Dr. Chapin, introduced the needle of a hypodermic syringe in the pleural sac, but failed to obtain any fluid. The hypodermic syringe seemed to be good, as tested by drawing up water from a tumbler. I then proposed bringing an aspirator on the succeeding day, for more thorough exploration, but the patient passed into a typhoid state, seeming to indicate the existence of meningitis as a complication. A *post mortem* examination revealed dilatation of the ventricles of the brain with a granular condition of the ependyma, and empyema of the left side corresponding to the site of the left lower lobe, and shut in by adhesions of the upper lobe. A small portion of the anterior part of the lower lobe was adherent to chest, near heart, and the rest was carnified and pressed upwards, inwards and backwards. The heart was not displaced. The lower part of the upper lobe of the left lung was hepatized. There was no adhesion of the lung over the space where I had perceived vocal fremitus; nor was any band-like adhesion, such as sometimes occurs, present.

These two cases, which have been observed within a period of eight months, are sufficient to show that vocal fremitus may be present over fluid in the pleural sac, and may even be exaggerated. The disappearance of the vocal fremitus in the one case after the removal of the fluid, and the results of the *post mortem* examination in the other, show that the vocal fremitus was conducted through fluid to the chest wall.

In addition to these cases, I have observed two others during the same period, in one of which a slight vocal fremitus existed over fluid in the left pleural sac. This was enough to cause one physician to doubt the correctness of the diagnosis, though the left was two inches larger than the right and the heart displaced. He, however, confessed, when a hypodermic syringe drew fluid from this portion, and an aspirator removed sixty ounces of serum.

In the other case the vocal fremitus was increased, but of this case I will make no use, as the patient escaped from my observation before I was able satisfactorily to determine the conditions present.

Again, cases present themselves in which the vocal fremitus is exceedingly feeble or absent on the healthy side, and then the absence of this sign has no especial value on the diseased side.

Such a case I have lately seen in a young man with rheumatic pericarditis and a small effusion in the left pleural sac. In this case vocal fremitus is absent at corresponding points on the two sides, but above the level of the fluid for a short distance it is considerably increased on the left or affected side; while at a corresponding point on the right side it is only feebly perceptible. Bronchial character of the expiratory sound is audible over the fluid and broncho-ægophony exists near its upper limit. I can very readily imagine that an incomplete examination might lead to the supposition of pneumonia. While I have been writing this article, the fluid has accumulated somewhat on the right side also, but the vocal fremitus remains as at first. On the other hand, cases have occurred in which pneumonia has been mistaken for pleurisy, with effusion, by very good observers. Some years ago I made the *post mortem* examination in a case of supposed pleuritic effusion. The autopsy revealed a

small aneurism resting on the left main bronchus, and this is completely occluded by a firm thrombus which had formed by the escape of blood from the aneurism into it by means of a small opening. The left lung was throughout in a state of grey hepatitis, and its bronchi were filled with purulent fluid. Those who had seen this case during life stated that all the signs of pleuritic effusion had existed, absence of vocal fremitus, of respiratory murmur, of vocal resonance, with the existence of flatness on percussion. If any suspicion of the real condition of affairs had been entertained it seems probable that absence of displacement of the heart, and of increase of the measurement of the affected side, might have corrected the diagnosis, considering the extent of disease. Since that time I have seen a second nearly identical case.

Again it sometimes happens that with ordinary pneumonia producing complete solidification of a lobe, considerable diminution or absence of the vocal fremitus may occur.

My friend and colleague, Professor Flint, is also in the habit of drawing attention to the greater value of absence of vocal fremitus on the right side as a sign of pleuritic effusion, and of its exaggeration on the left side as a sign of pneumonia, in view of the normal difference of vocal fremitus on the two sides.

It will be obvious that, in this article, I have considered that the more important physical signs, percussion and auscultation, have pointed out the site of the disease, but have not been able to establish the diagnosis.

ESPINET ON THE LEPER ASYLUM OF TRINIDAD.—Dr. Espinet (*Report of the Medical Superintendent of the Leper Asylum for the year 1874*, Legislative Council, June 1, 1875) reports the rate of mortality as diminished, and probably less than in any previous year since the asylum was established in 1843, the total number of patients being 114, the total number of deaths nine; of these nine fatal cases, five were of the tubercular, and four of the anæsthetic form. The immediate cause of death was in one chronic hepatitis; in two diarrhoea; in four exhaustion; in two dropsy. The diminished mortality is ascribed to several causes, viz., the exceptionally healthy condition of the island; the improved drainage of the asylum and surrounding swamps; the removal of surrounding brushwood; improved nursing; a regular system of labour and exercise introduced by Dr. Gavin Milroy, and the lesser number of patients brought to the hospital *in extremis*.

The popular belief that lepers are long-lived is an error; leprosy is, in the great majority of cases, an incurable disease, which progresses *per se* to a fatal termination, and lepers succumb to general diseases more rapidly than others. Children are more severely afflicted than adults; and it may, Dr. Espinet thinks, be laid down as a law that the severity and rapidity of progress of the disease are in proportion to the earliness of the period of life in which it is first developed. Leprosy is confined principally to the poorer classes, but it is met with in every race in the island, black, white, or mixed. Instances of the disease have been seen in Germans, Italians, Poles, Irishmen and Englishmen, after a residence of some years. The races most subject to it, however, are the Portuguese and Hindoos. In the latter the disease is confined principally to the male sex, six females only having applied for and

obtained admission to the asylum in six years, as compared with forty-eight males admitted, in addition to many others refused for want of room.

This comparative immunity of female coolies is in accordance with Dr. Carter's observations on leprosy in India, where he found the proportion of males to be 81.4 per cent. of the number affected, whereas in Norway it is only 56 per cent.

Dr. Espinet is of opinion that the Indian and Portuguese immigrants, in whom the disease appears after their arrival in the island, have it by inheritance, and not from hygienic causes, independent of family taint; and the period of incubation may be prolonged beyond the limit of fourteen years assigned by Professor Boeck, of Norway; in some cases even to thirty years or more. Leprosy is indeed most frequently inherited, but in certain cases it is contracted accidentally, in some way not easily explained. Danielssen and Boeck found that of 213 cases, the disease was hereditary in 185, and that it was of spontaneous development in 28 only. The hereditariness was more frequent on the maternal than on the paternal side, and in the collateral than in the direct line. In some cases there is a suspension of the disease, and patients in that condition may reach the average term of life. According to Dr. Carter, a period of from three to six years may, it is known, elapse before the return of pains, fever, or eruption, but how much longer a period is not determined. Such cases belong almost exclusively to the anæsthetic variety. The statement that children are born leprosy, or become so shortly after birth, is not borne out by Dr. Espinet's experience. He has never seen an instance of leprosy at an earlier period of life than four or five years, even in the children of parents in the advanced stage of both the anæsthetic and tuberculous forms. When the disease appears in early life, and before puberty, it checks both growth and development. Of ten male inmates between fourteen and eighteen years, eight do not exhibit the slightest marks of even approaching puberty; in the remaining two the sexual organs are fully developed, but the other signs of virility are only just beginning to show themselves. The female children gain little in stature; menstruation appears late, and is scanty and irregular.

Dr. Espinet considers that leprosy has some pathological connection with phthisis, epilepsy, and insanity. Full data as to the distribution of lepers in the island are wanting; but it would seem as if local peculiarities of soil, climate, and situation have little influence in the production of the disease, since patients come from most parts of the island, from places of the most opposite topographical character.

For the prevention of the spread and development of leprosy, the following measures are suggested.

1. Medical examination of immigrants before they are permitted to land, those affected with disease being either returned to their own country, or transferred to the leper asylum.

2. The segregation of lepers, and the separation of the sexes.

3. The mitigation of the leprosy diathesis in families, by hygienic measures, such as simple nutritious diet, regular exercise where practicable, and change of climate—to a place where leprosy is not endemic.

4. Early treatment of the disease by the preceding means, and by appropriate medicines.

The internal remedies found most beneficial in the incipient stage of leprosy, when the characteristic

stains only exist, are tonics, such as quinine, iron, cod-liver oil, Parrish's chemical food, and the so-called alteratives, iodide of potassium, liquor potassæ, and hyposulphite of soda.

The external applications used are baths of salt or fresh water, or medicated with sulphuret of potassium, and frictions with Chaulmoagra oil, tincture of iodine, *huile de cade*, or oil of the cashew-nut. The cashew-nut oil was employed after Dr. Beauperthuy's method with decided advantage in several cases, and yielded better results than any other plan of external treatment.

In one case of anæsthetic leprosy, of seven years' standing, there was slow and gradual return of sensibility to the limbs, perspiration partially re-established, increase of muscular strength in the limbs, considerable relaxation of the contractions of the fingers, and return of normal heat to the skin; but a relapse occurred after five or six months. In another case, however, the amelioration had continued up to the date of the report.

In the tubercular form, the tubercles may be entirely removed by the cashew-nut oil, and the skin apparently restored to its normal state; but the tubercles return in from three to eight months after the suspension of treatment, in greater luxuriance.

Twenty-two selected cases were treated after Dr. Beauperthuy's method by Dr. Brissac, at Guadeloupe, and in five an apparent cure followed; but whether this was permanent, has not been ascertained.

The cashew-nut oil is most beneficial in the anæsthetic form of the disease, and at its commencement, when, by its blistering action, it removes stains, and appears to restore sensibility, by liberating the extreme nervous filaments from the albuminoid deposits which surround them. When the main trunks and nervous centres are implicated, it does not seem capable of producing lasting good. Leprosy, being a constitutional, and not a local cutaneous parasitic disease, as supposed by Dr. Beauperthuy, should be treated principally by internal remedies; since external applications remove only effects, not causes of the disease.

W. B. CHEADLE, M.D.

KARRER ON THE PRESENCE OF ALBUMEN IN THE URINE OF EPILEPTICS.—No. 27 of the *Berliner Klinische Wochenschrift*, July 5, 1875, has a carefully written paper on this subject, by Dr. Ferd. Karrer, assistant medical officer of the lunatic asylum at Erlangen. He states that, in no. 59 of *Virchow's Archiv*, Dr. Huppert, of Colditz, published an article, entitled, 'Albuminuria a symptom of epileptic attacks.' His researches led him to conclude that 'every epileptic seizure, whether pronounced or abortive, is immediately followed by a transitory albuminuria.' He further concluded 'that the more frequent the attacks, whether masked or otherwise, the more violent they are; and the sooner afterwards the urine is examined, the greater, within certain limits, will be the quality of this abnormal albuminous infiltration.'

His method was to heat to boiling point about fifteen cubic centimetres of urine, and when partly cooled to add about eight drops of nitric acid; then to let it stand for sixteen or twenty-four hours in a cool place, and note the result. He classifies the albuminous reactions under three degrees. The first or slighter degree consists in slight turbidity or opalescence, to recognise which oblique illumination, or the shade of

some dark body (as the bar of a window, etc.) may sometimes be necessary. The second degree, which he considers the commonest, consists in more or less decided whitish clouding or turbidity, of unmistakable character. The third degree consists of flocculi and sediments. As his method rests on a single test, considerable stress is laid upon 'traces' of albumen, and very small quantities of it. The smallness of the quantity accounts for its having been so long and so frequently overlooked.

In the summer and autumn of 1874 Dr. Karrer spent some time in examining this question, with all the precautions advised by Dr. Huppert. He examined the urine of about a dozen epileptics, all of whom had been so ten years; all had severe attacks, and there was mental disease in all. In not one of these, although the urine was repeatedly examined just after the fits, did he find albumen in the urine. Although he attributes little importance to the opalescence of the urine in Huppert's method, this reaction was not forgotten. At first Dr. Karrer used three tests. (1) Boiling, with a small quantity of acetic acid; (2) Heat and nitric acid; (3) Nitric acid alone, and latterly (4) Ferrocyanide of potassium and acetic acid. As a reason for attributing but slight importance to the opalescent appearance after heat and nitric acid, he gives the following experiments.

The urine of seven male patients with chronic mental disease was treated (1) by nitric acid alone, and (2) by heat and nitric acid. In all of these, after standing twelve hours, there was more or less opalescence, and in one some turbidity. He now prepared, by diluting a 0.6 per cent. solution of egg-albumen, solutions containing 0.06 per cent.; 0.006 per cent.; and 0.0006 per cent., etc., and these were tested precisely as the urine, with the following results. The 0.0006 per cent. gave immediate turbidity, and after standing, a fine flocculent precipitate. The 0.0006 per cent. gave turbidity, and after long-standing, a very slight precipitate. With 0.00006 per cent. there was no reaction. Similar solutions were treated at ordinary temperatures with the ferrocyanide and acetic acid test, with the following results: In 0.006 per cent. copious flocculent precipitate; in 0.0006 per cent. tolerably copious precipitate; in the 0.00006 per cent. still fairly abundant precipitate. Even 0.000006 per cent. gave whitish turbidity in one trial, and (after 6 or 8 hours) some flocculi in another! The ferrocyanide and acetic acid test was now added to the urines which had been tested with nitric acid. They gave no reaction. Then ten cubic centimetres of urine and ten cubic centimetres of the 0.00006 per cent. albumen solution were mixed, so that each test-tube contained 0.00003 per cent. of albumen. In every case the ferrocyanide and acetic acid gave a pretty copious flocculent precipitate after about a couple of hours. In 0.000003 per cent. mixtures of albumen and urine, he could obtain no reaction in this way. He therefore concludes the prussiate of potash test to be far more delicate, and is inclined to consider opalescence with nitric acid as of little value. Therefore his method detects $\frac{3}{10,000}$ of albumen in the urine, though $\frac{3}{100,000}$ may still be problematical. He justly remarks that the presence of albumen should scarcely be inferred except two tests give a similar result.

[The reporter having himself devoted a good deal of time and trouble to the question of how best to detect albumen in the urine, and having also exa-

mined the urine of about thirty epileptics just after their seizures, begs to add to this paper of Dr. Karrer's the following remarks. (1) It is certainly not true that all, or even the majority of epileptics, have albumen in their urine immediately after the fits, so far as any of the recognised tests for that substance may be trusted. So far he thoroughly agrees with Dr. Karrer.

But (2) some epileptics do, undoubtedly, exhibit a transitory albuminuria, and this just after fits. This appears partially explicable by diet, as it chiefly occurred in those fed on a highly nitrogenous diet. (3) The reporter believes that sediments should be examined with the microscope, so as to correct the chemical tests, and further that albumen is present in urine in several forms, which differ clinically as well as chemically; and whilst he agrees that more than one test should be used, he dissents from the proposition that egg-albumen is identical with all or even most of the albumen present in urine. Will not some of our superintendents of asylums make fresh trials (by several tests) of the urine of epileptics immediately after the fits, and in the intervals?—*Ref.*]

RISEL ON A HYDATID CYST OF THE LIVER TREATED BY INCISION: RECOVERY.—The publication of Ranke's case from Volkmann's clinic (*Deutsche Zeitschrift*, 1874, no. 45) has induced Dr. Risel, of Halle, to publish the following case in no. 28 of the *Berliner Klinische Wochenschrift* (July 12, 1875). Mrs. F., aged thirty-seven years, sought advice in September, 1874, on account of pains in the right hypochondriac region, which had lasted about a year. For a week or two before applying they had much increased in severity, and were associated with vomiting and urgent desire to pass urine. She had given birth to a fourth child, whilst in a standing position, an hour and a half before being seen! She was slightly jaundiced. Between the mammillary and axillary lines there was a hard tumour, not fluctuating, but very sensitive to fine pressure, about two and three-eighths inches in its vertical, and four and three-quarters inches in its transverse measurements. It appeared attached to the liver. Its lower border, which was rounded, showed a slight crescentic notch, like the hilus of the kidney. Above this was apparently the thin edge of the liver. The tumour could be moved from side to side under chloroform, and so much so, towards the axilla, as almost to be pushed out of reach of the finger. The liver did not seem to move with it in these manœuvres. There was bile-colouring in the urine. The laxity of the abdominal walls greatly assisted in this examination.

Towards October the jaundice had vanished, there was obscure fluctuation, and the tumour had considerably increased in size. An exploratory puncture to the depth of one and a quarter inch brought away a liquid fluid containing chloride of sodium, but no albumen, and no trace of animal tissues. There seemed to be a little succinic acid ($C_4H_6O_4$) but the quantity of fluid was too small to allow its accurate determination. On November 9, about forty Carlsbad needles were inserted in the tumour within a space of about $3\frac{1}{4}$ by $1\frac{1}{2}$ inches. The whole was covered over with one of Lister's compresses. The skin in the vicinity of the needle-heads, and even the subcutaneous tissue, having ulcerated, nearly all the needles were taken out next day. On November 13, an exploratory puncture

showed that the contents of the cyst, now considerably more tense, were puriform. Next day, with some difficulty, a curved Simon's trocar was forced through the anterior wall of the cyst, and an India-rubber drainage-tube introduced. Very little fluid escaped through this. Her temperature rose from its previously normal limits to 99.7° in the morning of the 19th, and 104° Fahr. in the evening. On the 20th, an incision, rather more than an inch in length, was made with a bistoury through the thickened tissues, a director being passed alongside the drainage-tube. Nearly seventy ounces of purulent offensive fluid with a quantity of collapsed and in part bile-tinged echinococcus cysts of various sizes escaped. The remaining needles were removed, the cyst washed out with a 2 per cent. solution of carbolic acid; and a five-inch drainage-tube, as large as a finger, was left in, and one of Lister's compresses laid over all. During the next fourteen days many hydatids of varying size, but all collapsed, escaped. The cyst was frequently washed out with the carbolic acid solution, and treated antiseptically throughout. The further progress of the case (except for a transitory attack of erysipelas ascribed to an instrument not perfectly clean) left nothing to be desired.

W. BATHURST WOODMAN.

CHOATE ON HÆMATURIA.—In the *Boston Medical and Surgical Journal* for September 16, is a case of hæmaturia related by Dr. David Choate. It is as follows. J. M., the patient, was a man about forty years of age, of a robust frame and healthy countenance. He complained in May, 1874, of blood in his urine, reporting that it was seen first in February, three months previously, at which time it was small in quantity and lasted but three or four days. He was then free from it for about a month. From the date of its reappearance, it persisted uninterruptedly. The amount lost from day to day could hardly be conjectured. The quantity of urine and blood together was not greater than would be considered normal for urine alone, but the whole was invariably of a deep blood colour. When the urine was allowed to stand, there was deposited a layer of blood-corpuscles. The blood was always intimately mixed with the urine; it was never passed by itself, in liquid form or in coagula. The microscope discovered neither mucus nor pus nor casts; the whole field was filled with blood-corpuscles. On one occasion the microscopist saw what he suspected to be a cancer-cell. Albumen was present, but only in quantity proportioned, as it seemed, to the amount of blood. An increased frequency of micturition was spoken of by the patient as occurring in the early stage of the complaint; it lasted about three weeks, but after he came under observation there was none during the entire sickness. He had no pain in the region of the bladder or loins, or in the course of the ureters, with a single exception; and this just as the disease reached its climax, in November, a point to which reference will be made later in the report.

Contrary to advice, the patient continued at his work, favouring himself as far as possible in respect to lifting, until July 3, when he was induced by loss of strength and the hope that remedies might prove more efficacious, to cease from labour entirely. He continued still to go abroad into the air, avoiding all sudden and violent movements, till near the close of October. From this time he remained indoors, and soon afterwards was compelled, by the increasing debility and the vertigo and faintness consequent

upon assuming the erect posture, to take to his bed. The anæmic state was now fully developed, as the skin and mucous membranes clearly witnessed.

The disorder pursued its way, well-nigh unaffected by remedies, up to the fourth week in November. The hæmorrhage was so obviously passive that the medicinal treatment consisted almost exclusively of the administration of the various astringents. The only one of these that appeared at all to influence the flow, and which gave some promise of arresting it, was gallic acid, given at the suggestion of Dr. Mack (who saw the patient once), in doses of five grains every two hours. This was afterwards increased to seven grains every two hours, day and evening, and continued thus through several successive days.

On November 21, hypodermic injections of ergotine were begun. Of a solution containing two grains in a fluid drachm of glycerine and water, six drops (equivalent to about one-fifth of a grain) were administered twice daily; this was given on the 21st, 22nd, 23rd (one dose only this day), 24th, and 25th, the dose having been during this time increased by two drops, bringing it up to rather more than a quarter of a grain. On the 26th the stomach became irritable, and vomiting occurred; the medicine was therefore suspended. Vomiting persisted through the entire night of the 26th. On that day, however, the urine suddenly became clear, and so continued from that time onward. Some twenty-four hours later the patient had a sharp attack of pain in the course of the right ureter, followed by the passage of a small coagulum, apparently moulded by the ureter.

From the condition of extreme anæmia into which he had sunk, he slowly recovered.

INGLIS ON AN ANOMALY OF PERSPIRATION.—In the *Detroit Review of Medicine* for August is a communication by Dr. David Inglis, to the following effect.

Mrs. F., aged forty-five, strongly built, generally healthy, mother of four children, the youngest aged about eight years, gives the following history. Five years ago, her health, which had previously been good, began to suffer. She had leucorrhœa, and other symptoms of uterine trouble. She was also much afflicted with pains in all parts of her body, which, from her description, seem to have been of the nature of subacute rheumatism. After passing through the hands of various physicians, she came at last to a travelling 'root-doctor,' who left her a large quantity of his wares, to be taken in large doses. Hereupon her pains left her, but a trouble began which continued unabated up to the time when I saw her, some six weeks since, namely, profuse perspiration, brought on nightly by lying upon her right side. This phenomenon occurs regularly every morning after a night's rest in bed, and only then, her usual habit being to turn over on to her right side, and at once a general perspiration begins, which at once ceases upon her turning back on to her left side. She can lie upon her right side during the day, or early part of the night, without perspiring. If she do not turn upon her right side, and so secure a sweating in the morning, she feels much oppressed during the day, has a headache, and is poorly until she again has a sweat the next morning. If, owing to other causes, the sweating be stopped, she feels the same oppression and headache, and it was upon such an occasion that I was first called to

see her. Upon giving some sudorific she was soon relieved. Further, she is in summer, during warm weather, very prone to perspire, and has every summer much annoyance from a very abundant crop of sudamina, which causes an almost intolerable itching. The sweating in winter is not accompanied by sudamina, and the perspiration has at no time any peculiar odour. J. MILNER FOTHERGILL.

JASTROWITZ ON THE PATHOLOGY OF HEMIPLEGIA.—This paper (*Berliner Klinische Wochenschrift*, August 2, 1875), treats more of the diagnostic symptoms of hemiplegia than of the pathology of that disease.

In cases of coma where it is doubtful which side is affected, the author gives one or two symptoms which he has found useful in deciding that point. He considers that the condition of the pupil is of much value, because there are three sets of nerves concerned, viz., the sympathetic, the motor oculi, and the tergeminum. At the same time this very fact renders it difficult to state the exact portion of the brain which is affected.

In males there is a symptom which is of much wider signification.

This is the condition of the cremaster. It is well known that tickling or gently rubbing the inside of the thigh causes contraction of the cremaster; and drawing up of the testicle. This is caused by the irritation thus set up in branches of the crural nerve, the saphenus nerve, and the anterior branch of the obturator, being conveyed to the upper part of the lumbar enlargement of the cord, and thence reflected along the genito-crural nerve. His observations on this point have led him to the conclusion that, on the affected side, when this irritation is set up, the testicle is not drawn up, whilst on the sound side this action of the cremaster is rendered excessive. Generally as the paralysis passes off, this muscle also resumes its normal action, but the abnormal condition may remain for months and even years. The author finds that the best method of applying this test is to make pressure on the saphenus nerve, at the point where the sartorius at its lower end forms a groove with the vastus internus, about a handbreadth above the internal condyle. The value of this symptom is great, on account of the connection of the muscles affected with the muscles of the abdominal wall. Another symptom of value is the tendency the patient has to slip out of bed on the side which is not affected. This symptom being caused by the inability of the diseased side to support the weight of the sound side.

With regard to the symptom often mentioned in cases of nerve-disease, viz. 'Manus ad genitalia,' the author thinks this is due to irritation commencing in the brain, in the same manner as is grating of the teeth, etc. In meningitis, for instance, it is not difficult to conceive that either a peripheral irritation is set up or a hallucination, which causes the patient to convey the hand in the direction of the genitals.

DISEASES OF CHILDREN.

KIRSCH ON SCARLATINA AND TYPHUS FEVER.—In a contribution to the subject of the Diseases of Children, Dr. S. Kirsch, of Prague, relates a case of scarlatina with diphtheritis of the mouth and pharynx, caries necrotica of the anterior part of the lower jaw, its loss together with the teeth, nephritis, and recovery.

The child was five and a half years of age, and the fever in its early stage presented much severity of symptoms. In the diphtheritic process the tip of the tongue was involved and sloughed off, this being followed by dangerous hæmorrhage. The separation of the anterior part of the lower jaw followed this, while the occurrence of albuminuria and anuria added to the serious nature of the case.

The use of carbolic acid and permanganate of potash was resorted to in the treatment of the throat and mouth. Attention is also directed to the beneficial influence of quinine in the reduction of the evening temperature.

A second contribution is entitled 'A peculiar Prognostic Moment' in a case of typhus in a child. The unfavourable prognosis was founded on the fact that, very soon indeed after

the mother's pregnancy commenced, the husband died in a lunatic asylum from acute mania. It is supposed by the author of the paper that the constitutional condition of the child must have been so affected as to render it unable to withstand the effects of an attack, by no means severe, of typhus fever. The death of the child is believed to prove the value of the supposition.

WORONICHIN ON VARIOUS CAUSES INFLUENCING DENTITION IN CHILDREN.—Dr. Woronichin (*Fachbuch der Kinderheilkunde*, vol. ix.) has arrived at the following general conclusions on the subject of dentition in children.

1. In those which are not rachitic, dentition commences generally between five to seven months, and at eight months in the male, 12 teeth are evident, in the female 10. Where the child is rachitic, this occurs a month later.

2. The end of dentition is arrived at in the third year.

3. Dentition is backward in rachitic children.

4. Constitutional disposition and attention to nutrition, both exert influences on dentition. Children with good constitutional health and proper nutrition suffer less during the process of dentition than others less fortunate in these respects.

ROBERT J. LEE, M.D.

SURGERY.

FORBES ON TETANUS.—In the *Philadelphia Medical Times*, of June 12, is an account of a paper read before the College of Physicians of Philadelphia, on April 7, by Dr. William S. Forbes, on the history of a case of acute tetanus, beginning on the fourth day after an extensive burn, and advancing with great rapidity.

S. H., aged seventeen, was admitted to the male surgical ward of the Episcopal Hospital on the afternoon of February 5, with burns of his body and extremities from hot iron, which had been accidentally blown against him from a foundry. He had walked to the hospital, a distance of a mile and a half, the air at the time being very cold. He was burned severely from his waist to his heels; the greater portion of the burn being of the second and third orders of Dupuytren. He was at once put to bed, his wounds dressed with linseed-oil and lime-water, his whole person enveloped with cotton-wool, and half a grain of sulphate of morphia administered and repeated five hours later. The following evening he had a chill, and complained of pain in his extremities and along the spine. Morphia was given, the oil-dressing was removed, and replaced by the ceratum resinæ acidum. The following two days he felt quite comfortable; took food and a little morphia, which was the last he received.

On the 9th he had no desire for food; complained of soreness, and had a severe convulsion in the evening.

On the morning of the 10th, he had stiffness of the jaws, with pain in the back of his neck, and his mouth began to assume a tetanic grin. He was given milk and beef-tea, and five ounces of brandy during the twenty-four hours.

On the morning of the 11th there was marked opisthotonos with trismus, accompanied with great difficulty of swallowing, which began the evening before. His skin was hot, temperature 102° Fahr.;

his pulse 133, and his breathing thirty-two per minute. A teacupful of beef-tea was ordered every two hours, alternately with milk, to be taken day and night: and eight ounces of brandy in the twenty-four hours. He had a convulsion during the night.

In view of the excellent effects obtained by the use of nitrite of amyl in epilepsy, angina pectoris, etc., it was determined to try the virtues of the same drug on the contraction of the muscles in this case of tetanus, and to try it alone, without the intervention or administration of any other medicinal agent. Nitrite of amyl had been used previously in only three cases of acute tetanus, and each case terminated successfully; but other and well-known agents were at the same time administered. This case is the first in which amyl-nitrite has been used alone, and successfully, and its action recorded. It was first administered on the evening of the sixth day after the accident, and about forty hours after tetanus first discovered itself. Before the three drops had half evaporated, the heart's action became more quiet; and at each inhalation of the amyl afterwards it was generally observed to have a quieting effect on the heart's action. Towards the latter part of the treatment the pulse was among the eighties, although on giving the patient five drops on April 4, six days after he had ceased to inhale five drops twice daily, the heart's action was 132 and tumultuous. The eyes were suffused; the skin of the face and neck became very much congested; indeed, the whole surface of the body was more or less congested; but this soon passed away when the amyl was withdrawn. The three drops had scarcely begun to cause congestion when there was evinced a tendency to gape, and a few days afterwards gaping and yawning both took place at each inhalation until the administration of the drug was discontinued. This gaping and yawning was produced in each subsequent administration of the drug, which was given twice daily. A marked improvement was at once manifested in all his symptoms.

On the 14th, as he had another spasm, the dose was increased to five drops twice daily.

The amyl in the hospital giving out on the morning of the 18th, it was not replaced until the evening of the 20th. During this time he grew rapidly worse; the opisthotonos and the risus sardonius both returned, and his pulse and temperature rose rapidly. On recommencing the inhalation of nitrite of amyl he felt better almost immediately, and from that time progressed steadily to complete recovery.

On March 29, forty-six days after the first dose of nitrite of amyl was given, the patient appeared to be perfectly well. He could walk about, and eat and drink, and enjoy himself in every way as before the attack, except having a feeling of weakness. The nitrite of amyl was now discontinued; he had inhaled one ounce.

GLASS ON VENTRAL HERNIA.—In the *New York Medical Record* of Sept. 10, a case of traumatic ventral hernia is described by Dr. R. George Glass. E. S., fifty-eight years of age, was admitted into Bellevue Hospital, May 25, 1875, and gave the following history. He was working in a factory, filing metallic plates, and found it very convenient when at work to rest the material to be worked on the bench, and hold it firmly by pressing against it with his abdomen. This practice (he being a new hand and working hard) made him very tender and

sore in the abdominal region. In the month of October, 1874, shortly after beginning this work, he found a circumscribed point of tenderness in the abdomen, midway between the umbilicus and pubes, and in the median line. The following day it became worse, and in a few days ended in an abscess, which was opened by a physician. With the pus which followed came a few inches of intestine. At the end of six weeks he had recovered, and resumed work at his trade.

On the morning of the day of admission he was working on a machine run by hand. Projecting from the front of this machine, about three feet from the floor, was a dull piece of iron, in the form of a spike. Against this the patient, while suddenly leaning over, struck his abdomen, causing a rupture of the walls, and a protrusion of intestines.

On admission, the patient suffered considerably from shock and felt very weak. Before being admitted to this hospital, several attempts had been made at reduction of the hernia, without success—once under the influence of an anæsthetic. He had also taken a hot bath. Examination of the abdominal walls showed a loop of intestines, thirty-five or forty inches long, protruding from an opening about an inch and a half in length. This opening had taken place in the cicatricial tissue, in the site of an old abscess, which extended from the umbilicus downwards, in the median line, to the pubes. The wound was situated lying in a vertical direction, and occupied a position half-way between these two points. The intestine was deeply congested; and at one point, near the extremity of the loop, there was a dark discolouration, which looked very much like gangrene. Bloody serum exuded from the surface of the intestine.

The patient was anæsthetised, and, after the gut was washed, an attempt was made to reduce it, which was ineffectual, owing to the swollen condition of the intestines and the cicatricial rigidity at the opening. The upper part of the wound was made larger by the introduction of a hernia knife—care being taken to thrust the finger in between the peritoneum and abdominal wall, so as to avoid injury to the former—making an incision about an inch long; and, after stretching the wound with the fingers, the hernia was reduced. The wound was then closed by silver wire sutures and the patient kept moderately under the influence of opium for four or five days. He was discharged cured in eighteen days, with orders to wear an abdominal support.

LA GARDE ON ASPIRATION OF THE BLADDER.—In the *New York Medical Record* for September 4, a simple method of aspirating the bladder is described by Mr. Louis A. La Garde, as follows.

On July 10, 1875, a Mexican teamster, thirty-four years of age, entered the Post Hospital, with retention of urine of thirty-six hours' standing, resulting from organic stricture of the urethra. He was put on opium, and given hip-baths frequently during the first six hours after his admission. Catheterisation was attempted, but failed. He refused to submit to external perineal urethrotomy, which was urged as the only means of relief, in the absence of any of the modern instruments, for the relief of both the stricture and retention. There being no aspirator, and the opium and hip-bath treatment having failed, the case resolved itself into one of rectal or suprapubic puncture of the bladder. A happy idea occurred to me, which I received from my friend,

Professor Griffith, of Kansas City, in conversation last winter. I contrived an aspirator by means of a vacuum created in a quart bottle, into which was poured half an ounce of chloroform, allowed to evaporate by heat in a water-bath near the boiling point. While the last of the chloroform was evaporating, the bottle was stopped with a tight-fitting cork, through which a cannula was tightly adjusted. I attached a piece of India-rubber tubing, twelve inches in length (from a Davidson's syringe), to the end of the cannula, and fixed a hypodermic needle in the other end of the tube. Having everything ready, I thrust the needle into the bladder, two inches above the pubes, in the linea alba. From the fact that the bottle was still warm, and the remaining chloroform, in a state of vapour, occupied the space in the vacuum, the urine did not flow for perhaps ten minutes; but as soon as the condensation of vapour commenced to take place, the urine was seen to come through the cannula, at first drop by drop, and then in an uninterrupted stream. It continued to flow thus until the bottle lacked not more than two cubic inches of being full. The amount of urine removed measured two pints. The morning following the operation the patient passed urine through the urethra; and later on in the day his condition was so much improved that he considered himself well, and insisted on leaving the hospital.

J. MILNER FOTHERGILL, M.D.

VAN BLAEVEN ON THE USE OF SHEET LEAD IN SURGERY.—Dr. Van Blaeven, in an article in the *Archives Médicales Belges*, April, 1875, enlarges on the great advantages to be obtained in surgery, and especially in military surgery, by the use of dressings made of sheet lead. The dressings are thus made. The sheet of lead to be used is of the size and thickness of a sheet of good writing paper; it costs from ninepence to tenpence the pound, and does not require any special preparation. It is easily cut with surgical scissors, and if it be necessary to increase the stability of the severed leaf, the edges are folded over like a hem, with the back of the scissors. In some cases it is advisable to cut the dressing out of a sheet of lead twice or thrice doubled. The bandage is always fixed by strips of adhesive plaster only; for this purpose the plaster must be less brittle than it usually is, so that the strips may adhere immediately without the intervention of the heat of the skin. As a general rule, the apparatus should, if well made, reproduce as exactly as possible the form of the portion removed, mould itself perfectly to the wounded portion, overlap the periphery of the wound by about an inch and a half, and hold the subjacent parts equally. All the joints should be packed with morsels of tow, and finally the apparatus should be firmly fixed. This method of dressing is particularly suitable in the following cases:—Crushing of the fingers or toes; carrying away of any fleshy part; ablation of a part of the ear or nose, as by a bite, sabre-stroke, etc.; deep contusion with consecutive destruction of the tissues through gangrene of the mortified portions; ingrowing nails; deformity of the extremities, either congenital or consecutive, as webbed fingers, contractile cicatrices caused by burns, etc.; and compound and comminuted fractures. Dr. Van Blaeven remarks that the long-prolonged use of lead, especially when the skin is in process of regeneration, gives rise to excessively obstinate eczema, which has been observed though not explained. When this complication supervenes, the foil dressing must be

disused, and the cure finished by nitrate of silver and strips of diachylon plaster. It sometimes happens that in some subjects the flesh is apt to become covered with a shining pellicle, the granulations become weakly, lose their freshness and elasticity; this inconvenience is remedied by strong and repeated applications of nitrate of silver.

LETIÉVANT ON REMOVAL OF CANCER OF BREAST BY THE ACTUAL CAUTERY.—A woman, aged fifty-seven, came into M. Letiévant's wards for a tumour of the breast. This tumour, which was diagnosed as hypertrophic, presented an extraordinary development of the subcutaneous veins, and made the chances of hæmorrhage much to be dreaded. M. Letiévant, therefore, made the incision of the skin by the actual cautery, after which, the skin being detached, the tumour was enucleated. The incision made by the iron presented the form of an ellipse seven inches long and two and a third wide. The wound did not bleed; the cavity was filled up with dossils of lint steeped in Pagliari's solution. The wound gradually decreased, and progressively became almost linear. The patient was attacked by erysipelas when the wound was nearly cicatrised, but finally recovered. In the course of a discussion on this case, at a meeting of the Société des Sciences Médicales of Lyons, M. Icard declared that erysipelas was wrongly stated to be unfrequent after the use of the actual cautery, of which the above case is the proof. M. Laroyenne thought that the burn produced in this case might be the cause of this complication. M. Letiévant called attention to the fact that at that time an epidemic of erysipelas was in full activity, and added to his communication that the afferent vessels of the tumour were twisted and not tied. He believed that arterial torsion will be substituted for ligature. He has twice twisted the femoral artery in two amputations of the thigh. M. François related, in opposition to the practice of torsion, the case of a soldier who died from hæmorrhage after resection of the scapula, the arteries having been only twisted. In this case the operator was Langenbeck, when he was at Orleans in 1870.

CUIGNET ON CAPILLARY PUNCTURE OF THE INTESTINES.—Prompted by a case of peritonitis, with excessive tympanites, where capillary punctures with aspiration did not produce any immediate results, Dr. Cuignet has made a series of experiments on the dead body on aspiratory punctures. He arrived at the following results, tabulated in the *Bulletin Médical du Nord*, March 1875, p. 126.

1. The puncture should be made by imparting a rotatory movement to the needle, and holding it between the two fingers at the surface of the body.
2. The moment when the needle reaches the gaseous cavity is immediately perceived, as well as that on which it touches the opposite wall; the exact idea of the dimensions of that cavity is thus obtained.
3. The gas does not escape spontaneously, however much distended may be the cavity in which it is contained, and it is necessary to make aspiration so as to withdraw it.
4. Only the loop which is punctured empties itself, and it is necessary to puncture all the distended loops to obtain any notable relaxation.
5. Each punctured and flattened loop is replaced by the two on each side of it, above and below, which keep up the tympanites in the same region, so long as they are not emptied.
6. The gas only, or the gas and the diffuent matter of the intestine, may be evacuated as

may be desired, by graduating the depth to which the needle is inserted. 7. Finally, it is prudent to evacuate the liquid in the vicinity of the puncture.

WACKERHAGEN ON PLASTER OF PARIS SPLINTS.—Dr. C. Wackerhagen publishes, in the *New York Medical Journal* of September, a new method of making plaster of Paris splints. The displacement having been rectified, and the limb held in position by assistants, the latter is smoothly bandaged with cotton-wadding, prepared in the form of an ordinary roller; a flannel bandage, spread with dry plaster of Paris, and rolled, is soaked with warm water (to which about two fluid ounces of saturated solution of sulphate of potassium may be added) and applied to the limb, over the wadding, by circular and reversed turns. One layer of the flannel applied in this way is thought amply sufficient for support.

The author continues as follows. 'If it be desired to employ lateral splints, the dressing should be cut in the median line of the anterior and posterior surfaces. If antero-posterior support be preferred, it should be cut through the lateral surfaces. The splints should now be varnished on their inner and outer surfaces with shellac, or this preparation may be applied to the outer surface before removal. The shellac seems to permeate the dressing sufficiently to increase the strength of the splint, and at the same time renders it slightly flexible instead of brittle, as is the case when plaster of Paris is used alone.'

GUILHEMBERT ON EXTERNAL SYMPTOMS OF STRICTURE OF THE URETHRA.—Dr. Guilhembert studies in his *Thèse de Paris*, 1875, those structures of the urethra which, not being foreshadowed by troubles of micturition, dysuria, etc., always show more or less intense blennorrhagia. Others may give rise in the first instance, and without having given other signs, to acute or chronic orchitis, urinary abscesses, infiltration of urine, or to vesical catarrh. Thus, in presence of these different accidents, the information afforded by patients must not be held as sufficient; and even in the absence of all functional trouble with regard to the urinary passages, it is necessary to proceed to the exploration of the urethra by suitable means, of which the best is the *sonde à boule*.

PSYCHOLOGY.

REY ON LOCOMOTOR ATAXY.—The *Annales Médico-Psychologiques* (September, 1875) contains a paper by M. Rey on locomotor ataxy as observed in connection with insanity, and nine cases of patients admitted into the Asylum of Saint-Anne are given. M. Rey remarks that the complication of general paralysis is the one most frequently found in connection with locomotor ataxy, and that general paralytics, especially in the early period of the disease, show symptoms of ataxy in their attempts to protrude the tongue, in the movements of the eyelids, and in their walk. The numerous symptoms common to the two diseases may render the diagnosis difficult, but the writer is of opinion that there is one characteristic symptom of ataxy which will aid us, viz., the increased difficulty of co-ordinating the movement of walking when the eyes are closed. Nothing of the kind, he believes, is to be found in simple general paralysis. Of the nine cases, three are those of ataxy complicated by general paralysis. The first was that of a man, aged thirty-three, who in July, 1871, had disturbance of vision and strabismus, and soon afterwards agonising pains in the legs and slighter ones in the arms. He walked with difficulty. In November, 1872, his memory and intellect were affected, and he had attacks with loss of consciousness without convulsions. These were followed by violence; and in May, 1874, he was admitted into the asylum with well-marked symptoms of general paralysis, loss of intellect and memory, ideas of contentment alternating with those of hypochondria, periods of calm, and periods of maniacal excitement. The second was a man aged fifty-five, who had been treated in various hospitals during fifteen years for locomotor ataxy. Only a year before his admission did he manifest any mental symptoms. He was loquacious and self-satisfied with delusions of ambition, had solved the problem how to pay the national debt, and possessed millions. His speech was embarrassed and his tongue trembled. He was admitted in April, 1872, and died in June, 1873, in a congestive attack. Besides the ordinary *post*

mortem appearances of general paralysis, there was marked sclerosis of the posterior column of the spinal cord, and in the lower portion the commencement of sclerosis in the posterior portion of the lateral columns was perceptible. The third was a man aged thirty-five, who had been compelled to serve by the Commune, and was afterwards imprisoned, but finally acquitted. On returning home he complained of pains in his legs and difficulty in walking. He then had an attack with loss of consciousness, and was soon afterwards admitted into the asylum, in Nov. 1873. He had a difficulty in walking and pains in the legs. His mental faculties were weakened without delusions. His speech was embarrassed, and he had ambitious ideas of what he was going to do in his profession. At the age of nineteen he had syphilis with secondary symptoms. In all these cases M. Rey believes the locomotor ataxy to have preceded the paralysis. The other cases presented the disease complicated by mental affection, but without general paralysis. One was a woman, aged thirty. Five or six years previously she had begun to feel pains in her legs, with a burning sensation in the spinal region. She then had defect of sight and double vision. Three weeks before admission, she was unable to walk without assistance. Four or five months ago she had shown weakness of intellect and loss of memory, and when in the hospital of St. Antoine she had hallucinations, and cried out in the night, and was therefore sent to the asylum in Nov. 1874. She left it in May 1875, both the bodily and mental symptoms being relieved, but with pains and cramp still remaining in the legs. She could walk, but with difficulty. A fifth case was that of a man aged fifty. In 1871 he felt pains in the legs while in America. These attacked the whole of the inferior extremities, and gradually prevented his walking. He entered the Charité in June 1874, and then showed mental symptoms, delusions of persecution, and poison, with hallucinations of sight and hearing. He was transferred to Saint-Anne in October 1874, and in February 1875 the mental symptoms were unchanged, the ataxic symptoms being perceptible in the upper as well as the lower extremities. A sixth, male, aged forty-three, had syphilis at twenty-five, and was a masturbator at seven. At thirty he went to St. Petersburg, and, after residing there seven years, symptoms of ataxy showed themselves in pains in the lower limbs and cramps in the feet and hands. Sight was also impaired, and afterwards the power of walking. He followed his employment till June, 1874, having returned to Paris in 1867. He was admitted in November, with delusions of having committed great crimes, and hallucinations of sight and hearing. He was discharged in March, 1875, improved both bodily and mentally. The seventh was also a man, aged fifty-nine, who had delusions of persecution with hallucinations, and refusal of food; this passed away in a fortnight, and he was able to relate his history. He had been a soldier, had drunk, and contracted syphilis. During the siege, in 1871, after being exposed to damp, he had felt severe pains in his legs and his walking was impaired. Two years afterwards his sight failed, complete blindness ensued, and the mental symptoms supervened upon the latter. Number eight was a male, aged forty-four, who had served in the Crimea and Italy, and was a drinker. Eight years ago he awoke one morning with his legs paralysed. He partially recovered, but walked with difficulty. At the end of 1874 his sight began to fail,

and he soon became quite blind. His memory was defective, and he was admitted in March, 1875, in a state of dementia. The ninth was a man aged forty, who at twenty had had syphilis. For ten years he had had pains in the limbs, followed by dimness of vision, strabismus, and diplopia. In June, 1875, he was admitted in a state of melancholia, with impulse to violence. He suffers agonising pains in the lower extremities and twitchings. His sight is much impaired, the pupils are unequal. He cannot walk without assistance.

HOSPITAL ON EROTIC MANIA: DISEASE OF THE CEREBELLUM.—Dr. Hospital, physician of the Asylum at Clermont-Ferrand, relates (*Annales Medico-Psychologiques*, September, 1875) the case of a woman of thirty-four years of age, large and robust, who shortly after she became a widow showed signs of insanity, religious melancholia. One of her brothers was at the time under restraint. She left home and wandered about, and then came to Clermont-Ferrand with the idea of going to live with the Capucin Fathers. She entered the wrong house, and, being arrested, she declared her intentions in such a manner that there was no doubt of her insanity, and she was sent to the Asylum. She was almost imbecile, and scarcely noticed where she was, but constantly insisted on going out for the purpose already mentioned. Sometimes she would behave properly in order to gain her release. She would then become sulky when she failed. Two years later she became quieter and remained all day crouched in a corner; would not answer questions, but muttered continually to herself. Later she refused food, and succumbed to an attack of pleurisy about two years after her admission. The cranium was normal, as well as the dura mater. The arachnoid was filled with gelatinous serum. The cerebrum was without any distinct lesion, but in the right lobe of the cerebellum in the centre, towards the posterior and inferior region, there was a patch of softening of the size of a nut. The substance was in a state of pulp, and easily removed by the handle of a scalpel.

G. FIELDING BLANDFORD, M.D.

BROWNE ON ARACHNOID CYSTS.—To the current number of the *Journal of Psychological Medicine*, Dr. Crichton Browne contributes a paper on arachnoid cysts. After describing a more than typical—in fact, a very strikingly marked—case of this affection in a male patient, in the West Riding Asylum, in which these pathological products pressed upon both cerebral hemispheres with a weight of thirty-nine grammes, he proceeds to give some striking statistics founded upon the reports of no less than 1,240 *post mortem* investigations. Out of these cases, fifty-nine were due to arachnoid cysts—forty-three occurring in males, and sixteen in females, so that the liability of the male sex to this affection appears to be nearly three times as great as that of the female. In nearly one half of the cases recorded, general paralysis was the cause of death; and this latter occurred, as might be expected, in nearly one half of the cases, between the ages of thirty-five and forty-five. The left side of the brain, moreover, appears to be the more chosen site of the morbid change.

It has been established beyond all doubt by numerous observers that the cysts in question result from extravasation of blood, and that they are not due to an organisation of lymph poured out during an arachnitis. Sperling has artificially caused ana-

logous morbid products in the brains of rabbits by injection of fresh blood between the dura mater and the arachnoid membrane. In the cephalhæmatomata of infants an origin and changes may be discovered similar to those which take place in the intracranial hæmatomata of adults. Further than this, in the othæmatomata of the insane a connecting link seems to exist between the arachnoid cyst of the lunatic, and the bloody tumour beneath the scalp of the newly born infant.

It being granted, then, that arachnoid cysts are of the nature just hinted, the point to be determined is the source of the hæmorrhage. Some hold that it proceeds from the ruptured vessel of a false membrane lining the dura mater, resulting from a pachymeningitis; while, by others, it is thought to come from the vessels of the dura mater itself. Neither of these views is satisfactory. As the cysts never appear until the disease is far advanced—until much wasting of the brain has taken place—it is fair to infer that they are drawn from some of the vessels which become over-distended when wasting is established. The vessels which are most affected are the great veins running over the frontal and parietal lobes, returning blood to the longitudinal sinus. In support of this, the case of a female, who died at the age of fifty-three years, is cited in full. It is generally asserted that the effusions of blood giving rise to the cysts in question are traumatic in origin. According, however, to Dr. Crichton Browne's observations, the cause alleged plays but a small part in the causation of these products, but the spontaneous laceration of a vessel following upon a cerebral hyperæmia, which is very likely to affect such patients as are the subjects of the disease in question, may reasonably be cited as an efficient cause.

The treatment of arachnoid cysts must be, it will be concluded, a purely prophylactic one; but should it be known that an effusion of blood is actually taking place, this process might be checked by the administration of ergot and purgatives. When the blood is effused, but little remains to be done; though iodide of potassium may be tried, as a forlorn hope.

J. C. GALTON.

ROBERTSON ON UNILATERAL MENTAL PHENOMENA.—In the *Glasgow Medical Journal* for October there is a communication by Dr. Alexander Robertson on this subject. He writes: These unilateral phenomena consist of illusions and hallucinations, and possibly also of the peculiarities supposed to be due to the separate and independent action of the hemispheres. The first two have received but little notice in works on psychology published in this country. More consideration has been given to them by French writers. Thus Briere de Boismont, in his book on hallucinations, refers to Calmeil's observations on the phenomena in question, and more particularly to those of M. Michéa, who gave them the name of 'hallucination dédoublée.' Gall, too, relates a case of a minister of state in Vienna, who was constantly hearing insulting expressions on the left side, so that he was very often turning his eyes in that direction to see whence they came, although perfectly convinced on the right side of his head that they were delusions of the left side. Griesinger, too, had a patient in whom there were hallucinations of hearing on the left side throughout the duration of the insanity. A similar case is related by Schroeder Van der Kolk. It might seem that these unilateral sensorial disturbances were very rare,

but the writer thinks their rarity rather apparent than real. He consequently made a careful examination of 250 insane patients with the following results. Thirty-four patients were found with well-defined illusions or hallucinations of one or other senses. But there were many others where these special phenomena were so combined with other general delusions, or whose intellect was enfeebled, or who were obstinate or reticent, that trustworthy information could not be obtained from them. With regard to causation in these thirty-four cases, in fifteen the disorder was clearly due to alcohol; in five, to domestic trials; in two there was an hereditary tendency, and in ten the cause could not be determined. In thirty-one of the cases there were heard imaginary voices or unreal sounds. In twenty-nine there existed either at the time optical illusions or the memory of such illusions. Two suffered from disorders of taste, and in one there was also disturbance of smell; both these patients had auditory and optical hallucinations as well. In fourteen there were disorders of general sensation. Of the thirty-one cases of auditory disturbances, in five they were only heard in the left ear; in other five more in the left than the right; and in one only on the right side; while two stated that they were more distinct on the right than on the left side. Some cases are then given illustrating the subject. The number of cases in which the left side is the one affected, not only in Dr. Robertson's own cases, but in the cases quoted by him, is very large. As to the pathology of these cases, the portion of nervous system associated with the delusion is probably affected as it is in bilateral sensory disturbances. In some cases it would appear that the disease commences in the sense-organ, and thence gradually extends to the highest cerebral ganglia.

MEDICAL JURISPRUDENCE.

ULLERSPERGER ON CREMATION.—Some observations of interest open a paper on cremation by Dr. Ullersperger (*Friedreich's Blätter für Gerichtliche Medizin*, July and August, 1875). After referring to the serious importance which all religious bodies attach to the disposal of their dead, the author states incidentally that in Germany the use of crypts, except in special cases, is forbidden by law. He then shows that the question is not a new one, inasmuch as the abuse of churchyards was struggled against by Johann Peter Frank in the last century. After

referring to the general opinion of medical and other reformers as to the unhealthiness of graveyards, he shows that cremation is an effectual safeguard against all the evils of inhumation, and instances the permissive clause introduced by Professor Maggiorani into a sanitary bill passed in Rome in 1873, by which families have the option of burning in place of burying their dead. He then lays down his main proposition that 'Cremation is the only reasonable and quite harmless mode of disposal of the dead.' As to the unhealthiness of graveyards, a report of eight professional men appointed by the Conseil d'Hygiène publique du Département de la Gironde to investigate the question makes the following recommendations.

1. That there should be only one graveyard of the minimum size of 100 hectares, of which each religious denomination should have its special portion.

2. That it should be distant from the town, but not more so than twelve kilometers.

3. That the concessions hitherto allowed of embalming or burying in lead coffins be withdrawn, since these means have conduced even more than vaults to the preservation of corpses.

4. That no further renewal of concessions be made as to ground.

5. That the period of rotation in common ground be fixed at from fifteen to twenty years.

6. That no dead-houses be set apart for cases of simulated death. The period of time hitherto allowed for discovery is sufficient.

7. That in order to settle this question two visits be made by the medical man, the first under circumstances as they arise, the second before burial.

8. That exhumations be as little as possible allowed, and then only at stated times (from October 1 to April 1), except where they may be necessary for the requirements of justice.

9. That every effort be made to make graveyards as pleasing as possible.

10. That the erection of monuments be regulated by law, so that free ventilation and the absorption of the products of decomposition be not interfered with.

11. That the planting of trees, shrubs and plants be regulated.

12. That graves no longer in use be planted with trees and shrubs, and that they be not used for common burial before forty years have elapsed since the last interment.

13. That no transference of burial-places be made without the authority of the health-bureau, so that no danger arise to the public health from this cause.

14. That private property in graves should be sanctioned as little as possible; and finally interdicted entirely.

15. That the medical determination of cases of death be made practicable for the whole parish. That facilities for cremation be given.

16. That the size, distance, and number of graves, and so on, be officially regulated.

17. That metal shells intended for the conveyance of corpses undergo a searching examination, so that infection by them of the conveying carriages may be prevented.

These seventeen recommendations, involving, as the author thinks, clumsy and cumbrous machinery, are not to be compared with the simple and safe method of cremation. The next proposition of the author is: 'That no opposition whatever can be

made to cremation.' Like earth-burial, there are different modes of cremation.

Thus we have: 1. Cremation in open fire: 2. In more or less open ovens where the corpse is in immediate contact with the burning material: 3. Cremation in closed stoves where the corpse is in contact with the heated gases evolved, not with the burning material itself: 4. Cremation in muffles (*Muffeln*), where the corpse is consumed by heated air.

Siemens's stove has been recognised as the most suitable. It can consume a body in about five hours, the temperature rising to from 600° to 800° Cent. (1112° to 1472° Fahr.). A corpse requires from fifteen to twenty years to moulder in the ground. As to cost, no man can for a moment compare the charge of 400*l.* to 500*l.* which a Siemens's stove costs, with the price of a graveyard. If next we think of what happens in churchyards, the tendency of population to accumulate in centres, and the consequent heaping up and over-heaping of corpses, with their deadly influences on dwellings, water, soil, and worst of all, the very air, we must recognise that cremation is not only advisable, but that it is absolutely necessary. Epidemics must owe, if not their origin, their spread and continuance, at least, to such causes; while all these evils disappear before cremation. The disposal of the dead must not be suffered to contaminate or endanger the living.

As to the religious and affectional disposal of the dead, no feeling of human nature need suffer; for (1) all the offices and customs of the church, affectionate honour to the deceased, tenderness for the feelings, etc., remain undiminished and uninterfered with; (2) the corpse does not become a source of infection, and leaves no dangerous residua, while the remains offer the most beautiful opportunity for the exercise of the tenderest feelings of the heart; and (3) from beginning to end cremation is associated with no dangers to the performers of it, nor to persons or families dwelling near.

The author next refers to various examinations into the effects of water impregnated with products of decomposition from graveyards; among others, to those of Dr. Aijr in the case of the hamlets of Rotondella and de Bollita. Reference is also made to Professor Selmi's observations in Mantua on the facility with which putrid fermentation and the appearance of bacteria are induced in a solution of glycogen on the addition of matter which he had traced to originate from graveyards.

The account of a case in which a Jewish merchant had buried his wife, but, on opening the grave with the permission of the Rabbi, to his horror discovered that the face-handkerchief was smeared with blood, and that there were other marks of a struggle which indicated that the woman had been buried alive—is referred to, with the remark, that, had cremation been resorted to, the unfortunate husband would have been for ever spared the pain of knowing what had happened. Other remarks of historical and general interest close this paper.

A PHYSICIAN OF THE OLD SCHOOL.—*L'Union Médicale* of November 18 asserts that at Benemaclet, in Spain, there is a physician who has attained the ripe age of 105 years, and is still in practice. This centenarian has a wife who obediently lives as long as her husband, being in her 103rd year.

VON HOLTZENDORF ON MURDER AND CAPITAL PUNISHMENT.—In a paper entitled 'Murder and Capital Punishment: Researches in Criminal Politics and in Psychology,' derived from lectures delivered in the Universities of Berlin and Munich, Franz von Holtzendorf gives an exhaustive review of the relations of capital punishment, and deals with the subject under the following heads.

1. The punishment of death, advocated by some as the most terrifying preventive of murder, is shown not to be so. Piety, patriotism, honour, as also the strongest temptations to crime themselves, outweigh it; for the state only threatens an evil which, in the course of things, must arrive sooner or later. And the degree of terror which such a menace implies depends (a) on the greatness of the evil; (b) on the probability and certainty of its occurrence; (c) on its proximity in time; (d) on the probable success of a well-planned defence; and (e) on the consideration whether fear of death or contempt for it is the more powerful motive.

2. If it be said that execution is more terrible than natural death by reason of its frightful surroundings, it is answered that this terror acts only on noble natures, and that any ignominious punishment would have as terrifying an influence on them as capital punishment.

3. The certainty and probability of the incidence of the evil. There is always room to hope for non-detection of the crime, non-discovery of the criminal, acquittal, or pardon.

4. What are the chances of conviction and condemnation? Murderers do not often look so far forward as this. The larger number of murderers are apprehended, but a minority take subtle steps (as by disfiguring or destroying the corpse, or by using such means as make it doubtful whether murder, suicide or misadventure has taken place, or by the suggestion of an *alibi*, or simulating insanity, etc.) to render detection difficult. And even after apprehension there are further chances of escape, since juries demand stronger proof in cases of murder than of other crimes; and in France, for instance, there is the rider of 'extenuating circumstances'; and in Germany, where this is not allowable, a verdict of 'not murder' is returned, when the proof is not sufficient.

5, 6, 7, 8. Danger of death, as something far distant, does not terrify the criminal. It is, in fact, a far more powerful influence on those who put the law in force; judge, jury, prosecuting and defending counsel, being far more afraid of participating in a wrong punishment, than the criminal is that it will fall on him. As for the facility with which criminals feel terror (*Abschreckungsfähigkeit*) the non-commission of crimes often occurs from want of motive, from want of criminal disposition, from a feeling of moral sense, honour, and rectitude, from want of opportunity, or from fear of punishment. But the last motive is the least potent. If the disposition to maintain order were not supported by the strength and universality of the moral motive, even the code of a Draco would be powerless to prevent crime. And if to-morrow murder were declared free from punishment, the consequence would by no means be universal murder, since respect for life does not in civilised countries require such help to maintain it.

9. As little powerful is punishment as a terrifying influence where the motive to murder is some affront

to honour (duelling for instance) or some love affair (for instance, the desire to die with a lover whom one cannot marry), etc.

10 and 11. Execution either in public or within the prison walls has by no means the terrifying influence that is supposed. For the influence of a public execution depends entirely on the behaviour of the culprit, either contempt on the one hand, or a very dangerous reflection on the modes of justice on the other, being evoked according as the criminal admits his guilt and repentance, or dies boldly asserting his innocence. Then as to execution within the prison walls, this is practically not different from the other, since the press gives full accounts of it, which in turn frequently induce the commission of crimes like those for which the criminal suffers, through the tendency to imitation. The very existence of capital punishment leads men who think they have had enough of life to commit some crime worthy of death in order to undergo the punishment.

12. When blood is shed so easily by capital punishment, the mere fact is calculated to lessen the respect for human life; and that the punishment is a legal one, is no counterbalance of this feeling. All experience shows, on the other hand, that diminishing the severity of punishments is accompanied by a corresponding decrease in the commission of crime.

13. In England the effects of diminished severity of punishment were very noticeable. In 1780 there were 240 persons condemned to death; yet the public insecurity was great. With the mitigation of the extreme penalty to transportation, a corresponding improvement took place in the public security. Theft being punishable with death, and the punishment being quite disproportioned to the wrong, numerous acquittals took place; while, with the abolition of the punishment, a marked reduction in the number of cases occurred.

14. Capital punishment as conducing to public safety. To those who say the murderer is a dangerous person, against whom society has a right to be protected, it is replied that protection does not necessarily involve the death of the murderer, and it is shown from statistics that it is more than doubtful whether capital punishment really prevents the commission of murder.

15 and 16. Society has other means than capital punishment for protecting itself from murderers. Death might have been necessary in uncivilised times, or in exceptional circumstances, as war or foreign invasion, but not in peace. Besides, death prevents any hope of ameliorating the moral state of the culprit, and it is by no means the case that murderers are in other respects the most immoral criminals.

17, 18. Capital punishment in relation to its rightness. The rightness of a punishment depends (1) on heavenly revelation; (2) on the ethical principle of vengeance; (3) on its practical efficiency as expiation or atonement. In reference to the first consideration, neither the Old Testament law of retaliation, nor the metaphorical New Testament 'sword,' can be relied on for the perpetuation of capital punishment in modern society.

19. As to point two, the gravity of a crime depends not only on its objective consequences, but also on the subjective condition of the criminal, and therefore the same crime may be in gravity a very variable quantity. So with capital punishment, since the value of life, and therefore of its deprivation,

varies in different circumstances. The principle of expiation and atonement, therefore, is an impracticable fiction.

20, 21, 22, and 23 are devoted to the agreements and differences between murder and homicide. Premeditation is the main distinction; but premeditation is very difficult to define or prove in many cases.

24, 25, 26. The religious view of punishment as a God-appointed method of expiation of crime is quite antiquated, and, besides, society easily justifies its own conclusions by reference to Heaven. Capital punishment may be wrongfully inflicted, and the fear that this may take place from time to time justifies the desire to abolish capital punishment. The difficulty is not got over by carrying out the sentence only after confession of his crime by the accused, since criminals have frequently falsely accused themselves; and, on the other hand, many who were guilty have never admitted it. The right of pardon can be justified only as a resource against incomplete legislation. In England the number of pardons depends on the state of public opinion for or against capital punishment; in Germany, on the conscience of princes. Since 1870, the German Emperor has not confirmed a single capital sentence.

TOXICOLOGY.

WHITE ON 'IVY-POISONING.'—In the *Boston Medical and Surgical Journal* for September 2, Professor White gives some account of 'ivy-poisoning.' After describing the plants, he goes on to say: 'The virulent principle of these plants (the *Rhus toxicodendron* and *Rhus venenata*) is a volatile acid which exists in all their parts, but especially in the leaves. All persons are not affected by it, but many who can handle the vine, *rhus toxicodendron*, with impunity, are poisoned by the tree, *rhus venenata*, so much more virulent is the latter. Actual contact with the plants is not in all cases necessary for the production of their poisonous effects, on account of the volatility of their active principle; and there is good reason to believe that persons highly sensitive to the poison not unfrequently suffer from passing by places where the vine grows abundantly. The plant is supposed to be most actively virulent during the flowering season in early summer, but cases of poisoning occur with great frequency throughout the autumn, when its leaves take on their seductive colouring. Even in the winter the twigs and stems are often found still alive for mischief by those who handle them.

The peculiar effect of the poison is alike in kind upon all who are affected by it, but varies greatly in intensity. The inflammation it excites upon parts coming in contact or contiguity with it is that of an acute eczema, characterised by the eruption of vesicles of a peculiar lurid or brownish-red colour, which may subsequently burst and exhibit the later phases of this efflorescence, as in other acute inflammations of the skin. In addition, there is more or less of swelling and redness of the parts affected, sometimes to a very marked degree, so that great deformity may thus be produced, and the face of the patient be changed out of all recognition. These changes in the tissues of the skin are accompanied by intense itching and burning, and often great suffering is undergone by the patient in consequence.

Fortunately the affection is of short duration, the acute stage lasting ordinarily but a week or ten days under treatment, and its whole course rarely exceeding three or four weeks. Moreover it is not a dangerous affection, although a person severely poisoned over a large surface may present a frightful appearance to his friends. Its effects, however, are never more than skin deep. The eruption generally shows itself within three or four days after contact, sometimes within twenty-four hours. The period of incubation may, however, be prolonged to five or six days in some cases, and fresh blisters may continue to appear for two weeks or more. No danger of contagion by contact with the eruption upon another person is to be feared. The portions of the body most commonly affected are the hands and face, the parts naturally most exposed to contact; but other parts handled by the former immediately after contact and before washing, may have the poison thus transferred to them and be similarly affected. No scars or permanent injury to the skin or general system are to be apprehended in ordinary cases.

A few words with regard to the treatment of rhus poisoning may not be inappropriate in this connection, especially in relation to the means to be immediately used, those to which the term antidote may be properly applied. The poison, as has been stated, is a volatile acid. An alkali would therefore suggest itself as the most fit agent to counteract its action. Thorough washing of the parts, as soon as possible after contact with the poison, in cooking-soda water, or in strong soap-suds, especially those of soft soap, which contains an excess of alkali, is therefore the best primary treatment. When these or other alkaline preparations are not to be obtained, an abundance of water alone should be used as soon as possible. After absorption has taken place, or the eruption has begun to show itself, less benefit is to be expected from such applications alone. Remedies are then to be used which will best control and shorten the inflammatory process in the tissues of the skin; those, in fact, which are found to be most efficacious in corresponding stages of acute eczema. Among these are some which have a special reputation, as solutions of acetate of lead or sulphate of copper, applied frequently as a wash. Perhaps nothing is better than common black wash used as an evaporating lotion for half an hour at a time, twice daily, the lime water acting also as a chemical antidote, if possibly such action is still in season at this later stage. In the intervals between the applications of these washes the parts may be kept covered with cold-water dressings, with plasters of diachylon ointment, or with a powder of starch and oxide of zinc, according to the rules familiar to physicians for the treatment of acute eczema. By these means the process is checked and shortened, and the sufferings of the patient greatly alleviated.

In conclusion, a brief word of caution is given to sojourners in the country who are unacquainted with these poisonous plants. Avoid any vine or bush growing by rocks, fences, and woodsides, with glossy leaves arranged in threes, and in the autumn any particularly brilliant tree in swampy places, with leaves resembling, but broader than, those of the common sumach.

J. MILNER FOTHERGILL, M.D.

RECENT PAPERS.

Researches on Poisoning by Powder of Cantharides. By M. V. Galippe. (*Gazette Médicale*, June 19.)

OBSTETRICS AND GYNÆCOLOGY.

MILLER ON PUERPERAL FEVER.—In the *New York Medical Record* for August 3, is an article on the abortive treatment of epidemic puerperal fever, by Dr. J. H. Miller. He says: Knowing from long experience that attention to little things frequently makes up the difference between failure and success, I will describe minutely the course pursued in nineteen cases that fell under my observation during the existence of the epidemic.

Upon entering the lying-in chamber and examining its hygienic condition, my first efforts are directed to the proper adjustment of the bed, in order to secure it from liability of being soiled by the discharges—cleanliness being regarded of primary importance. I direct two heavy comforts to be folded upon themselves and placed lengthwise upon the anterior part of the bed, and a sheet folded in the same manner upon the comforts. These will be sufficient to absorb the discharges before reaching the bed proper. Before making a digital examination I wash my hands with soap and water, cleanse my nails thoroughly, and anoint both hands with carbolated oil, and as soon as the labour is completed I remove everything that is soiled and let her down upon a clean, dry bed. I place a large folded napkin, carbolated, under the nates to receive the lochia, and then proceed to anoint her abdomen and thighs with carbolated oil, and place a single cloth saturated with carbolated oil over the entire genital organs. I then order her a glass of whisky-toddy. The carbolated oil was applied as above thrice daily for three days, and twice per day for two days more. It is both antiseptic and antipyretic. A generous diet is allowed throughout.

For the purpose of securing speedy uterine mural condensation, I order fluid extract of ergot in half-drachm doses thrice daily for the first three days, and twice daily for two days longer. I regard it of the utmost importance to have an early contraction and condensation of the uterine walls, in order to close the mouths of the uterine veins, for the liability to puerperal fever is to a great extent owing to the open, patulous condition of the mouths of the uterine vessels, allowing thereby easy ingress to the mycelium of the spores of microscopic fungi or to the shoals of the swarming bacteria, and thus invading and poisoning the whole uterine, peri-uterine, and peritoneal tissues. Secure by all means an early condensation of the uterine walls, and you thereby lessen the liability to puerperal fever in a ratio with the contraction of the calibre of the uterine veins; and with occasional washing the vagina with tepid water slightly carbolated, that condition of the puerperal state which is so inviting to the invading causes is so materially changed and protected as to render her security almost certain, and reduce the danger to zero.

Unremitting vigilance on the part of the physician is frequently the price of the patient's life. One visit every twenty-four hours is not safe practice. Three visits per day for the first three days, and two visits daily for two days more should be made in every case of labour during the epidemic.

The careful employment of the thermometer at each visit, in order to detect the brewing of the coming storm, is of the highest importance.

Perhaps without the use of these precautionary

means those nineteen cases might have passed unscathed through all the fierceness of the epidemic, and, on the other hand, had it been practised more generally, the fatality of the epidemic might have been much more limited. It is only by more extended observation in this direction that we can arrive at just conclusions; for it is only by prophylactic and abortive means that we can expect to do our patients full justice, because in fully established cases the pathological lesions are too grave to be overcome in a large majority of instances.

Notwithstanding the prophylactic means employed, four of the nineteen cases manifested unequivocal evidences of incipient puerperal fever; three upon the second day and one upon the beginning of the third day of their confinement.

The abortive treatment was brought into requisition at the very earliest manifestations of the disease, and with decisive effect.

Quinine is the remedy *par excellence* in the abortive treatment of puerperal fever. It neutralises any toxic action from malaria already in the system; it diminishes pyrexia; it slows the pulse, prevents the formation of pus, and is inimical to the existence of bacteria. Ten grains every four hours I have found to be sufficient, although in one case I gave twenty grains to start with, and with the happiest results; and at the end of twenty-four hours in all four of the cases everything was pleasant and satisfactory. In addition to the above, although I have had no experience with them, I would recommend the use of salicylic acid, both locally and internally, and also the use of thymol. It is my candid conviction that, if these suggestions are implicitly carried out, epidemic puerperal fever will be disarmed of its terrors.

As a corollary to the above, I will formulate the chief points for practice.

1. The most scrupulous cleanliness to be observed by all concerned.
2. Unremitting vigilance on the part of the physician.
3. The antiseptic treatment by carbolated oil, and by salicylic acid and by thymol.
4. The early condensation of the uterine walls by means of ergot.
5. The thrice daily employment of the thermometer.
6. Large doses of quinine in the incipency of the disease.

J. MILNER FOTHERGILL, M.D.

YANDELL AND MCCLELLAN ON BATTEY'S OPERATION.—The new operation of spaying, in cases other than those in which ovariectomy is a recognised method of treatment, is discussed in the *American Practitioner* for October. This is done in an American fashion, namely, giving a report of an interview between two physicians and the operator.

The objects of the operation are described as follows: To stop diseased or pernicious ovulation; to effect the change of life; to revolutionise the whole female economy, and thus throw off an otherwise incurable disease. Dr. Battey suggests, if he does not actually assert, that he confines his operation to cases where life is endangered or where health and happiness are destroyed—cases which are utterly hopeless of other remedy this side the grave.

These statements do not agree with the facts which are found by an analysis of the cases and otherwise. In his first case Battey supposed the ovaries to be healthy, and is still of this opinion. In

all the others, the ovaries showed unmistakable disease. In ten operations, eight ovaries were cystic, the cysts varying in size from that of an orange to that of a cherry. In one case the patient had amenorrhœa, convulsions, recurring hæmatocele, repeated pelvic abscesses, incipient tuberculosis from pulmonary congestions, etc. Several of the cases passed under the head of ovarian neuralgia; several had intractable dysmenorrhœa with pelvic deposits of old lymph; one had ovarian insanity, etc. There is not one of these diseases of cases of which it can be said that they are utterly hopeless of other remedy. Far from it.

Batley prefers vaginal ovariectomy as done by Thomas and Noeggerath, to his former method of spaying by opening the abdomen above the pubes. The operation is simple. The uterus is pulled down and fixed, the peritoneal cavity is opened through the roof of the vagina, the ovary or ovaries pulled down and removed by the écraseur. About ten minutes are consumed in crushing the pedicle. No ligatures or sutures are used, and no foreign body left in the tissues. Ether alone is used to produce anæsthesia. The operation occupies about an hour. The removal of both ovaries is now recommended.

Batley's operation has been done upon eight women ten times, a second operation being resorted to in two cases, to remove the second ovary which had been left. Two women died. This is a mortality as great as after ovariectomy.

Six operations were done in Louisville, and of these we have some notes to indicate the nature of the success in the survivors.

Case I.—The patient is urgent in her demands for the removal of the remaining ovary.

Case II. was operated on a second time, and is Case V.

Case III.—The operation was performed in August 1875. Dr. Leachman reports an entire subsidence of all uncomfortable symptoms. The patient has not menstruated since the operation, although the menstrual molimen has been upon one occasion well marked.

Case IV.—Operation performed September, 1875. The most favourable results are anticipated.

Case V.—Operation performed September, 1875. The coccygodynia is persistent.

Case VI.—No remarks. Probably one of the fatal cases.

As indications of the probable utility of this operations nothing can exceed the unsatisfactory character of these statements. The profession, however, is indebted to Dr. Batley for even the little that is given.

From the recency of Dr. Batley's experience, little value is attachable to his remarks on the menopause which the operation is intended to produce. He says that in most of his cases the full results of the menopause have not yet been developed. This is the work of months or years. In two cases the change seemed to occur at once in all its completeness.

Dr. Batley says that his patients, without exception, lost nothing whatever by the operation. Two, however, lost their lives. Three were alarmingly ill, and in great danger.

Dr. Batley impugns the remarks on his operation by Dr. Matthews Duncan, in his address on opening the obstetric section of the British Medical Association in August last. But he has failed to show any

reason for a modification of what was then and there said.

The profession will look with eagerness for further reports regarding this novel proceeding, and meantime awards to its bold originator and practical advocate a liberal meed of praise.

J. MATTHEWS DUNCAN, M.D.

CHANTREUIL ON CONDITIONS OF THE UMBILICAL CORD INTERFERING WITH PREGNANCY AND DELIVERY.—The undue length of the cord, by imparting to it a greater degree of mobility and making it describe a greater number of circuits, may expose it to compression, either because it coils itself round the foetal parts, or because it is obliged, so to speak, to leave its natural situation (a hollow situated at the anterior part of the fetus and resulting from its rolling round on itself), or because it prolapses.

Dr. Chantreuil, according to an analysis of his inaugural thesis published in the *Archives Générales de Médecine* for September, 1875, sets out by first studying the coiling of the umbilical cord. The coils are often found round the neck, but rarely round the trunk or limbs, which are not often encircled by the cord without the neck also being involved in the coils. The average frequency of these coils is about one in every six deliveries. The predisposing causes are stated by many writers to be excessive length of the cord, excess of the liquor amnii, and small size of the foetus. The determining causes are the undue movements of the foetus and of the mother. The diagnosis of coils may be made by taking note of a certain number of signs, some probable, some presumptive. The first are likewise signs of the shortness of the umbilical cord; sudden retreat of the head, a little hæmorrhage after every pain, pain confined to a fixed point of the uterus, protracted labour, elevation of temperature. The second set of signs are furnished (1) by palpation of the abdomen. Charrier was able by this means to feel a loop of the cord coiled round the back of the foetus. (2) By auscultation. Sometimes beats which are isochronous with those of the foetal heart are heard along the course of the cord. (3) By vaginal examination. The finger alone can seldom reach the coils. The whole hand should only be introduced in cases of absolute necessity. (4) By digital examination of the rectum. Hoake is the first writer who recommended digital examination of the rectum, to diagnose the coiling of the cord round the neck when the head is still impacted. The first finger is introduced into the rectum, pressing on the foetal head until it reaches the neck, when it encounters the coils, which are easily recognised by the pulsations of the cord. But M. Chantreuil justly remarks, that in a great many cases the diagnosis is only made at the moment when the foetal part is expelled, because the cord is then accessible to vision and touch. The prognosis of the coils varies with the presentation. In that of the vertex and face, they are accompanied by compression at the moment of the passage of the head. In the presentation of the pelvic extremity, the prognosis is more serious, because it is impossible to disengage the cord, except during version. Sometimes it is even necessary to cut it. The coils round the neck are the most serious. The prognosis is not necessarily in harmony with the number of turns. If the coils be discovered during pregnancy, premature delivery may be found necessary. Lamolle, Barton, and Albert Adolphe divided the cord during delivery.

M. Chantreuil thus summarises the rule to be followed. (1) There should be no interference during pregnancy; this is a rule without any exception. During delivery, the disengagement of the fœtus should be looked for, and the neck examined with the hand, so as to make certain if there are any coils. If possible, they should be uncoiled; if not possible, they must be cut. (2) If the life of the child be in danger, the forceps should be applied before the expulsion of the head. Coiling in the case of twin-pregnancy requires no special consideration.

When, instead of remaining in relation with the hollow formed by the anterior plane of the fœtus, the cord is rolled up on itself, it runs the danger of being compressed, and death often supervenes without any suspicion of the cause. M. Chantreuil examines these cases under the head of abnormal situation of the cord.

In the fourth chapter of his thesis, he passes in review cases of absolute or relative shortness of the umbilical cord. In his opinion, diagnosis is almost impossible during pregnancy and the first moment of delivery, and can only be made with any precision at the moment when the fœtus presents itself. Prognosis is not a very serious matter for the mother, except in certain abnormal cases, where shortness occasions hæmorrhage by premature detachment of the placenta or inversion of the uterus. In the child, on the contrary, the prognosis is much more serious, as it may succumb, not only in consequence of the tension of the umbilical cord, but also as a consequence of the rupture.

In another chapter Dr. Chantreuil treats of the knots of the cord, which may be simple or complicated, according as their structure varies with their duration. The conditions which favour their production are the length of the cord, the abundance of the liquor amnii, the movements of the mother, and the excessive movements of the child.

M. Chantreuil likewise examines torsion of the cord, distinguishing between a physiological and a pathological torsion. The former consists in turns or fractions of circumvolutions, in which the whole length of the cord is involved. It has no disastrous effect on the fœtus. The second variety of torsion is characterised by a number of circumvolutions only affecting one portion of the umbilical cord, at which point the jelly of Wharton is rare, or even altogether wanting. The size of the vessels is diminished, and their walls are drawn closely together. Whilst these vessels are still permeable, they should be driven up with sufficient force to overcome the obstacle. It will then be easy to understand to what extent the foetal circulation is interfered with during life.

M. Chantreuil considers at what period of pregnancy torsion of the cord supervenes. To answer this question he reports Dobra's statistics, including sixty-four cases. In thirteen fœtuses it occurred at three months, in fifteen at four months, in five at five months, in eight at six months, in twenty-two at seven months, and in one at eight months. This shows that torsion of the cord is not met with in the two first months of pregnancy; it comes on sometimes from the third to the seventh month of gestation; it must therefore be remarked that it is impossible to fix the commencement of the torsion in a definite manner. However that may be, when once the torsion occurs, pregnancy does not go on to the full term. Torsion has no direct effect on the

mother; it acts on the fœtus only; it may not only produce stenoses of the umbilical vessels, but their rupture and that of the entire umbilicus.

The author then proceeds to investigate the anomalies of the insertion of the cord, whether on the placenta or on the fœtus. One of the most interesting sections of the thesis is that relating to the velamentous insertion, that is to say, to that particular mode of inversion characterised by the disassociation of the umbilical vessels, and their distribution to the membranes before reaching the placenta. This anomaly, of which the discovery is erroneously attributed to Benckeser, had been studied by Wurberg in 1773, by Sandifort in 1778, and especially by John Frederic Lobstein, of Strasburg, in 1801. M. Chantreuil, therefore, attributes to these writers, and not to Benckeser, whose work appeared in 1831, the merit of having made velamentous insertion known. According to Hüber, it occurs when the vessels of the cord come into connection with the decidua serotina. This insertion makes abortion with foetal hæmorrhage of likely occurrence, as well as prolapsus, so that its prognosis is always serious for the child. In further sections of his work, Dr. Chantreuil treats of adhesions of the cord, both to the child and to the amnion, of the variations of thickness, of the anomalies of the vessels, and of tumours of the umbilical cord. The adhesions of the cord as a rule are only present in cases of monstrosity. Variations of thickness, either from excess or deficiency, have generally no influence on the fœtus. Anomalies of the vessels and tumours of the cord are often co-existent with adhesions of the placenta.

PINARD ON THE INDICATIONS AGAINST VERSION IN SHOULDER-PRESENTATIONS.—Dr. A. Pinard, in his *Thèse d'Aggrégation*, defines version by external and internal manipulation, and then goes on to describe the method of operation in breech presentation. He then comes to the contra-indications which result (1) from the non-dilatation of the orifice; (2) from the too deep impaction of the fœtus; (3) from a too great narrowness of the pelvis. Amongst the causes which oppose themselves to the dilatation of the orifice and prevent the accomplishment of version, the writer quotes cancer and fibrous tumours of the neck of the uterus. The writer then quotes a certain number of cases in which the too deep impaction of the fœtus prevented version. The retraction of the uterus, the result of fruitless attempts at version or of taking oxytocic medicines, is one of the most formal counter-indications against pelvic version. The author afterwards examines how the accoucheur should proceed in narrowness of the pelvis when there is breech-presentation. In pelvis which are constricted, but still show an extent of 7 to 9 centimètres in their promonto-pubic diameter, version must be performed. But when the diameter is under 7 centimètres it becomes a question what is to be done. M. Pinard separates these pelvis into two categories: in the first he places those which measure from five to six centimètres and a half; in the second, those which measure less than five centimètres. In the pelvis of the first category, M. Pinard admits that version is sometimes possible but extremely difficult. It is only after having bruised, torn, lacerated, even perforated the genital canal, that the cephalic extremity is extracted. If we leave out of the question the labour and fatigue of the accoucheur, and only look to the mother and child,

what is the result? The child is crushed to pieces, the mother is exhausted and weakened, and, notwithstanding all the skill of the operator, such disorganisation of the genital parts may come on that, as a rule, death will be the consequence. The author then cites a series of cases in support of his views, and adopts the following conclusions. In pelves which measure from five to six and a half centimètres, if it be ascertained that the child is dead, version is still the only operation to which recourse can be had. But if the infant be living, version should be rejected, and recourse had to another operation. Pelvic version is impracticable in contraction under five centimètres. In the second part of his thesis, the author reviews the means by which version may be replaced: 1. When the neck is neither dilated nor dilatable; 2. when the fetal portion is too deeply impacted; 3. when the uterus is constricted either by a prolonged labour or by the immoderate use of oxytocic drugs; 4. in extreme narrowness of the pelvis.

OPHTHALMOLOGY AND OTOLOGY.

SEELY ON THE AURICLE.—In the *Ohio Clinic* of May 1, in the present year, appears a popular paper upon the auricle of the ear, read by Professor Seely before the Cincinnati Literary Club. After describing the normal anatomy of the organ, which is further illustrated by a woodcut, he passes on to certain 'physiological considerations' as to the function of the auricle. Humboldt's statement is mentioned, how that the troops of wild horses in South America divide into three sets, according to the direction of their ears—those that direct them forward being in the van; those that turn them to the side occupying the centre; while those which direct them backward bring up the rear—the troop being thus warned against danger from whatever direction it may threaten. The auricles of the horse were further regarded by Müller as an index of character—*e.g.* the vicious horse, as is well known, carries the ears thrown back, etc. The opinions of various physiologists are further discussed as to the utility of the auricle in man as a collector of sound-waves [Helmholtz's name, curiously enough, being conspicuous by its absence throughout the whole

article—*Rep.*], the experiment of Schneider being mentioned, who found that if all the various external depressions or cavities of both conchæ be filled with wax, it will be impossible to know the direction of sonorous waves, unless one of the auditory canals be casually turned in the direction of the sound. Hermann and Dunglison state that hearing is not at all impaired, except for a few days at first, by the removal of an auricle. [The reporter has seen in the clinic of Professor Gruber, in Vienna, a man, one of whose auricles had been completely eaten away by lupus, who stated that his hearing was quite unaffected. In this case it may reasonably be objected that, owing to the gradual—and piecemeal, so to say—removal of the concha, the rest of the auditory organ would be able gradually, and therefore insensibly, to adapt itself to the new conditions.] The 'Spitzohr,' as the Germans term it, of Darwin is next discussed, and a figure is given of a specimen. The following quotation from the celebrated novelist Hawthorne is further given:—"Donatello," playfully cried Miriam, "do not leave us in this perplexity. Shake aside those brown curls, my friend, and let us see whether this marvellous resemblance extends to the very tips of the ears." "No, no, dearest Signorina," answered Donatello, laughing, but with a certain earnestness, "I entreat you to take the tips of my ears for granted. I shall be like the wolf of the Apennines, if you touch my ears ever so softly. None of my race could ever endure it. It has always been a tender point with my forefathers and me."

Some regard the auricles in man as rudimentary organs, such as the 'plica semilunaris' at the angle of the eyelid, and others. It has been suggested, however, that though functionally almost useless, they may be of some medico-legal importance—*e.g.* in the determination of the age of a fetus; to which end the following measurements have been made. The longest, or vertical, diameter in a fetus of ten to eleven weeks is 2 millimètres; of three months, is 4 to 5 millimètres; of four months, $5\frac{1}{2}$ to $7\frac{1}{2}$ millimètres; of five months, 8 to 12 millimètres; of six months, 14 to 17 millimètres; of seven months, 16 to 24 millimètres; of eight months, 26 millimètres; of nine months, 26 to 28 millimètres; of the new-born infant, 33 to 36 millimètres. (These measurements have been made from preparations in alcohol; if made on the fresh subject, they would probably be a little greater.) According to Joux, moreover, no other organ of the human body so uniformly descends, still retaining its peculiar feature, from father to child. [It will be remembered that the auricles afforded an important point of non-identity in the celebrated 'Tichborne case.' 'The difference between the ears of Roger and of the defendant afford evidence which it is no exaggeration to term 'startling.' The ear of the defendant is longer by one-third, the greatest length being largely due to the detached pendulous lobe, which in Roger had no existence.' Vide fourth edition of Guy and Ferrier's *Principles of Forensic Medicine*.—*Rep.*]

Dr. Laycock and Dr. Mitchell have made many important observations as to the pathological import of the variations of the external ear, and to these reference is duly made in Professor Seeley's paper. In those, for instance, with slowly progressing general paralysis, the lobe of the auricle is not only soldered to the cheek, but its posterior half is, as it were, cut in half, and the helix defective. The latter structure and the lobule, according to Laycock,

often vary in size in the same individual, under varying conditions of mental or encephalic health, being flaccid when he is depressed, while they regain their usual plumpness on the return of mental vigour. Lavater, Joux, and Stahl assert that the auricle has a physiognomic significance. [It is remarkable that this is in direct opposition to the opinion of that most acute of all observers, Aristotle, who expressly declares of the ear, in cap. 9, lib. i. of his *Historia Animalium*, ἡὸς δ' οὐδὲν σημαίνει—'but it is of no physiognomic import.'—*Rep.*]

Attention, too, is very rightly directed to the observations of Winkelmänn in his well-known *Geschichte der Kunst des Alterthums*, and especially to the statement that by the artists of antiquity no part of the head was more carefully elaborated than the ears; so much so, that these organs afford the best indication as to whether a work of art put forward as antique is genuine or not. [The antique statues of Faunus, as showing their brute affinities, however beautiful the rest of the body, all have the 'Spitzohr,' while the ears of the boxers, or 'Pancratiasts,' owing to frequent fights, are swollen, as though with the othæmatomata not rarely seen in lunatic asylums.—*Rep.*]

Joux [like all enthusiasts, not excepting the prince of epicures, Brillat-Savarin, whose fourth aphorism runs thus: 'Dis-moi ce que tu manges, je te dirai ce que tu es.'—*Rep.*] goes so far as to exclaim: 'Show me your ear, I will tell you who you are, where you came from, whither you are going.'

JOHN C. GALTON.

GRUBER ON A NEW METHOD OF OPENING THE EUSTACHIAN TUBE AND VENTILATING THE TYMPANIC CANITY.—Finding that the passage of the Eustachian catheter is not always easy, or possible, and that the patient sometimes evinces a dislike to its use, Professor Gruber gives, in the *Monatsschrift für Ohrenheilkunde* for October, a description of a method which he considers has some advantages over what are called Politzer's and Lucae's methods, which are those usually employed instead of the catheter. For the passage of air up the Eustachian tube, it is necessary that the structures effecting the closure of the pharyngeal space in other directions will withstand a considerable amount of pressure. The act of swallowing, or some similar motion, is sufficient for this purpose; but as it is not always easy or painless for patients to swallow, Professor Gruber has endeavoured to ascertain by what other motion the same end can be arrived at. He says that the simple pressure of the root of the tongue on the posterior segment of the palate simultaneously with a forcible expiration is enough. This motion of the tongue separates the space of the mouth from that of the pharynx, and at the same time presses the soft palate upwards and backwards. The air which at the same moment is driven by the expiration into the pharynx cannot find an exit through the mouth or nose, but, pressing out the soft palate, causes it to form a firmer and more resistant wall, the more forcible the expiration. The nozzle of the caoutchouc bag having been previously introduced into the nostril, the bag is forcibly emptied, in the same way as in Politzer's method, synchronously with the expiration.

The teaching of these motions to the patients usually met with in a clinique would be, however, a matter of difficulty; and Professor Gruber has, by observation on himself and others, determined that

the articulation of the syllable hck=hkk, or huck, causes the same motions to be made by the tongue and palate. The closure of the pharyngeal space is effected in different degrees by the utterance of the syllables hack, heck, hick, hock, huck, hck, the closure being greater the later the expression stands in the series. When these syllables are spoken peculiar changes in the ear are to be observed; sometimes a motion of the tympanic membrane, and sometimes a noise like to that which is heard by Valsalva's method. Gruber believes this to arise from the same cause, viz., the passage of air through the Eustachian tube. In a foot-note he says he has made a series of manometric observations which he will publish when completed.

The closure of the pharyngeal space and the opening of the Eustachian tube as above described, he puts to practical use as follows. 'The operator stands or sits, as is most convenient, with the patient *vis-à-vis*. The end of the nozzle of the bag, which is held in the hand of the operator, is inserted one centimètre into the nostril of the patient. The operator now closes with the index and middle fingers of the other hand the nostril upon the nozzle of the bag, and while the patient at his command pronounces one of the before-mentioned syllables, the bag is forcibly squeezed, and the air is distinctly heard to pass through the tube into the tympanic cavity.'

Professor Gruber thinks that by inclining the head to one shoulder, and acting through the nostril farthest from that shoulder, the air passes in a greater degree up the Eustachian tube corresponding to the nostril blown through.

He believes this method has the following advantages over Politzer's.

1. It is much simpler, as it does not require the patient to swallow, which may be painful to him, and it does away with the objections raised by some patients to take water out of a tumbler common to many in a crowded clinique.

2. The patient is able to continue the closure of the pharyngeal space longer, if necessary, than by swallowing, so that air can pass for a longer time up the tube.

3. The force of the air through the tube can be better regulated by the use of the different syllables on the scale above given.

4. When the patient passes the air-douche for himself at home, he can regulate more easily the strength of the current. W. LAIDLAW PURVES.

CUIGNET ON SIMULATION OF MYOPIA OR OF HYPERMETROPIA BY RECRUITS, BY MEANS OF CONVEX OR CONCAVE GLASSES.—In order to test the accuracy of the widely prevailing belief that recruits, in order to obtain exemption from military service, are in the habit of simulating these errors of refraction by accustoming themselves to read through very powerful glasses, Dr. Cuignet (*Recueil d'Ophthalmologie*, July 1875), carried out a series of experimental trials upon the eyes of twenty-one non-commissioned officers who were stationed in Algeria.

These soldiers were chosen as being intelligent and reliable subjects, fairly educated, in good general health, and one and all possessing a nearly normal range and acuteness of vision. They could read Jaeger, no. I. at 12", and Jaeger, no. XX., at about 20'; and their average age was twenty-six.

Dr. Cuignet proceeded as follows. To three of

the soldiers he gave -15 glasses, and instructed them to use them in reading Jaeger VIII. for an hour in the morning, and for another hour in the afternoon. With a day or two of practice these men could read this type fluently, and -12 glasses were given them; at the same time -15 glasses were given to a second set of three men, so that one set of observations was made to check the other, and in this manner the entire number were gradually exercised in the use of glasses of higher power, -10 -8 -7 -6 -5½, and even -4 glasses being eventually employed. The trials extended from eight to twelve days, an interval of rest being allowed before the glasses of the highest power were employed. The results were that six were unable to read with -5½, ten were able to read with -5½; and five were able to read with -4. With all of them the effort to read with -6 was painful and difficult; and of those who succeeded in reading with -4, only two eventually did so with ease, the other three being only able to do so with extreme difficulty and when the type was brightly illuminated; the two former were slightly myopic and their optic disks were small, elliptical and bordered by choroidal atrophy.

Of sixteen of these men, not one was able to read Jaeger XX. at a distance with -glasses, such as -4 -5 -6 or -7.

From the above observations, Dr. Cuignet concludes that it is only with extreme difficulty that a recruit could learn to read with -5½ glass, and that it would be beyond his power to do so with -4 if his refraction was emmetropic; his success in doing so would reveal a certain amount of myopia; hence it appears that the test required by the Board of Examination, that the recruit should read with -4 glass, is practically sufficient to prevent or to detect deception.

In the same manner these soldiers were exercised in the use of convex glasses, and it was ascertained that sixteen were unable to read Jaeger no. VIII. with +8 glass, and although three were able to do so, they were unable to do it with +7, and not one of them was able to read it with +6, which is the test required to prove the presence of hypermetropia in sufficient amount to incapacitate for military service.

In Dr. Cuignet's opinion it follows, then, that it is impossible for a recruit to escape the service by simulation of this kind, and that the tests at present employed by the military surgeons are sufficiently stringent.

FAVRE ON FAULTY PERCEPTION OF COLOURS AFTER INJURIES TO THE HEAD.—Several writers of repute, and amongst them Desmarres, have placed cases upon record, in which Daltonism had followed severe injuries to the head. Dr. A. Favre has searched the records of these and of similar cases, and has published the result (*Lyon Médical*, July 25, 1875.) The occurrence of this faulty perception of colours after blows upon the head, either with or without a wound, and especially after contused wounds in the neighbourhood of the eye, is thus placed beyond doubt; but it is by no means constant, and Dr. Favre is not in a position to say positively that it is more frequent after an injury of a particular kind, or that it is always associated with injury of any one special region. The ophthalmoscope has not as yet revealed any appreciable lesion within the eye; and in those instances in which the phenomena have been noticed before the patient's death in con-

sequence of injury, no information has been gained from the *post mortem* appearances.

In the majority of cases, the defect of vision has been transient; but in one or two it has lasted for some weeks; in one instance of which Dr. Favre writes, the defect was first noticed when some weeks had passed since the injury. In no case yet on record has the defect been noticed as a permanent condition.

It is interesting to note the particular error which such patients commit. For the most part the complementary colour is seen by the patient; thus red has appeared to be blue, and blue red, to a man who had received a contused wound of the upper eyelid; and another patient who had received a sharp blow upon the eyeball with the finger, saw everything which was red as though it were green. In several instances the neighbouring colour has been seen; thus blue has appeared to be green, and green has appeared to be yellow.

Such facts as these are of great importance to all who from their occupation have to do with coloured light; this is especially the case with sailors and with railway *employés*, who are also very often exposed to the risk of injury. There are various branches of work in which an exact appreciation of colours is of great importance; one of these mentioned by Dr. Favre is the process of making the kind of steel known as Bessemer steel; during this process the workman has to watch very closely the play of colours which takes place in the metal under operation, while it is obvious that he himself is running no little risk.

BOWATER J. VERNON.

FANO ON DATURINE AS A MYDRIATIC.—The results of numerous cases collected by Dr. Fano, and communicated to the *Journal d'Oculistique et de Chirurgie* for August and September, are as follows.

1. With a solution of daturine (1 part in 3,000) dilatation of the pupil of a healthy eye is obtained in from twenty to twenty-five minutes.
2. The action of daturine is as prompt as that of atropine; the two solutions employed being of equal strength.
3. The instillation of a daturine collyrium (1 in 600) produces dilatation of the pupil at the end of twenty-five minutes, and in young subjects in a shorter space of time.
4. The instillation of an atropine collyrium produces mydriatic effects rather more promptly than the instillation of a daturine collyrium.
5. If, in vasculo-plastic keratitis, accompanied by a non-dilatable state of the pupil, daturine be inefficacious in bringing on this dilatation, the atropine also remains ineffective.
6. But in these same kinds of keratitis, daturine sometimes produces dilatation of the pupil, when atropine has not exercised any action of the kind. If the daturine collyrium do not produce dilatation of the pupil in certain cases of vasculo-plastic keratitis, in which the mydriatic effect of the atropine is also not more appreciable, the daturine seems to exercise a special action over the vessels of the cornea, which diminish in size under the influence of the alkaloid of datura stramonium.
8. The daturine collyrium therefore appears superior to atropine in certain cases of chronic and vasculo-plastic keratitis.

DERMATOLOGY.

HEBRA'S TREATMENT OF SKIN-AFFECTIONS.—Dr. Rudolf Tauszky, of New York, writes in the *Ohio Clinic*, August 21, 1875: Experience in this city has taught me that the formulæ used by Hebra for the treatment of the affections of the skin are generally not known to general practitioners, especially is this the case with druggists. When I have had occasion to prescribe Vlemingx's solution or pilulæ Asiaticæ, or spiritus saponis alcalinus, etc., druggists invariably sent their clerks to my office to inquire what my prescriptions meant. The readers of the *Clinic* will, I hope, pardon me, those at least who do not make the treatment of skin-diseases a specialty (for the latter, of course, these lines are not intended), for briefly communicating the mode of treatment successfully used in Vienna.

1. In *seborrhœa*, Hebra rubs the scabs with a soft sponge which has been dipped in oil, and afterwards applies, if the scalp be affected, a flannel cap upon it, which has also been well soaked in oil; over this

another cap made of oiled silk is placed and left there for two hours, after which time the softened scabs are removed with soapsuds. If the layer of scabs be very thin, the oiling alone is quite sufficient for the purpose of removing them. The treatment of these crusts is, therefore, a very simple and efficient one; anointing them with simple cerate, washing the scalp with soap and water, or using:

R Spermaceti,
Olive oil, aa q. s.
M. S. ointment.

or in very obstinate cases he uses:

Green soap (sapo viridis) ʒij,
Spirit. vini rectificati (alcohol) ʒj,
Filter and add spts. lavandulæ ʒij.
S. External use.

With this latter mixture use at the same time the cold douche. On the hairy scalp, alcohol or French brandy should also be used with a soft sponge, when the green soap mixture is being used.

Another good and valuable prescription in the hypersecretion of the sebaceous glands is the following:

R Ætheris sulphur. ʒss,
Alcohol rectificati ʒj,
Tinct. benzoës,
or aqua de Cologne ʒj,
S. Wash.

In infiltrations of the skin use ointments, for instance:

R Oxydum zinci,
or Hydrargyri præcipit. album
or Carbonas plumbi.

Of either of these one drachm to the ounce of simple cerate, or use:

R Oxyd. zinci,
Carbon. plumbi aa ʒj,
Spermaceti ʒj,
Olei olivæ quantum sufficit ut fiat unguentum molle.
S. ointment.

In *seborrhœa* of the genital organs apply amyllum, semina lycopodii pulv., talcum Venetum (Venetian tallow) or pulv. oxyd. zinci, or pulv. alum. plumosi.

2. Against *comedones* Hebra uses soaps of potash or soda, pressing or squeezing them out by means of a watch-key, or he prescribes as a wash:

R Carbonate of potash ʒj,
Distilled water, one pound.
S. Wash. Use several times a day.

or

R Carbonate of potash ʒj.
Distilled water ʒij.

S. Touch the efflorescences with a hair-pencil dipped in this solution.

In very obstinate cases:

R Lac. sulphuris,
Glycerini,
Spirit. vini rectific. (alcohol),
Potassæ carbon.,
Ætheris sulphuric, aa ʒij

S. To be applied in the evening with hair pencil, and washed off in the morning.

If dependent on scrofula or tuberculosis, of course these affections have to be treated on general principles.

3. *Milium*, *Strophulus*.—Use fomentations of milk, bran poultice, afterwards wash with soap, or use:

R Carbonate of potash ʒj,
Distilled water a pint.

Mix and bathe with it. If soft, prick the epidermis with a

bistoury or lancet, and press the contents out with a watch-key.

4. *Molluscum Contagiosum*.—Small tumours are squeezed out, larger ones have to be extirpated or ligatured.

5. *Hyperhydrosis* ; profuse sweating.

R Empl. diachyli simpl. liquefacti,
Olei lini aa q. s.

S. To be applied and left on for twelve hours ; to be continued by making a fresh application night and morning for eight or twelve days,

or

R Empl. diachyl. simpl. liquefacti,
Empl. lithargyri fusci,
Olei lini, aa q. s.

M. D. S. To be thickly spread upon linen and applied to the feet for nine days, changing the application once every three days. The epidermis soon peels off, after which use foot baths, and either of the following powders are to be used locally : Starch, lycopodium, cream of tartar, alum, etc.

6. *Pustula Maligna. Carbuncle*.—If the affection be limited to a small space, use the actual cautery, or cauterise with caustic potash. Excision will arrest the disease in the same manner.

7. *Erythema* generally disappears by itself without medication. Only in erythema nodosum, horizontal posture of the extremity ; cold applications either alone or with aquæ Goulardi ; tepid applications if the cold be not well borne.

8. *Intertrigo*.—Dusting the parts with semen lycopodi, or starch, or alum, or

R Unguenti cinerei,
juniperi aa ʒij.

M. S. Ointment, apply morning and evening.

or

R Oxyd. zinci ʒj,
Amyli puri ʒj-ij.

S. Powder to be used locally twice daily.

If the epidermis be removed, in abrasions use spermaceti, and cold applications. If there be pustules : (*Intertrigo pustulosum*) applications with :

R Hydrarg. sublimati corros. gr. j,
Aquæ destill. ʒj.
M. S. External use only.

9. *Urticaria*.—Use cold baths or locally diluted acids ; to allay itching, touch—with rub—with alcohol. If caused by indigestion, give an enema or cathartic to remove the cause. In the chronic form, the so-called papulosa, great benefit is derived from the application of mercurial plaster, applied in the evening and left all night.

10. *Erysipelas*.—In high fever, quinine, give acidulated drinks. As long as there is swelling and pain, use ice-bags. If the disease abates, use warm fomentations. If the erysipelas be spreading (*Erysipelas migrans*), use on the border mercurial ointment. Dust the inflamed part with amylum.

11. *Herpes*.—Dust the vesicles with amylum or apply crème celeste ; warm applications with narcotic herbs are recommended, and pencilling with collodium. In herpes zoster against the neuralgia which sometimes remains,

R Morphii muriat. gr. x,
Aquæ destill. ʒij.

S. 5-10 drops hypodermically applied,

or

R Emplastr. diabol. ʒss,
Ext. opii aquosi,
or Laudani puri ʒj.

S. Plaster, spread upon leather or linen and fasten on the affected part with a strap and left until the pain subsides, or until an artificial eczema is produced.

In herpes of the mouth :

R Permanganatis potassæ ʒij,
Aquæ fontanæ ʒvijs.
S. Mouth-wash.

12. *Miliaria, Sudamina*.—Starch locally, or

R Olei rusci ʒj,
Alcohol rectificati ʒvj.

D. S. The affected part to be lightly touched with this.

13. *Eczema*.—If dependent upon constitutional causes, these have to be treated. In chlorosis, preparations of iron are given. If dependent on general debility, wine and a generous nourishing diet ; meat, fish, etc. : if the eruption appear periodically, being preceded by febrile movements, quinine : in obstinate cases, arsenic and carbolic acid internally, with fresh air and attention to hygiene. The local treatment, however, is most important, more so than the general constitutional. And here the ointment made of adhesive plaster, dissolved in linseed oil, unguentum diachyli album, the *schmierseife* solution of caustic potash and the preparations of tar : oleum rusci, oleum fagi, or oleum cardini play an important part. To remove the scabs, especially from the scalp or the face of children, use locally cod-liver oil, sometimes olive or linseed oil, or oil of almonds, mutton tallow, simple ointment, crème celeste, spermaceti, cold cream, or hog's lard. The hydrotherapeutic treatment is applicable to recent, general, acute cases. Hebra recommends the wet pack, which can be made use of in hospital as well as in private practice. It is the following. Place an equally large piece of India-rubber over a mattress, over this two folded bed sheets, over this one or two woollen blankets, finally two wet sheets (and the urinal), the latter to be placed between the thighs of the patient. The upper sheet answers for the trunk and upper extremities, the lower for the lower extremities. The shower-bath, for instance, an ordinary watering-pot, is arranged near the bed. After the use of the shower-bath, the sheets are drawn tightly over the patient, and over all his coverings another blanket is placed. The patient soon feels warm, commences to sweat, and the itching and burning soon improves. This manipulation is to be repeated at least four times in twenty-four hours. The room must be moderately heated, and it is well for the patient to take some exercise after the wet pack and the douche before going to bed.

If the eczema affect only the fingers, hands, or feet, Hebra recommends India-rubber gloves or stockings ; but these must be cleaned twice by being placed in fresh water, and the extremities must be washed and cleaned at the same time before the India-rubber is again applied.

If the skin be infiltrated, and where there is a good deal of watery secretion, the parts are to be washed with green soap. These have to be dried and diachylon ointment is to be worn upon them, sometimes for weeks. If the skin is peeling off, scaling, preparations of tar have to be used. His formulæ are these :

R Melted adhesive plaster,
Oil of linseed, boiled, aa ʒij
Oil of lavender 6 drops
S. Diachylon ointment.

or the same ointment modified :

R Olive oil ʒiv,
Litharge ʒj.
Heat till you get a soft ointment, and add
Olei lavandulæ gtt. x.

S. Thickly to be spread upon linen, and to be changed twice in twenty-four hours.

The salve has to be held tightly to the affected part by means of a bandage. But these ointments are not applicable on hairy parts. Here carbolic acid, or solution of borax, or spiritus saponis alcalinus answer best.

R. Acidi carbol. ʒj.
Olei olivarium ʒvj.

M. S. This mixture is to be applied gradually, and is briskly rubbed into the affected part with a stiff brush, and is to be washed off with soap and water, lukewarm (as in shampooing),

or

R. Acid carbol. ʒj.
Glycerini,
Bals. Peruviani aa ʒij,
Spirit. vini. rectificat. ʒvj.
S. To be used like the former,

or

R. Boracis Venetæ,
Aluminis crudi, aa ʒj,
Glycerini ʒij.

S. To be applied morning and evening with stiff brush (like soap in shampooing).

On the scalp Hebra uses the spiritus saponis alcalinus, the formula for which is :

R. Saponis viridis (green soap),
Alcohol. rectificati ʒj;
Filter this solution, and add
Spirit. lavandulæ ʒj
S. Alkaline spirits of soap.

Or the so-called 'schmierseife' of Hebra, which is in extensive use, is made as follows :

R. Lixiv. caustic. (spec. grav. 1.333.) ʒijj,
Adip. ceti ʒvj,
S. Schmierseife.

The affected parts are to be rubbed with this schmierseife with a flannel, and the patient remain wrapped in woollen blankets during the treatment ; or the soap is soon removed with tepid water, and the parts are covered by cold applications. In eczema of the nose he uses, after cleansing the nostrils with lukewarm water, pledgets of lint with diachylon ointment into the affected nostril, or

R. Zinci sulphur. gr. vj,
Aquæ laurocerasi ʒj,
Glycerini ʒij.

Lint dipped into this liquid to be introduced into the nostril. Or

R. Oxyd. zinci ʒij,
Ung. glycerini ʒj.

To be applied in milder cases—eczema simplex. In intertrigo he recommends the following :

R. Oxyd. zinci ʒj,
Unguent simpl. ʒj.
M. f. ointment.

or

R. Mercurii præcip. albi,
Zinci oxyd. aa ʒss.
Axungiæ ʒj.
S. Ointment.

or

R. Zinc. oxidi ʒj,
Amyli puri ʒj,
S. Powder.

or

R. Amyl puri ʒiv,
Pulv. iridis florent.
Alum. plumosi, aa ʒij.
S. Powder.

or

R. Sulph. zinci ʒj,
Aquæ destill. simpl. libr. j.

Where there is a large secretion, especially in

eczema of the face, to be applied by means of cloths, which have to be saturated with it.

Or

R. Cupri sulphatis ʒj,
Aquæ destillatæ, libram j.

Also applied by means of cloths.

Or

R. Kali caustici ʒj,
Aquæ destillatæ, libram j.

In pityriasis rubra and eczema squamosum.

R. Olei cadini,
Saponis viridis aa ʒss.
Alcohol. rectificati ʒiv.
Twice daily with brush.

In addition to this, he dusts the patient with one of the powders, starch, etc., and uses the continued bath.

R. Olei cadini,
Olei jecoris aselli.
S. To be rubbed in.

or

R. Olei cadini ʒij,
Glycerini ʒij.
S. The same as the former.

The application of these tar preparations is made after the parts have been well rubbed with schmierseife (see above), and washed with tepid water.

In very obstinate eczema papulosum, especially on the lower extremities, but only once or twice a week, he applies :

R. Caustic potash ʒj,
Distilled water, ʒij.
S. Apply once or twice a week.

In the same manner he uses :

R. Mercur. sublim. corros. ʒj,
Æther. sulphur. ʒij,
Collodii ʒss.
S. To be applied after the bath.

The description of the treatment of pemphigus, acne, sycosis, impetigo, ecthyma, psoriasis, lichen, prurigo, combustio, congelatio, lupus, syphilis, scabies, favus, teleangiectasia, carcinoma epitheliale, herpes tonsurans, pityriasis versicolor, and eczema marginatum, onychomycosis, and pediculi pubis and vestimentorum, are reserved for a future occasion.

LONGWORTH ON PRURIGO.—In the *Cincinnati Clinic* for July 10, is a paper by Dr. Longworth, in which he says :

It is the extremities on which the disease manifests itself with greatest intensity, and the side of extension is always more affected than the side of flexion. The forearm is more thickly covered by the eruption than the arm; the thigh still more than the forearm and the leg more than all. It is in this latter situation that one who has had some experience can sometimes make the diagnosis with his eyes closed, by passing his hand rapidly over the anterior surface of the tibia, which produces on the dry roughened integument of this region a peculiar sound like that produced by passing the hand over the stiff, short hairs of a nail-brush, or over coarse wrapping paper, while at the same time a peculiar prickling, tingling feeling is imparted to the fingers. In certain regions the skin is invariably free, or very nearly so, from disease, although the rest of the body be thickly covered, viz., the skin over the side of flexion of the joints. Thus, no matter how extensive the eruption may be, the following regions are always unaffected : the axilla, the bend of the elbow, the palmar surface of the wrist and hand, the groin and genitals, the

hollow of the knee, and the sole of the foot. Finally, the lymphatic glands in the upper part of the thigh in the neighbourhood of the saphenous opening often become enormously enlarged; this is always the case when eczematous patches and pustules, the result of continued scratching, are present on the lower extremity. These tumours frequently attain the size of the adult fist.

True prurigo is fortunately not a very common disease; it begins, as a rule, in very early life, and continues with occasional remissions and exacerbations until its close. At certain times, after appropriate treatment, and occasionally in summer, the patient appears quite free from disease, the respite is, however, short, and unless treatment is persisted in it is sure to return. Upon whomsoever prurigo fastens itself, it will be very likely to prove his life-long companion and accompany him to the grave. The sufferings and torments of the unhappy victim of this disease are beyond description. Fierce and intolerable itching gives him no respite day or night. It is a constant presence with him; moral fortitude enables the patient to bear the pain of most chronic disorders, but the itching of prurigo is intolerable. Pain elicits sympathy, but itching carries with it an idea of the ludicrous or repulsive, which only increases the torments of the sufferer. Although feeling the deepest pity for the patient, I have often been unable to repress an involuntary smile to see a poor creature, a prey to this disorder, as soon as he is uncovered for examination, begin to tear his own flesh after the manner of a wild beast, and with a peculiarly exaggerated expression of despair on his countenance. Indeed the facial expression of a sufferer from prurigo is peculiar; it is severe, sour, ascetic; he answers only in monosyllables, never dilates on his sufferings, but is easily moved to tears, even if a bearded man, by a little sympathy from the surgeon. His manner is easily explained—he expects no sympathy from anybody; he has been an object of ridicule or disgust his whole life long to all with whom he has come in contact. As a boy and youth he has been plagued by his school-fellows and reproved by the teacher for his constant habit of scratching; later in life, especially if he belong to the labouring classes and is unable to secure a separate room or a separate bed, he is made sport of by his companions or bed-fellows, or even turned out of their society, either because in their ignorance they fear contagion, or because they are disturbed in sleep by his never-ceasing scratching. An object of disgust and aversion to his fellow-creatures, cut off from the enjoyments of friendship, or even, it may be, from the blessings of wife and children, what wonder is it that he finally loses all moral courage, and that tired of his miserable existence he at last puts an end to it with his own hands? Suicide, it is well known, is not uncommonly resorted to as the last cure of prurigo.

J. MILNER FOTHERGILL, M.D.

MÜNCHMEYER ON URTICARIA.—In the *Berliner Klinische Wochenschrift* (no. 20 of this year), Dr. Münchmeyer relates two unusual cases of this affection. One was in a boy eight years old, and occurred in the course of a slight febrile attack, with bronchial catarrh and gastric disturbance. On the second day two wheals appeared on the abdomen; others followed on the back and shoulders, and by evening the child's trunk was nearly covered with these five large patches. The general symptoms were not

altered, and—what has often been noticed in *Urticaria febrilis* of children—there was no local irritation and scratching. Two days later the other patches had disappeared, but around the two on the abdomen, which remained as red spots, had formed two much larger concentric circles, which together occupied the entire abdomen. These also had entirely disappeared by the sixth day of the illness, which was then at an end.

The other case was one of ordinary round itching and smarting wheals, which constantly appeared on the cheeks and chin of a healthy young soldier, when exposed to cold wind. The writer adds an anatomical description of the local oedema and anæmia, characteristic of urticaria and of the artificial wheals which may sometimes be produced by subcutaneous injections. He advocates the view that the condition depends primarily upon inhibition of the vaso-motor nerves, produced either by an external irritant, or by the reflex action of some drug or other excitant on the gastro-intestinal surface.

 On Sporadic Pellagra. By M. Béhier. (*Le Progrès Medical*, November 6.)

MEDICAL CHEMISTRY.

ZWEIFEL ON MECONIUM.—Zweifel (*Archiv für Gynécologie*, Band vii. p. 474, and abstract in *Centralblatt für die Medicinischen Wissenschaften*, no. 37, 1875) employed as material the contents of the great intestine of still-born children. The microscopic investigation gave the interesting result, viz., the existence of hæmatoidin crystals with the characteristic Gmelin's reaction. By extracting the meconium with chloroform and evaporating it, bilirubin crystals could be obtained. They were no longer contained in the yellow evacuations, and thus disappeared with the other constituents of the meconium. As chemical constituents of meconium were found: biliverdin, bilirubin, bile-acids, viz., taurocholic-cholesterin, mucin, traces of formic acid, and the higher volatile fatty acids, and non-volatile fatty acids. Negative results were obtained for grape-sugar, glycogen, paralbumen, leucin, tyrosin, albumen-peptone, lactic acid. The quantity of water in the meconium was almost 80 per cent., the ash about one per cent. The fat in fresh meconium was 0.772, and the cholesterin 0.797 per cent. Two analyses of the ash are given. The composition per cent. is—insoluble substances, 2.1; phosphate of iron, 3.41; sulphuric acid, 23.0; chlorine, 2.53; phosphoric acid, 5.44; lime, 5.7; magnesia, 4.0; potash, 8.6; soda, 41.0. In relation to the excreta

of adults, the high percentage of sulphuric acid and diminution in phosphoric acid is noticeable.

BOISIN AND LOISEN ON THE INFLUENCE OF BOILING DISTILLED WATER ON FEHLING'S SOLUTION.—E. Boisin and E. Loisen (*Comptes Rendus*, tome lxxix.) have found that pure distilled water when boiling reduces Fehling's solution employed for testing for sugar. Thus fifty cubic centimètres of water can reduce one cubic centimètre of solution. Ordinary spring water does not do this. A series of substances hinder the reduction, when they are added to the distilled water previously; especially lime-salts, ammonia, and soda-salts. With a quite pure solution of grape-sugar some chloride of calcium must be previously added to the Fehling's solution. The authors recommend this as a means of testing the purity of distilled water.

WM. STIRLING, D.Sc., M.D.

REPORTS OF FOREIGN SOCIETIES.

ACADEMY OF MEDICINE IN PARIS.

October 19. *Puncture of the Pericardium*.—M. H. Roger read the first part of a report on a case of paracentesis of the pericardium, communicated by M. Chairon, in which puncture gave issue to more than 1,000 grammes of liquid. Entering on the question from the general point of view, M. Roger affirmed that puncture of the pericardium is not like puncture of the pleura, and that there are two conditions necessary to the operation:—1. The size of the effusion; 2. The urgency of the symptoms. It is necessary first to specify what is understood by large effusion. M. Roger estimates it at a minimum of 500 grammes; below that, there is no cause for surgical intervention. In the majority of cases the very considerable effusions, and even medium ones, are easily recognised, especially by percussion. Many errors may, however, be committed, especially if, instead of being simple, the pericarditis be complicated with endocarditis, pleurisy, or tubercles. As an example of these mistakes, beside the case of tumours of the mediastinum, dilatation of the heart and pleurisy may be cited; sometimes, without knowing it, instead of the intended paracentesis of the pericardium, thoracentesis has been performed, and *vice versa*. And yet to perform pericardial paracentesis it is of the greatest importance to be certain of the diagnosis. Going on to the considerations drawn from the nature of the liquid, puncture seemed to M. Rogers to be contra-indicated in active dropsies of the pericardium, in sanguineous effusions, and in purulent collections connected with a general infection. In very considerable effusions of the pericarditis, puncture may be specially useful. With reference to the method of operation, the spot to be preferred is the fifth intercostal space; at an intermediate point between the nipple and the sternum, rather nearer to the former, always being guided by the apex of the heart. Beyond this point it would be easy to wound the surrounding organs. Many instances are recorded in which the heart has been wounded, even by capillary instruments. They, however, as well as experiments, demonstrate the innocuity of cardiac punctures. The aspiratory method, by the aid of capillary trocars, should have preference over other methods, which ought to be given up. What, however, is definitely the thera-

peutic value of paracentesis in pericardiac effusions? The indication for operation is rarely found, in consequence of coexistent or ulterior complications. It is always difficult, notwithstanding the capillary method; it is incomplete, for it can scarcely be repeated several times, nor kept up, like thoracentesis, by accessory means, washings out, etc.; but in certain circumstances, as in the large acute or chronic effusions of rheumatism, and in large chronic effusions of which the tubercular nature is not evident; operation is indicated. Out of a table of fifty-four cases, one cure only and several deaths are found; certainly it may be said that the disease itself is extremely serious when it shows itself under conditions which call for paracentesis. In some cases the pericarditis is cured by the fact of the evacuation of the liquid; but it leaves general adhesion which subsequently brings on an organic affection of the heart. Accordingly, the success will only be relative in a tuberculous patient, destined to succumb after a longer or shorter respite to the progress of the diathesis. To conclude, paracentesis of the pericardium has no curative power, but is formally indicated as a palliative, and sometimes as a last resource. It will always be a bold intervention; but one which is sometimes dictated and justified by necessity.

November 9. *Removal of the Uterus in Irreducible Inversion*.—M. Denuce, of Bourdeaux, read a note on the ablation of the body of the uterus in irreducible inversion. The conclusions of the memoir were these. 1. External hysterotomy is a surgical resource only to be used in extremity; but valuable in cases of irreducible inversion which endanger the life of the patient. 2. This operation does not show a larger mortality than the majority of capital operations. 3. It the present state of science it ought to be made preferentially by ligature, bearing in mind all the improvements which that method has received. 4. The first months of an inversion, even the first year, should as much as possible be subjected to repeated attempts at reduction, to lactation, which generally suppresses hæmorrhages, and to every kind of palliative measure. 5. Operation should be reserved for cases acknowledged to be irreducible, and for that already remote period of the disease when the uterus has become completely retroverted and has taken a fresh definite form, undergone by circumjacent organs, and which affords a much smaller field for peritoneal inflammation, which must be avoided at all hazards.

Disorders of Vision.—M. Jules Guérin intervened in the discussion on M. Giraud-Teulon's work, to claim his part in modern oculistic researches; a part which he regrets to see forgotten in consequence of the researches of the German and Dutch schools. Accommodation is not, as these schools and M. Giraud-Teulon assert, the result of the sole action of the ciliary muscle; the motor muscles of the ocular globe contribute equally to it, and the cornea modifies its form in accommodation. In strabismus the changes of the eye, far from being primary, as the German and Dutch schools affirm, would be conclusive on the contraction of the muscles of the eye. In certain affections of the eye spectacles are not the only resource, but also certain surgical operations performed for the last thirty years by M. Guérin.

Nov. 16. *Inoculability of Tubercle*.—M. Metzger read a second memoir on the non-inoculability of tubercle. Relying on more than 130 experi-

ments, he concluded that the nodules developed from inoculations have no resemblance whatever to tubercles, because in the majority of cases they are re-absorbed; because they may be produced by the inoculation of different substances; because in the inoculation of tuberculous substance, experiment only gives results in proportion as the matter employed is in a somewhat advanced state of decomposition.

On the Movements and the Functions of the Stomach.—M. Leven read a memoir on this subject. According to the researches of the writer, the function of the stomach does not consist in peptonising azotised matters; if the gastric juice has the power of converting albuminoid matters into peptones, the conversion is not effected in the stomach. The function of the stomach is to store up the food, to drive it into the intestine, if in the natural condition they are divided, as milk and raw eggs; if on the contrary, they are not divided, then to divide and drive them into the intestines. It is therefore not accurate to say that the only function of the muscular fibres of the stomach is to place the food in contact with the gastric juice. After having summed up the results of numerous experiments instituted by him on dogs, M. Leven concludes: 'To sum up, milk and raw eggs do not remain in the stomach; they are driven from it unchanged. If meat remain there for some hours it is because it is bulky and cannot make its exit until it is reduced, we have noticed that it reaches the intestine unchanged. Reduction and division of the meat is due both to the gastric juice and the *membrana muscularis mucosæ*. The gastric juice facilitates the action of the *membrana muscularis*. If, in the theory now in vogue, the *membrana muscularis* is only considered as a secondary one, it is because experimenters have been under unfortunate conditions for seeing it perform its functions well. If they have attributed an essential function to the gastric juice, it is because, only being conversant with one portion of their subject, they have exaggerated the importance of that which they have studied. They have never yet been able to discover in the stomach the peptones which it is credited with creating. Their theory, therefore, is only founded on hypothesis. That the gastric juice with which the fibrillæ of the meat is impregnated, helps to peptonise it in the intestine with the other digestive liquids which empty themselves into it, is however probable. But in the stomach the gastric juice with the *membrana muscularis* does nothing for the non-divided food but what the chemist does when he wishes to act on a substance; it triturates it, and then the liquids secreted by the pancreas and the liver are able to act chemically on it in the stomach.'

ACADEMY OF SCIENCES IN PARIS.

September 1. *Non-Regeneration of the Crystalline Lens.*—A note was read by M. Gayat, of Lyons, designed to show that the crystalline lens does not become regenerated in the rabbit, nor probably in the human subject. In young rabbits some transparent masses, having an analogous composition to that of the crystalline lens, are observed; but in older rabbits these productions have different characteristics from those of the crystalline lens. These masses arise from the development of the crystalline portions which have been left in the capsule.

September 27. *Pulverisation of Blood.*—A note was read by M. G. Le Bon on the transformation of blood into a soluble powder, and the physical, chemical, and alimentary properties of this powder. Blood reduced to powder is insoluble in water and impervious to pepsine. Commercial extracts of blood do not contain any hæmoglobin. The writer has succeeded by a special apparatus in reducing blood into a soluble powder containing a somewhat large amount of hæmoglobin. This preparation, therefore, at the same time, contains very nutritive elements and is easy of digestion.

October 4. *Pulsation of the Heart and Arteries.*—M. Bouillaud read a paper on new researches on the pulsations of the heart in the normal condition, and on the registering of these pulsations, as well as those of the arteries. The author showed a sphygmographic tracing, destined to demonstrate that the pulse is naturally dicrotic, and shows four beats corresponding to the pulsations of the heart. The first part of the arterial revolution gives an ascending line representing the first beat of the artery; the second part is composed of three elements, of which the one forms a hook with the first line, and corresponds with the short pause; the second element is a depression answering to the arterial systole; finally, the last element gives an oblique line, indicating the long pause of the artery.

October 18. *Neuralgiform Osteitis.*—M. Gosselin presented a memoir on trephining and gouging of the long bones in cases of neuralgiform osteitis. M. Pingaud communicated a case of trephining successfully performed for neuralgiform osteitis of the frontal bone. This case demonstrated that osteitis may take on the same form and be cured in the same way in the flat as in the long bones. The patient had suffered from a subperiosteal abscess, preceded and followed by neuralgic pains to such an extent as to produce a true aura epileptica, as well as epileptiform attacks. Trephining put an end to all these accidents, and also showed that the frontal bone did not contain any pus in its hollows, but a fungous tissue much resembling it.

Treatment of Varix.—M. Bergeron forwarded a note on the mechanism of sanguineous coagulation in the treatment of varix by simple isolation of the veins. This method of treatment has been recently proposed by M. Rigaud, of Nancy, and it is interesting to know what is the direct cause which produces coagulation in these cases. His experiments have led him to note the following facts. When the isolation of a vein is performed, the cellular coat and the vasa vasorum are destroyed to a certain extent. From default of nutrition, a progressive gangrene is then produced. This gangrene, which spreads from layer to layer in the tunics of the vessels, kills the epithelial layer, which no longer receives any aliment, and acts as an inert body, bringing on coagulation of the blood.

Phosphorus Necrosis.—M. Magitot demonstrates in a paper on the subject the pathogeny and prophylaxis of phosphorus necrosis. The conclusion of this paper is that necrosis of the maxillary bones, having its origin in phosphorus poisoning, has for its sole cause its invariable and exclusive way of entrance, a certain variety of dental caries—penetrating caries. The rules of hygiene, which M. Magitot is thoroughly convinced should completely abolish necrosis in factories where phosphorus is used, should be laid down as follows. 1. The heads of factories should be legally compelled to

have the mouths of their workmen examined before engaging them. Every person found to be affected with penetrating caries should be rejected, or not allowed to work until the caries is stopped or cured, or the removal of the tooth is followed by a complete healing of the gum. 2. All those persons who only show signs of gingivitis, or a caries of the first stage, may be admitted to the factory with impunity. 3. An inspection of the persons employed in the factories every six months will make known those workmen who have become affected with penetrating caries since the engagement.

November 2. *Unipolar Electric Excitation of the Nerves*.—M. Chauveau terms unipolar excitation the local action exercised by electric currents on the nerves, at the application point of an electrode, when this electrode alone is in contact, immediate or mediate with the nerve, kept in place in its normal relations, and can scarcely act efficiently except at the point of contact itself, on account of the great diffusion which immediately disperses the current in all directions. The laws of unipolar electric irritation in relation to the two poles of the pile during the passage of the continuous current may be formulated in the following simple terms. 1. For every individual whose nerves are in a perfect physiological condition, there is an electric value, as a rule very slight, sometimes moderate, rarely very high, which gives to the two poles the same degree of activity in the case of unipolar excitation of the nervo-motor fasciculi. 2. The contractions produced by positive excitation and negative excitation with this intensity type of the current, are equal both in amount and in duration. Below this intensity equal currents produce unequal effects with the two poles; the activity of the negative pole is greater. When tetanisation is produced by these weak currents, it is never with the positive pole on the nerve. 3. Above the value type of the intensity of the current, the inequality is produced in an inverse sense. It is the positive pole which shows the greatest activity, and the difference often considerably increases with much regularity with the intensity of the current, if the limits above which the nerves become changed or, at least, fatigued, are not overpassed. Absolutely permanent tetanisation; very often obtained when the positive pole is on the nerve, never shows itself when it is the negative pole, if the currents are sufficiently strong. 4. These strong currents act also in an unequal manner on the sensitive nerve fasciculi, according to the nature of the pole in contact with the nerve; but the inequality is reversed instead of being symmetrical with that which shows itself in the muscular contractions produced by the excitation of the motor nerves. With strong currents of perfectly equal intensity, even the mediate application of the negative electrode on the nerves is more painful than the application of the positive electrode. 5. It is sufficient to compare these laws with those of the bipolar excitement of the nerves forming isolated conductors to see what extreme changes this study of unipolar excitation is destined to exercise over the general theory of electronus and electric excitation. The medical employment of electricity is specially likely to profit largely by these researches. In fact, the new indications given to physicians by the study of unipolar excitation for the application of electricity to the diagnosis and therapeutics of nervous affections may be considered as an immediate practical result.

Action of Bile on the Organism.—A note from MM. Feltz and Ritter supplemented their paper on the action of bile in the organism. The presence of the biliary salts in the blood and urine is produced under the influence of certain organic and inorganic poisons, administered in a given manner. The quantity of these salts varies with the nature of the poison. The writers have tried the following substances; phosphorus introduced into the stomach dissolved in oil, in dissolved blood, in glycerine; tartar emetic, administered by the digestive passage and by inoculation into the blood; the arseniate of soda and arsenious acid ingested into the stomach; finally, septic substances injected into the venous system. Scarcely perceptible in poisoning by phosphorus, the quantity of biliary salts, revealed by Pettenkoffer's reagent, goes on increasing in slow septic poisonings, poisonings by tartar emetic, arseniate of soda and arsenious acid. The presence of biliary salts in the urine implies with certainty contamination of the blood, for they are only found in the urine twenty-four hours later. It is to the increased secretion endeavouring to expel the poison, that this accumulation of biliary salts in the organism appears to be due.

REVIEWS.

The Mucous Membrane of the Uterus, with special reference to the Development and Structure of the Decidua. BY GEO. J. ENGELMANN. New York, 1875.

The author, along with Dr. Kundrat, made a large number of investigations on the above subject in Vienna and Berlin. The result of their joint works were published by Dr. Kundrat in Stricker's *Medizinische Jahrbücher* for 1873. Dr. Engelmann, wishing to correct some of the views expressed in their previous communication which he cannot endorse, and which were developed after he left Vienna, has been led to produce in English his own views of the results of the joint investigation.

The Uterine Mucous Membrane in its Development up to the Time of Puberty.—The essential difference between the fully developed and infantile uterus consists in the absence of all glandular structure in the latter, nor do we meet with any trace of glands during the first years of life, during which the membrane increases but little in thickness, averaging about 0.0078 inch (0.02 mm.). In the third or fourth year the first traces of the development of the glands appear in the shape of small crypt-like depressions, either simple or in clusters of two or three with a common opening; a delicate epithelium lines these sinuses, for glands we cannot yet call them. From this time onwards very few changes take place until after the tenth year, when the uterus develops more rapidly, the glands forming straight ducts, sometimes extending even into the muscular stratum.

The Fully Developed Membrane during its Period of Rest is closely and inseparably attached to the muscular tissue, there being no submucous areolar tissue. The uterine glands possess no basement-membrane.

The Tumefaction of the Uterine Mucous Membrane during the Menstrual Period is partly due to hypertrophy of its superficial layers. These being rich in embryonic cells, grow far above the original open-

ings of the glands, circumvallating them, and thus causing the funnel-shaped depressions, those small pits, which make the ostia seem enlarged. The upper part of the glands is also much enlarged; their lower part, like the stroma surrounding them, remaining unaltered. Anatomical experience does not bear out the current theory that the menstrual changes in the mucous membrane come and go as rapidly as the menstrual period itself. During the period of menstrual hæmorrhage there is more or less marked accumulation of fat-granules within the interglandular cells of the upper layers of the membrane, with fatty degeneration of its blood-vessels, and of the glandular and surface epithelium. The relation of these changes to the menstrual discharge is, according to the author, one of cause and effect. Not only are these changes found to exist, developed independently of the hæmorrhage, but they are in fact the cause of that hæmorrhage. The entire epithelium of the surface is not lost during the retrograde metamorphosis.

Normal Development of the Decidua.—The appearance of the uterus in the third week of pregnancy is thus described. The decidua vera of the first week of pregnancy is characterised by a prolific development of the mucous membrane, especially of the interglandular tissue of its upper layers, and by an increase in the length and volume of the glands themselves. The appearance of the openings of glands on both surfaces of the decidua reflexa and of the longitudinal course of their ducts within its tissue proves that this membrane is developed from folds of the mucous membrane whose approaching borders unite with each other. The author finds that the villi of the chorion do not regularly enter the gland-tubes, but that the adhesions existing are owing to an agglutination of the parts and to the growth of the serotinal tissue around the villi. The changes in the decidua in the second month, and from the fourth month to the termination of the pregnancy, are then described. The development of the placenta, and the retrograde metamorphosis of the membranes, are also discussed. As to the expulsion of the decidua during normal parturition, the parts of the maternal membranes adherent to the ovum are the whole of the decidua reflexa, the entire upper cellular layer of the serotina, and the more superficial parts of the upper stratum of the vera; the greatest part of the decidua vera and the spongy lower half of the decidua serotina remain *in utero*. As to the mode of regeneration of the mucous membrane after parturition, the author states that in the second week only a thin film, hardly to be called a membrane, is left on the inner surface of the uterus, and it already begins to assume the appearance of an active germinating tissue, still retaining the well-marked yellowish-red colour. Only the deepest layers thus remain; these are thoroughly infiltrated with round cells, and but few of the fatty disintegrating cells are to be seen. This process lays open the fundi of the glands in which the glandular cells have been preserved, the deepest part of the glands now forms part of the surface, and their epithelial lining appears as that of the surface. An active cell-proliferation now begins in these remnants of the glandular epithelium, as seen in the segmentation of the nuclei. The paper is illustrated by fourteen figures.

WM. STIRLING, D.Sc., M.D.

On Ovarian Dropsy and Ascites, their Diagnosis and Treatment; also on Prolapsus of the Uterus.
By RICHARD EPPS, M.R.C.S. London: Simpkin, Marshall & Co., 1875.

This book is a jumble of ovarian dropsy, ascites, and prolapsus uteri, the cases reported to enforce the theories are most of them incomplete, and those which are exceptions to this rule are given without anything to guide the reader in forming an estimate as to the correctness of the diagnosis. The chief object of the book appears to be to encourage repeated small aspirations in place of tapping in the ordinary way; but, as the cases given appear to have ended either in putrefaction, suppuration, and hectic, or in the patient disappearing of her own accord after submitting to some dozen aspirations, we imagine that neither members of the profession nor their patients will be encouraged to repeat the experiments of the author. The book displays a great want of knowledge of the subjects on which it professes to give instruction.

NEW INVENTION.

BERNARD AND CO'S DOUBLE DISTILLED SCOTCH WHISKY.

FOR the last few years, purity in alcoholic stimulants has become a desideratum of greater importance than in former times. When brandy was a true distillate from wines suitable for the purpose, gaining its stringency from the oak cask, and its flavour and mellowness from age, no spirit could be considered better adapted for medicinal and dietetic use. But since the largeness of the demand for brandy has increased, and it is distilled from strong coarse, or inferior wine, and also from murks or marks (that is, the residue after pressing the grapes), brandies, except those costing greatly enhanced prices, obtainable only from a few firms, have been justly regarded with suspicion by the profession, owing to the frequent presence of fousel oil. Scotch whisky has therefore taken a position as a stimulant which requires a most careful scrutiny on the part of the profession to assure themselves that they are not recommending an even more objectionable form of alcohol, in which the liability to contamination by fousel oil may be quite as frequently suspected. Many attempts have been made to ensure freedom from these poisonous constituents. Age has always been more or less successful; but the expense attending storage, the loss by evaporation, interest of money, and insurance risks, all combine to render a really mature old whisky almost as expensive a luxury as the finest and purest old brandy. A great stride has already been made in the endeavour to procure purity by scientific means. Messrs. Bernard and Co. have succeeded so far that the whisky they produce, by an entirely new method of distillation, is as free from fousel oil as the purest previously attained after keeping for ten years. Certificates have been given approving this purity from three separate and independent investigations, and on this score, supported as it is with the guarantee that the whole of the whisky is equal to the samples analysed, Messrs Bernard and Co.'s double distilled Scotch whisky must rank foremost among the purest alcoholic stimulants which can be easily procured.

RECENT FRENCH BOOKS.

Published by G. Masson.

Étude d'hygiène privée et sociale ; par A. Lacassagne, professeur-agrégé au Val-de-Grâce. Grand in-18 de 560 pages. Paris, 1875.

Étude toxicologique sur le cuivre et ses composés ; par le docteur L.-M.-V. Galippe. In-8 de 168 pages. Paris, 1875.

Nouvelle méthode de traitement de la goutte, de la gravelle unique et du rhumatisme gouteux ; par le docteur Zénon Pupier. In-8 de 40 pages.

De la catalepsie chez les aliénés ; par Ch. Louis, docteur en médecine, ancien interne des asiles d'aliénés, etc.

Importancia clinica de la temperatura en la fiebre tifoidea, these de Justiniano Alfredo Ledesma, de Buenos-Ayres.

Influence de la pression de l'air sur la vie de l'homme, climats d'altitude et climats de montagne ; par M. le docteur Jourdanet. Prix : 30 fr.

Les bandages et les appareils à fractures. Manuel de déligation chirurgicale, contenant la description d'un certain nombre de bandages nouveaux ; par M. le docteur Guillemin, médecin-major des hôpitaux militaires. Prix : 6 fr.

Recherches sur l'anatomie et la physiologie du cœur, spécialement au point de vue du fonctionnement des valvules auriculo-ventriculaires ; par M. Marc Sée, chef des travaux anatomiques à la faculté de médecine de Paris. 1 vol. In-4 de 67 pages avec 4 planches. Prix : 6 fr.

De l'emploi du bromure de potassium dans les maladies nerveuses ; par M. le docteur Auguste Voisin, médecin de la Salpêtrière. Mémoire couronné par l'Académie de médecine. 1 vol. In-4 de 260 pages, avec une planche en couleur. Prix : 8 fr.

De la transmission de la syphilis entre nourrices et nourrissons, et notamment par l'allaitement, avec considérations médico-légales ; par M. le docteur Camille Appay. 1 vol. In-8 de 124 pages. Prix : 2 fr. 50.

De la nostalgie ; par M. le docteur Ang. Haspel. Ouvrage couronné par l'Académie de médecine. 1 vol. In-4 de 168 pages. Prix : 3 fr.

Contribution à l'étude de la maladie kystique bénigne du testicule ; par M. A. Perriquet. In-8 de 53 pages, avec une planche. Prix : 2 fr.

De la dégénérescence palustre ; par M. le docteur Edouard Burdel. In-8 de 35 pages, avec 8 photographies. Prix : 3 fr.

Des congestions actives et de la contraction autonome des vaisseaux ; par M. le docteur Onimus. In-8 de 24 pages. Prix : 1 fr.

Traité des maladies des reins et des altérations pathologiques de l'urine ; par M. le docteur Lecorché, médecin des hôpitaux, etc. 1 vol. In-8 de 840 pages. Prix : 12 fr.

Du vaginisme, ses causes, sa nature, son traitement, suivi d'une leçon clinique de M. le professeur Lorain ; par M. le docteur Lutaud. In-8. Prix : 2 fr.

Note sur le traitement préventif de la fièvre puerpérale ; par M. le docteur Triaire. In-8. Prix : 2 fr.

Published by P. Asselin.

Nouvelle doctrine physiologique ; par le docteur E. Bernard (de Partenay). 1 vol. In-8 de 236 pages. Toulouse, chez Gimet et chex Labouche, libraires, 1875.

Published by A. Delahaye.

Guien (Dr. Arsène). Guide du voyageur sur mer ou Traité complet du mal de mer. Paris, 1876. Prix : 2 fr.

Lebert (Dr.). Traitement de l'angine couenneuse par la glace, suivi d'un appendice sur le meilleur moyen de se procurer cette substance en toute saison. Paris, 1875. Prix : 1 fr. 50.

Leçons cliniques sur les fractures de jambe faites à l'Hôtel-Dieu au mois de janvier 1875 ; par M. le professeur A. Richet. Paris, 1875. Prix : 2 fr. 50.

Mauriac (Ch.). Clinique de l'hôpital du Midi. Diminution des maladies vénériennes dans la ville de Paris depuis la guerre de 1870-1871. Paris, 1875. Prix : 2 fr.

Published by J. B. Baillière and Son.

Nouveaux éléments de physiologie humaine comprenant les principes de la physiologie comparée et de la physiologie générale ; par H. Beaunis, professeur de physiologie à la Faculté de médecine de Nancy. Paris, 1876. Prix : 14 fr.

MISCELLANY.

M. WURTZ is appointed Professor of Organic Chemistry at the Faculty of the Sciences of Paris.

PRO BONO PUBLICO.—A new society, comprising more than a hundred members, has been formed in Paris. The members bind themselves by a special testamentary disposition not to be interred after death ; but their bodies are to be delivered to the dissecting-rooms of the various medical schools for dissection.

THE PARIS ACADEMY OF MEDICINE has lately been enriched by two legacies. M. Desportes has bequeathed to it a sum of 30,000 francs, to found prizes or award premiums for researches on therapeutic subjects. M. Demarquay has also left a legacy of 100,000 francs to the same body, with which either to found an asylum or to endow a prize for a subject to be left to their own choice.

KANT AND DARWIN.—A volume bearing this title, and which forms a contribution to the history of the doctrine of development, has lately issued from the German press. The author aims to prove that the great Königsberg professor was really the author of what is now called 'Darwinism.' David Strauss, on the other hand, claimed the same honour for Goethe.

CHICORY.—Many persons have a well-grounded objection to the addition of chicory to their coffee. They will find fresh reasons for their objection in the circumstance that four persons have recently been poisoned at Rouen by the use of coffee, with which was mixed what was sold as chicory, but proved to be chicory mixed accidentally with the root of henbane, probably growing in the same field, and carelessly mixed with it.

PROFESSOR HUXLEY has received the necessary sanction of the Lord President of the Privy Council and of the Royal Society, and has accepted the invitation of the Senatus of the University of Edinburgh to take charge again of the Natural History department during next summer session, Professor Wyville Thomson's term of absence having been prolonged in order to enable him to complete the work he is charged with in the *Challenger* surveying expedition.

IN accordance with the will of Professor Jüngken, of Berlin, his collection of scientific works and all his surgical instruments have been presented by his widow to the Augusta Hospital, and a letter of thanks has been sent to her by the Empress Augusta. The Royal Saxon Academy of Sciences at Leipzig has also received a donation from the late Dr. Hermann Härtel of 30,000 marks, to be expended in helping German students to prosecute scientific inquiries.

THE following is the list of office-bearers of the Royal Medical Society of Edinburgh, for the session 1875-76. *Presidents*.—A. R. Turnbull, M.B., C.M. ; A. R. Coldstream, M.B., C.M., L.R.C.S., Ed. ; Thomas R. Ronaldson, M.B. C.M. ; Thomas D. Wilson, M.A., M.B., L.R.C.P. and S. Ed. *Secretaries*.—George Ogilvie, B.Sc. ; Leslie Ogilvie, B.Sc. *Curator of Library*.—J. J. Cox, M.B., C.M. *Curator of Museum*.—J. Graham Brown, M.B., C.M. *Treasurer*.—J. R. Young. *Sub-Librarian*.—John Turner.

THE LATE SIR CHARLES WHEATSTONE has bequeathed to the corporation of King's College all his scientific books and instruments, or such portion as the Professor of Experimental Philosophy may think proper to select ; together with all the medals and diplomas awarded to him by societies, both at home and abroad, and a pecuniary legacy of 500*l.*, to be expended in scientific apparatus ; to the Royal Society of London the portrait of the Hon. Robert Boyle and all the framed portraits of scientific men in his possession, also a pecuniary legacy of 500*l.* to be added to the Wollaston Donation Fund.

A FEMALE SURGEON OF THE SEVENTEENTH CENTURY.—The Camden Society have lately issued an interesting volume, entitled *The Autobiography of Anne, Lady Halkett*. From a memoir of this lady, published in George Ballard's *Memoirs of Learned Ladies*, we find that she was born in the early part of the seventeenth century, and that, as was not uncommon with ladies of rank in that age, she received a liberal education; her favourite studies being theology and physic. She is said to have attained great proficiency in surgery, and effected so many cures in medicine that people came even from Holland to seek her advice. In her *Autobiography* Lady Anne gives a description of the plan of treatment she adopted in the cases of some soldiers wounded at the battle of Dunbar, which gives a favourable impression of her surgical attainments.

THE Zoological Station on the Island of Penikese, established by the late Professor Agassiz, has had to be given up. The endowment provided by Mr. Anderson proved to be insufficient to meet the high cost of living in this cheerless and barren spot; and the persons who came to avail themselves of the advantages of the establishment were found to be quite incompetent to conduct researches into the marine life around them. The place got into debt, and the concern was wound up, Mr. Alexander Agassiz paying the deficit out of his own pocket. Mr. Agassiz has recently built himself a house at the southern extremity of Newport, Rhode Island, and proposes to invite one or more students to join him from time to time in investigating the marine animals which the tide brings in great multitudes almost up to his door.

INSECTS IN THE PITCHER-PLANT.—In a recent number of the *Transactions of the Academy of Science of St. Louis*, Mr. Charles Riley describes the curious habits of two insects which occur alive in the pitchers of *Sarracenia variolaris*. The first is a small moth (*Xanthoptera semi-crocea*), which lays its eggs within the pitcher. The young caterpillars there weave a gossamer-like web, and feed on the cellular tissue of the leaf. The putrid remains of insects previously captured, which have perished, are covered over by the excrements of these caterpillars. The second is a dipterous insect (*Sarcophaga Sarracenie*). The mature fly is stated to drop a number of the larvæ into the pitcher, where they feed on the decaying remains of other insects, and finally burrow through the bottom of the pitcher into the ground, where they undergo their transformations.

THE COCA LEAF.—In an introductory address to the Edinburgh Botanical Society, Sir Robert Christison, its president, related some experiments he had been making with a view to test the 'coca leaf,' which, he explained, was not to be confounded with the well known cocoa. In Peru, where it grows, coca is reported to have remarkable nourishing properties; and, in order to ascertain the precise nature of these, he chewed the leaf by way of stimulant on the occasion of two ascents of Ben Voirlich. On reaching the top he felt greatly fatigued, and began to chew his coca; with the result that he was able to make the descent, not only with firmness, but with almost juvenile elasticity. He further stated, that by its use he had found himself able to walk sixteen miles with ease, although when he attempted this feat without such nourishment he felt greatly fatigued.

INSECTIVOROUS PLANTS.—The *Botanische Zeitung*, no. 44, of the present year, contains an account of a series of experiments by MM. Will and Reess on the alleged absorptive and digestive power chiefly of *Drosera*. Made without knowledge of Mr. Darwin's experiments, these researches amply confirm, as far as they go, the conclusions of that writer, that the tentacles on the leaves have the power of absorbing and digesting nitrogenous substances. An attempt was made to analyse the so-called 'ferment' contained in the acid secretion from the glands. It was found to consist of a mixture of volatile fatty acids, among

which formic acid (which was not found by Professor Frankland) was readily detected. The presence of propionic and butyric acid was also inferred from the smell. Experiments to determine whether the glandular hairs of other plants, as *Primula chinensis* and *Hyoscyamus niger*, had also any absorptive power, produced, like those of Mr. Darwin, only negative results.

A 'RESPIRATION-CHAMBER.'—A writer in the *Agricultural Gazette* gives the following account of one of the 'respiration-chambers,' of which there are now four in Germany. The one described is at the physiological station at Kulthurn. 'Here, again, we have a method of research peculiar to German investigators, and which has yielded a rich harvest of results. We were fortunate enough to see the chamber in action. It is built of iron, with glass windows, and when closed is perfectly air-tight. The apparatus connected with the chamber admits of air being slowly drawn through it, the air as it leaves the chamber being measured, and the amount of water, carbonic acid, and other gases present in the air being determined. As the composition of the air which enters the chamber can be equally ascertained, all the data necessary for an exact experiment are obtainable. In the respiration-chamber the animal to be experimented on is placed, receiving at the same time a diet of known composition. Everything that the animal takes into its system in the form of food is known, and everything that leaves the animal as excrement, or by perspiration or respiration, is also known; by difference, therefore, the constituents retained in the body of the animal can be ascertained. By this painstaking and thorough method of investigation many important facts have been brought to light. Thus, it has been shown that fat is formed in the animal from the albuminoids contained in the food, while in the older view of nutrition it was supposed that fat was exclusively formed from sugar, starch, and other carbo-hydrates. Another fact established is that oxygen is stored up in the system during sleep, and re-evolved as carbonic acid during waking hours.'

HOW TO BRING UP CHILDREN.—The *Revue Britannique* gives some details of the peculiar methods adopted by the women of some savage tribes for the physical training of their children. Amongst the Aleuti, if a new-born infant have the presumption to cry, the mother carries it stark naked to the banks of the river, and, whether the season be summer or winter, plunges the babe into the water until it is quiet. Amongst some tribes they will not give the new-born infant any food until the fourth day, in order to teach it to fast. Amongst the Columbians, the mother rolls the babe in the snow to harden it; and babies of fifteen months old have been seen tucked up on the back of a horse and manfully holding the bridle whilst they jog along. Amongst the Californians, directly a child is born it is thrown into the water. If it swim, it is taken out again and receives all proper care; if it sink, it is abandoned, and the body is not even buried. Amongst the New Mexicans the children are left to themselves as soon as they are capable of finding their own food. When food is scarce, the parents abandon or kill them. The Chinooks have an agreeable fashion of flattening the heads of their offspring. They do not think a face can be beautiful, unless it present a straight line from the root of the nose to the top of the head. To attain this desirable result, the child is tied into its cradle directly it is born, and kept in it from three months to a year. A piece of wood or leather is placed on the forehead and kept there by ligatures, which are tightened every day until the cranium has taken the desired form. It may be imagined that the poor child, with its little black eyes half starting out of their orbits, presents a miserable spectacle. Curious to relate, however, it is stated that the little ones do not suffer much, and are not injured in body or mind. A woman who did not conform to this custom would incur universal opprobrium, and the child would be as much despised by its compatriots as if it were a circular-headed European.

WEST LONDON ENTOMOLOGICAL SOCIETY.—Under the auspices of this society, an exhibition of great interest to students of entomology has lately been held at the St. Mark's Institute, George Street, Oxford Street. The society itself, though not a old one, it having been started in 1868, is in a flourishing condition. Though it is composed almost entirely of working men, and the subscription is extremely small, the entrance fee being but one shilling, and the subscription one penny per week, it is quite self-supporting, and no appeal has been made to the outside public for funds to carry on its work. The exhibition which lasted two nights was free, and the entire cost was borne by the society itself. The exhibitors numbered about thirty-four, and these included professional naturalists as well as amateurs. The lepidopterous insects, or moths and butterflies, formed the principal feature of the show, and in this class Mr. Vaughan exhibited every species of British crambites; while Mr. Meek had a number of specimens showing the life-history of sixty-six different species of British moths and butterflies. The exhibition was not entirely confined to insects, as there was a remarkably fine collection of birds' eggs, and some very excellent skins of wild animals, as well as stuffed birds and heads of dogs, bulls, etc. The different specimens were well and tastefully arranged, and the exhibits generally were in an almost perfect state of preservation. It may be stated that though there were a few exotics, the show was principally British, and most of the specimens exhibited had been obtained by members of the society, the chief hunting-ground being Epping Forest, in the preservation of which the members naturally take a lively interest.

CANNIBALISM.—Cannibals, says the *Journal des Debats* in an article on Colonel de Brazza's scientific mission to Africa, exist in several parts of the globe, in New Zealand, South-east Australia, Polynesia, the Malay Islands, the Celebes, Molucca, and the Philippine Islands. The civilisation introduced by the Spaniards in this part of the Archipelago has greatly diminished these barbarous customs. They are, however, encountered still in the interior of Africa, India, South and North America, and in Polynesia, where the most ferocious are found in the islands of Viti. Anthropophagy, or the eating of human flesh, is variously practised in these countries. In New Zealand they eat the eyes and the heart, under the belief that the victim is not struck off from the Book of Life unless they do so. In South America cannibalism is the authorised mode of sepulture, each family roasting and eating its dead. In India there are still some families who kill and eat those of their number who are afflicted with incurable disease. In one part of Sumatra, anthropophagy is established as a legal system. The penal code condemns to be eaten alive all persons found guilty of adultery, also burglars, and all prisoners of war. The victims in these three cases are carried to a public place, tied to a post, cut up into pieces, and eaten morsel by morsel by the populace. Women, however, are not allowed to attend these feasts. It is said that, when the victim is an adulteress, it is the husband who comes up first to the stake and chooses a tit-bit—generally the ears—which he cuts off and eats with the utmost relish. When everybody has helped himself to a piece of flesh, and nothing is left but the skeleton of the condemned, the chief of the party appears, cuts off the head, and carries it away as a trophy. These monstrous executions are conducted with the greatest deliberation, each of those present eating his piece of human flesh with the conviction that by doing so he is performing an act of justice. Cannibalism is still practised by the Huron tribes of North America, the Iroquois in Canada, and the Caribbe tribes, the primitive inhabitants of the Lesser Antilles, and the southernmost parts of America. They are found in small numbers still in Venezuela and Guiana (Guayana), and are considered very enterprising, warlike, and ferocious. From Africa, which is now being explored, we may expect some further disclosures; and the *Journal des Debats* states as a fact that among the Jagas race in Africa,

better known as the Cassawages, not far from South Guinea, the bodies of men and women, cut up into joints, are exposed for sale, just like butcher's meat, in the tribal market-places.

UNIVERSITY OF LONDON.—The following is a list of the candidates who have passed the recent second M.B. examination:—**First Division.**—Batterbury, George Henry, King's College; Batterbury, Richard Legg, King's College; Garlick, George, University College; Hetley, Henry, Guy's Hospital; Hobson, Lewis John, University College; Hullard, Jean Arthur, B.Sc., University College; Jameson, Leander Starr, University College; May, Bennett, Birmingham General Hospital and Sydenham College; Rose, William, King's College; Smith, Herbert Alder, St. Bartholomew's Hospital; Verco, Joseph Cooke, St. Bartholomew's Hospital; Voelcker, George Henry, University College. **Second Division.**—Bogg, Thomas Wemyss, University College; Buchanan, Arthur, Guy's Hospital; Crespín, Edgar Reginald Legassick, Guy's Hospital; Crétin, Eugène, St. Bartholomew's Hospital; Maclean, Thomas Edwin, University College; Moore, George Edward, King's College; Palmer, Frederick John Morton, Guy's Hospital. The following candidates passed the examination for Honours. **Medicine.**—**First Class:** Batterbury, George Henry (Scholarship and Gold Medal), King's College; Verco, Joseph Cooke (Gold Medal), St. Bartholomew's Hospital; Crétin, Eugène, St. Bartholomew's Hospital. **Second Class:** Hetley, Henry, Guy's Hospital; Garlick, George, University College; Moore, George Edward, King's College. **Third Class:** Hobson, Lewis John, University College; Voelcker, George Henry, University College. **Obstetric Medicine.**—**First Class:** Smith, Herbert Alder (Scholarship and Gold Medal), St. Bartholomew's Hospital; Batterbury, George Henry (Gold Medal), King's College; Verco, Joseph Cooke, St. Bartholomew's Hospital. **Second Class:** Garlick, George, University College; Buchanan, Arthur, Guy's Hospital; Hobson, Lewis John, University College; Hullard, Jean Arthur, B.Sc., University College. **Third Class:** Hetley, Henry, Guy's Hospital; Jameson, Leander Starr, University College; Voelcker, George Henry, University College. **Forensic Medicine.**—**First Class:** Verco, James Cooke (Scholarship and Gold Medal), St. Bartholomew's Hospital; Jameson, Leander Starr (Gold Medal), University College; Hullard, Jean Arthur, B.Sc., University College; Voelcker, George Henry, University College; Crétin Eugène, St. Bartholomew's Hospital; Hetley, Henry, Guy's Hospital.—The following gentlemen have passed the M.D. examination: Crocker, Henry Radcliffe, B.S., University College; Duncan, Andrew, King's College; Eastes, Thomas, Guy's Hospital (Gold Medal); Philpot, Joseph Henry, King's College; Sturge, William Allen, University College; Yeo, Isaac Burney, King's College (Obtained the number of marks qualifying for the Medal). **Logic and Moral Philosophy only:** Hoar, Charles Edward, King's College; Houghton, Walter Benoni, B.S., University College; Leech, Daniel John, Manchester Medical School; Lewtas, John, University, Edinburgh and Netley Hospital; Lowe, Walter George, St. Bartholomew's Hospital; Nicholson, Arthur, King's College; Rigby, James Arthur, Guy's Hospital; Taylor, Herbert, St. Bartholomew's Hospital.—The M.S. Examination (for Logic and Moral Philosophy only), has been passed by Gould, Alfred Pearce, University College.—The following have passed the B.S. Examination.—**First Division:** Hullard, Jean Arthur, B.Sc., University College; Maclean, Thomas Edwin, University College; May, Bennett, Birmingham General Hospital.—**Second Division:** Hobson, Lewis John, University College; Jameson, Leander Starr, University College; Rose, William, King's College; Voelcker, George Henry, University College. **Examination for Honours.**—**First Class:** Hullard, Jean Arthur, B.Sc. (Gold Medal), University College; May, Bennett, Birmingham General Hospital, and Rose, William, King's College (equal).
